Preface

The Second International Conference on Performance–based and Life-cycle Structural Engineering (PLSE 2015) was co-organized by the School of Civil Engineering of The University of Queensland (UQ) and the Research Institute for Sustainable Urban Development (RISUD) of The Hong Kong Polytechnic University (PolyU), and was held on 9-11 December at the Brisbane Exhibition and Convention Centre, Brisbane, Australia. The PLSE conference series was initiated by Prof. Jin-Guang Teng of PolyU to provide an international forum for scientific exchanges and international cooperation in the areas of Performance-based Structural Engineering and Life-cycle Structural Engineering as well as their integration. Indeed, Performance-based Life-cycle Structural Engineering, based on the full integration of the two areas, offers an exciting new direction for structural engineering within the context of sustainable urban development.

The inaugural PLSE conference, jointly organized by the Faculty of Construction and Environment and RISUD of PolyU, was held in Hong Kong, China on 5-7 December 2012. The inaugural conference saw almost 300 delegates from around the world. PLSE 2015 continued the success: the conference program comprised about 180 presentations, including 10 Keynote Lectures and 6 Invited Lectures; 5 mini-symposia and 3 special sessions were also organized as part of the conference. The papers were contributed by researchers and practitioners from 33 countries around the world and cover a wide range of topics. The first day of the conference, the Industry Day, provided an exciting platform for academia-industry conversations.

The success of the conference was due to the support and efforts of many individuals and organizations. On behalf of the Organizing Committee, we would like to thank all authors for their submissions, all Keynote and Invited Speakers for sharing their excellent work and fruitful discussions during the conference, all mini-symposium and special session organizers for the important roles they played in encouraging experts in their respective research areas to attend the conference, and our industrial participants for taking time to enrich the conference program and share their experience. We also thank members of the International Advisory Committee, the International Scientific Committee and the Organizing Committee as well as other experts who helped us with paper reviews and in promoting this conference all around the world.

We wish to thank all financial sponsors of this event for their generosity: MTS Systems Corporation, Australian Calibrating Services, WSP Parsons Brinckerhoff, and the Confucius Institute. Without their support, it would not have been possible to organize this conference with the same magnitude and degree of success. We look forward to their continued support for our future events.

We also received support from 6 organizations as non-financial sponsors of the conference. They helped us to promote this conference via multiple channels, thus generating a high level of international interest. As a result we received papers from many countries around the world. We thank them all for their support and hope they will continue to support us for future events.

Arinex Pty Ltd served as the conference manager for PLSE 2015. They contributed greatly towards making this event a reality. They worked from the beginning with us in ensuring the smooth execution of every step. We thank them for their professional service.

Our thanks also go to the student volunteers, Mr. Ryan Cork , Mr. Leo De Waal, Mr. Yashar Doroudi, Mr. Richard Emberley, Mr. Jack Foote, Mr. Shuan Jiang, Mr. Chuang Miao, Ms. Li Min, Ms. Ya Ou, Ms. Carmen Gorska Putynska, and Mr. Hao Zhou for their tireless efforts throughout the organization of the conference. Thanks are also due to all colleagues at the UQ School of Civil Engineering office, led by Ms. Cindy Van Der Gevel, who offered their help in many ways during the organization of the conference.

PERFORMANCE-BASED ENGINEERING FOR MULTIPLE HAZARDS: THE ROLE OF STRUCTURAL RELIABILITY AND RISK ASSESSMENT

Bruce R. Ellingwood*
Department of Civil and Environmental Engineering, Colorado State University,Fort Collins, CO 80523-1372 USA.*Email: bruce.ellingwood@colostate.edu

ABSTRACT

Buildings, bridges and other civil infrastructure facilities are designed by current codes and standards using provisions that invariably are prescriptive in nature. While facilities so designed usually possess adequate levels of safety under design-basis events, other environmental or man-made events may cause them to suffer damage or loss of function, leading to economic losses, with uncertain impacts on the building occupants, owners and the community that they serve. The new paradigm of performance-based engineering enables structural engineers to achieve more reliable and informative prediction of civil infrastructure behavior and control of performance across a range of hazards. When supported by a risk-informed decision framework founded on structural reliability principles, performance-based engineering provides stakeholders with a structured framework for thinking about performance objectives, uncertainty, and how public safety and socio-economic well-being may be threatened by the failure of civil infrastructure to perform under a spectrum of hazards.

KEYWORDS

Civil infrastructure, hazards, loads (forces), performance-based engineering, reliability, risk, structural engineering.

INTRODUCTION

Civil infrastructure facilities, including buildings, bridges and transportation networks, and public utilities, must be designed to withstand demands imposed by their service requirements and by environmental events such as extreme windstorms, floods and earthquakes. The design provisions found in current codes and standards governing structural design are prescriptive in nature, in that they provide unambiguous and easily interprete4d direction to the structural engineer. While buildings and other structures designed by such provisions usually possess adequate levels of safety under design-basis loads, the occurrence of other service, environmental or anthropogenic events may cause them to suffer various states of damage or loss of function, often under loads that are less than the design-basis loads, leading to substantial economic losses. These losses, in turn, may severely impact the facility owner or occupant and often have a substantial and highly uncertain ripple effect in the surrounding community and its social and economic institutions. Recent infrastructure failures have been widely publicized by ubiquitous media coverage, which has led to an increasing public awareness of infrastructure performance in the United States and in other modern societies. In this era of heightened public awareness of infrastructure performance and community resilience, the engineering profession is seeking improvements to building and construction practices to achieve levels of performance beyond what currently is provided by prescriptive code provisions.

At the root of ensuring safety, serviceability, functionality, durability and other infrastructure performance objectives is the fact that structural loads, strength and our ability to model their interactions through advanced analysis are uncertain. This uncertainty gives risk to risk, which must be managed by codes and standards at socially acceptable levels and at reasonable costs. In recent years, the advantages of structural reliability and risk analysis tools in providing the essential framework for modeling uncertainties associated with structural engineering practice and for trading off investments in infrastructure risk reduction against limited resources (Ellingwood 2001; Faber and Stewart 2003) have become apparent. Many countries have already adopted so-called probability-based limit states design (PBLSD) methods utilizing such tools (Ellingwood 1994, 2000).

First-generation PBLSD criteria, in their present form, are consistent in format and application with traditional engineering practice. They are prescriptive, quantitative, and detailed. They are applicable to a broad group of materials and building products. Component behavior is modeled accurately, for the most part. Supporting

databases have developed remarkably over the past four decades. System behavior, on the other hand, is not reflected explicitly, other than in earthquake-resistant design,[1] and the relation between building performance and stakeholder expectations, while positively correlated, is still unpredictable. Current reliability benchmarks were established as part of the original code calibration and benchmarking process performed in the late 1970's (Ellingwood 1994, 2001). Performance in first-generation PBLSD was measured solely by the limit state probability, P_f (or its surrogate, the reliability index, β); consequences of failure were addressed only indirectly, by stipulating higher reliabilities for limit states that were perceived as having more severe consequences. In the intervening three decades, there has been a growing recognition that failure probability is only one of three essential components of risk; consequences and decision context (Who is the decision-maker? How broadly distributed are the consequences?) are equally important (Elms 1992). In first-generation PBLSD, increasingly severe consequences were reflected only indirectly by stipulating higher reliability indices for more "critical" limit states and decision context was not considered. Finally, at a fundamental level, prescriptive criteria (whether or not based on structural reliability) create the illusion that meeting the code minimums results in a satisfactory building. There is ample evidence from recent natural disasters that this is not the case. The devastating effects of recent natural and man-made hazards have prompted a search for design methods to limit the social and economic impacts of low-probability, high-consequence events, which are outside the traditional design envelope but are the source of many disastrous failures.

In short, current prescriptive design procedures have developed over many decades *ad hoc*, represent a collection of requirements that are difficult to follow and are sometimes contradictory in nature, are not directly tied to the performance they are intended to ensure, are not always reliable in achieving the desired protection for society, are sometimes excessively costly to implement, and may not be targeted at appropriate performance goals (Hamburger 1996). The new paradigm of performance-based engineering enables structural engineers to achieve more reliable prediction and control of civil infrastructure performance across a spectrum of hazards and offers society the opportunity to invest in avoid future losses in a more efficient manner.

PERFORMANCE-BASED ENGINEERING

Performance-based engineering replaces the traditional prescriptive design approach with a design process that is aimed at providing a connection between the building design and the owner and occupant-expected performance, which includes, but often exceeds, the traditional requirements for life safety that are embedded in current codes and standards. These expectations often extend to monetary loss and disruption or loss of function. Specifying a level of expected performance to a given hazard scenario and quantifying the consequences to the owner if such a hazard were to occur provides a basis for more informed decisions for achieving the desired performance. The basic premises of performance-based engineering are that performance levels can be quantified and tailored to stakeholder needs; that engineering computation has advanced to the point where performance can be predicted analytically with sufficient confidence; that uncertainties can be modeled; and that risk can be managed at an acceptable level. Perhaps most important, PBE provides a vehicle for implementing risk-based concepts into structural design and for communicating risk among stakeholders in the building process and to the client. Indeed, it may be said that modern probabilistic risk assessment methods are essential to the successful implementation of performance-based engineering: they provide a framework for managing the impact of uncertainties on performance and guide engineering decisions in an era of technological innovation, competition and financial constraints (Elms 1992; Corotis 2009).

In the United States, PBE has focused to date on two areas: fire engineering and earthquake engineering. In both areas, the motivation is clearly economic. Fire protection traditionally has relied on component qualification testing (according to *ASTM Standard E119* or *ISO Standard 834*), with acceptance criteria relying on survival to a "standard" fire for a prescribed rating period. Many of these test procedures have been in existence for nearly a century. They stipulate an unrealistic fire (one that presumes an inexhaustible fuel supply during the rating period), do not distinguish differences in compartment ventilation or composition, and do not account for realistic structural loads, thermal effects or conditions of structural restraint. Perhaps most importantly, they focus on fires that are localized in compartments and do not address the impact of the fire on a structural system. As a result, many structural components and systems that are known to perform acceptably under realistic fire exposures are penalized or proscribed (NISTIR 7563, 2009). The Society of Fire Protection Engineers is moving its standards program for fire-resistant design toward PBE (SFPE 2007), and the *AISC Specification* (2010) has an Appendix on structural design for fire conditions that first appeared in the 2005 edition. The European Convention for

[1] In ASCE Standard 7-10, the seismic design requirements purport to result in a structural system with an incipient collapse probability of 1% in 50 years.

Constructional Steelwork has developed a model performance-based fire engineering code (ECCS 2001). Such activities on the international scene will accelerate the development of improved quantitative methods for engineering structures for fire safety. In the earthquake engineering area, the recent push toward performance-based is typified by recent research on building seismic performance factors (FEMA 2009) and *ASCE Standard 41-13* (ASCE 2014), dealing with seismic retrofit of existing buildings. The motivation to adopt PBE for earthquake-resistant design is three-fold: to enhance building performance for clients who insist on a higher level of performance than is guaranteed by current code minimums; to better upgrade existing structures that are judged unsafe following an earthquake; and to limit the economic and social consequences of structural damage to communities following an earthquake. Implementation of PBE for both fire and earthquake-resistant design generally requires an explicit consideration of the behavior of specific structures, modeled as integrated systems, an obvious departure from traditional prescriptive structural design methods which focused on member and component behavior.

Several new initiatives for PBE in the United States are pending. The first is a proposed ASCE Standard for disproportionate collapse, scheduled to begin balloting in late 2015 or early 2016, in which the design requirements are based on the perceived hazard and the vulnerability of the building in the community (NISTIR 7396, 2007). The second is a new activity to develop performance-based provisions for wind engineering (NIST 2014), motivated by the damage to building construction and enormous economic losses suffered in Hurricanes Katrina (2005) and Sandy (2012) and the Tuscaloosa, AL and Joplin, MO tornados (2011). Although there are examples of limited uses of PBE for wind effects on a project-by-project basis, little information has found its way into practitioner usage, and performance requirements and acceptability criteria beyond the customary life safety objectives remain to be developed. Finally, in the area of hurricane storm surge and coastal inundation, current performance requirements are completely qualitative in nature; there are no performance-based design metrics for either individual buildings or communities, and the design premise has always been that evacuation is the primary mitigation strategy for life safety. In an era of climate change and its impact on coastal communities, this premise warrants re-examination.

Current performance-based criteria are risk-informed, to the extent that the risk can be measured by the probability of failure. Recent proposals for PBE often have included a matrix in which one axis describes increasing severity of hazard (e.g. moderate, very large) and the second axis identifies different performance level (maintenance of function or continued occupancy, life safety, collapse prevention). Buildings in categories where life safety or economic consequences differ [one such categorization is that in of *ASCE Standard 7-10*] are placed in appropriate bins in this table. The focus of current design practice is on life safety under severe events. The role played by probability and structural reliability principles in the development of such a matrix is evident.

RISK ASSESSMENT AND ENGINEERING DECISION ANALYSIS

Risk involves three components: hazard, consequences, and context (Elms 1992). The hazard is a threat or peril - earthquake, fire, terrorist attack - that has the potential for causing harm. In some instances, the hazardous event (or spectrum of such events) can be defined in terms of annual frequency. More often than not, however, it is necessary to envision a set of hazardous scenarios, without regard to their probability or frequency of occurrence (Garrick et al. 2004). The occurrence of the hazard has consequences – damage to or collapse of the constructed facility, personal injury, direct and indirect economic losses, damage to the environment – which must be measured by an appropriate metric reflective of the decision-maker's value system. Finally, there is the context – individuals or groups at risk and decision-makers concerned with managing risk may have different value systems and may take different views on how investments in risk reduction must be balanced against available resources.

Quantitative measures of risk are required to achieve ordinal rankings of decision preferences. The basic mathematical framework for risk assessment of a constructed facility is provided by the familiar theorem of total probability:

$$\lambda_{Loss > \vartheta} = \Sigma_H \Sigma_{LS} \Sigma_{DS} \, P[Loss > \vartheta | DS] \, P[DS|LS] \, P[LS|H] \, \lambda_H \qquad (1)$$

in which λ_H = annual mean rate of occurrence (for rare events, λ_H is numerically equivalent to event probability P[H]); P[LS|H] = conditional probability of a structural limit state (yielding, fracture, instability), given the occurrence of H; P[DS|LS] = conditional probability of damage state DS (e.g. negligible, minor, moderate, major, severe) arising from structural damage (this term provides the interface between structural engineering and economic loss), and $\lambda_{Loss > \vartheta}$ = annual frequency of loss exceeding ϑ, given a particular damage state. If the hazard is defined in terms of a scenario (or set of scenarios), the risk assessment equation becomes,

$$P[\text{Loss} > \vartheta|\text{Scenario}] = \Sigma_{LS}\Sigma_{DS}\, P[\text{Loss} > \vartheta|D]\, P[DS|LS]\, P[LS|\text{Scenario}] \quad (2)$$

The parameter ϑ is a loss metric: number of injuries or death, damage costs exceeding a fraction of overall replacement costs, loss of opportunity costs, etc. depending on the objectives of the assessment.

Eq. 1 and Eq. 2 deconstruct the risk analysis into its major constituents and, as an added feature, along disciplinary lines (Ellingwood 2007). Reading these equations from right to left conveys the order in which the risk assessment and mitigation process should be approached. An analysis of the frequencies of competing hazards allows trivial hazards to be screened and appropriate risk mitigation strategies to be devised for those hazards that lead to unacceptable increases in building failure rates above the de minimis level. It should be noted that the profession of structural engineering and its codes and standards impact the probabilities P[LS|H] in Eq (1) and P[LS|Scenario] in Eq. 2, and first-generation probability-based codes, such as LRFD, are aimed at reducing these probabilities to an acceptable level for life safety, which has been the historical performance goal for the structural engineering profession. Structural engineering has little impact on the other probabilities (frequencies) in these equations, and it is little wonder that when the control of economic or social losses is of importance, the practice of structural engineering, in and of itself, may be insufficient to ensure that the performance goals are met. At an advanced level of implementation, PBE would allow the design team to achieve the performance goals of the project (presumably encapsulated by a mutually agreed-upon set of values of $\lambda_{\text{Loss} > \vartheta}$ or $P[\text{Loss} > \vartheta|\text{Scenario}]$) by adjusting the terms within Eq. 1 and Eq. 2 by a combination of siting, architectural, structural, and other design strategies, provided that the overall loss metrics were not exceeded. There are already a few examples of such an approach in existing criteria for design against disproportionate collapse (NISTIR 7396 2007).

If the scenario approach is adopted because of a lack of data on hazard frequency, the loss (risk) estimate is conditional, and the risk estimate cannot be benchmarked against competing risks associated with other hazards. Moreover, the screening process is difficult when the hazard cannot be quantified. On the other hand, many decision-makers find the scenario approach more understandable than a fully coupled risk analysis. Whether a fully coupled risk analysis or a scenario analysis is used, cost-effective risk mitigation strategies require appropriate attention to all terms in Eq. 1 and Eq. 2 and thus a multi-disciplinary approach to risk mitigation. All sources of uncertainty, from the hazard occurrence to the response of the structural system, must be considered, propagated through the risk analysis, and displayed clearly to obtain an accurate picture of the risk.

RISK TOLERANCE, ACCEPTANCE AND COMMUNICATION

In first-generation probability-based design, the performance (risk) metric of choice has been the annual (or 50-year) failure probability (Ellingwood 1994, 2000, 2001). Situations identified as having progressively more severe consequences of failure are addressed indirectly by reducing their target probability. This approach, while useful for the narrow scope of probability-based code development, has some drawbacks for performance-based engineering and risk assessment of general civil infrastructure. For one, most stakeholders and public decision-makers are not trained in or comfortable with the tools of quantitative risk analysis, especially when the decision process involves rare events. Indeed, regulators often are skeptical of quantitative risk assessment, and may suspect that it might be used to justify socially or politically unacceptable decisions. For another, focusing solely on the probability without considering the consequences omits an important dimension of the assessment and decision process, noted previously. Low-probability events can be exceedingly risky; considering the diversity of civil infrastructure, it is difficult to see how it is possible to collapse all the consequences – mortality, direct and indirect economic losses – into a change of one to three orders of magnitude in the target probability. While it is difficult to quantify consequences in terms of loss, it is clear that this is what many building owners, engineers and regulatory officials in the civil arena want.[2] The "average annual loss" is sometimes cited as an appropriate risk measure but the distribution of loss determined from Eq. 1 (due to the epistemic uncertainties involved in loss estimation) can be very broad, and no central measure – mean, median or mode – represents loss adequately. So, while the average annual loss might be meaningful for an insurance provider underwriting a large portfolio, it is less useful for the individual attempting to measure risk to an individual facility, particularly an individual or decision-maker who is risk-averse. Other metrics must be sought.

Decisions regarding risk mitigation, once $\lambda_{\text{Loss} > \vartheta}$ or $P[\text{Loss} > \vartheta|\text{Scenario}]$ have been determined, depend on the decision-maker's view on the acceptability of risk and on how investments in risk reduction should be balanced

[2] Stakeholder workshops held in the aftermath of extreme natural hazards (e.g., Northridge Earthquake) have conveyed this message clearly.

against available resources. Most individuals are risk-averse, while governments and large corporations tend to be more risk-neutral (Slovic 2000). Recent studies, summarized by Corotis (2009), have indicated that *acceptance* of risk is based more on its *perception* than on the actual probability of occurrence and that biases in perception, whether or not they are well-founded, shape decisions. Reid (2000) has suggested that individuals view risks as negligible if they are comparable to mortality risk from natural hazards (on the order 10^{-6}/yr) and as unacceptable if comparable to mortality from disease (on the order 10^{-3}/yr in the 30 to 40 age group). Consideration of acceptable risk in quantitative terms for civil infrastructure facilities, the construction of which often has been regulated by public codes, is a relatively new development (Ellingwood 2001, 2007).

CONCLUSIONS

Performance-based engineering provides a vehicle for implementing risk-informed concepts into structural design and for communicating risk among stakeholders in the building process and to the client. PBE has already gained acceptance in earthquake engineering and fire-resistant structural design, where the incentives for its adoption as an alternative to traditional prescriptive methods are strongly economic in nature. Current research initiatives to extend the performance-based approach to other hazards, such as extreme wind, storm surge and coastal inundation, and tsunami effects, and to develop design procedures in which the risks due to competing hazards are properly balanced and investments in risk reduction can be targeted appropriately will bear fruit in the next decade. The worldwide interest in community resilience (McAllister 2014) will further motivate the development of performance-based engineering, because it is difficult to see how community performance goals regarding response/recovery from extreme hazards can be met without a performance-based approach. These initiatives will provide risk-based performance assessment tools for buildings and other structures that are accessible to a spectrum of stakeholders with different skills and talents. The benefits of such an approach are an improved ability to assess the effectiveness of various risk mitigation strategies in terms of risk reduction per dollar invested, and thus a better allocation of public and private resources for managing risk.

ACKNOWLEDGMENTS

Financial support for the research conducted over many years, and summarized herein, has been provided by the National Science Foundation, Oak Ridge National Laboratory, the National Institute of Building Sciences and the National Institute of Standards and Technology. This support is gratefully acknowledged.

ABSTRACT

Structural optimization plays certain role from concept development, numerical algorithm to practical solution in the performance and life-cycle based structural engineering. This presentation briefly reviews the history of structural optimization and its application in civil engineering. Structural topology optimization and surrogate model-based optimization approach together with metaheuristic algorithms is discussed in more detail. The relation of structural optimization with performance based and life-cycle based structural design is illustrated through some of our research work on reliability-based design optimization and damage-reduction optimum deign of structural system. These works provide some optimization methodology, design concept and numerical algorithms, which may facilitate the performance based and life-cycle based structural engineering.

KEYWORDS

Structural optimization with uncertainty, performance-based design, topology optimization, reliability-based design optimization, damage-reduction optimum deign.

INTRODUCTION

History of structural optimization can be traced back to the early work by Michell (1904). In 1950-1960s, a surge of study on structural optimization was observed in the literatures. Optimum designs of elastic truss, frame, grillage and structural element such as beam, column and plate attracted a great attention in structural engineering community and were solved by analytic approach and variational method (Rozvany and Prager, 1979; Rozvany 1989). It is interesting to note that many well-known researchers of structural optimization such as Prager and Rozvany have the background of civil engineering.

Since 1960's the advent and fast development of modern computer together with the finite element method and mathematical programming pushed the numerical method of structural optimization to the central stage of modern structural optimization. In late 1970's and 1980's there were two major numerical approaches: both Optimality Criterion approach and Mathematical Programming were the hot research topics. The approximate concept (Schmidt 1976) and sequential approximate programming such as SLP (Sequential Linear Programming), SQP (Sequential Quadratic Programming), SCP (Sequential Convex Programming) (Fleury

1986) and MMA(Method of Moving Asymptotic) (Svanberg 1987) were developed. As these methods are gradient-based optimization algorithm, an efficient sensitivity analysis is critical (Arora 2004). In FEA (Finite Element Analysis) context, the DSA (Direct Sensitivity Analysis), Adjoint Sensitivity Analysis and SAM (Semi-Analytic sensitivity Method) (Cheng and Liu 1987; Pedersen et al. 1989) were developed for structural size and shape optimization. Soon after, the specific software was developed for the numerical solution of large scale structural optimization problems. Application of structural optimization becomes more frequent in areas such as aeronautic and aerospace industries. Serious attempts, including teaching structural optimization in classroom and introducing students the new technology, were also made to expand its application in civil engineering (Hernandez et al. 2015).

In theoretical aspect, several progresses were seen in 1980's. Study on the bimodal optimum design of clamped column (Olhoff 1977) opened the way of the non-differential sensitivity analysis of multiple eigenvalues. It was later found that many optimum structures have multiple buckling loads or vibration frequencies. Optimum design of thin solid elastic plate for minimum compliance (Cheng and Olhoff 1981) pointed out the need of including microstructure in the optimization formulation, which was recognized as pioneering work of the modern topology optimization.

Nevertheless, a widespread application of structural optimization remains quite challenging in civil engineering. There are many reasons. First of all, design problem in civil engineering usually involves a very large number of constraints and design variables. Many design constraints are from the design code provision and are mostly not given in the form of algebraic or differential equations. The values of design variables are often discrete and limited within the list given by industrial standard. Structural weight is only a part of design objective, sometimes less important than the cost of construction, manufacture and attached facility in the building. The mathematical formulation of structural optimization in civil engineering is much more complicated than that in the other engineering field. Moreover, it is often difficult to isolate one structural part from the whole structural system. Voices from civil engineering community continuously press the structural optimization community to tackle real engineering problems instead of simple academic examples. New benchmark optimization problems were proposed and discussed in recent literatures (Alimoradi et al. 2010, Mueller et al. 2012).). On the other hand, there were already a number of well-developed softwares in civil engineering providing optimization function for specific type of structures. For example, the member size optimization of tall buildings is a well-established field of application for large scale optimization algorithms. In such cases where the initial cost of construction is high, the economic advantage of optimal engineering design is obvious. Research in this area has been vigorously explored since the early 1990's.

In recent years, two important developments in structural optimization open a new perspective to its application in the area of civil engineering. One is the fast development of structural topology optimization, which will be elaborated in the next section. Another is the surrogate model based optimization approach together with the emerging meta-heuristic algorithms, made possible by ever increasing computational power available in daily design activities.

The surrogate model based optimization approach relies on the results of physical experiment or expensive numerical simulation for the given structural system at a number of sample points. With a well-designed DOE (Design Of Experiment), such data can help construct approximate mapping between the interesting input parameters and the structural response output, i.e. a surrogate model. Then numerical optimization techniques

are applied to find the optimum designs of the surrogate model, which is rough approximation of optimum design of the original optimization problem. For this approach to help practical engineering design, it has following general requirements:

Designer has reliable software as a black box for the problem analysis

Designer manages to formulate the optimization problem, that is, to identify a reasonable set of critical design variables and important structural response to be constrained or included in objective function. This can be obtained from analysis software or the user self-coded algorithm.

The emerging meta-heuristic algorithms (Kaveh and Talatahari2009; Saka and Geem 2013), such as GA (Genetic Algorithm), PSO (Particle Swarm Optimization), colony optimization, chaos optimization algorithm (Yang et al. 2007; Yang et al. 2014) and tabu search etc., are strong complementary methods of gradient-based optimization. They have provided alternative tools to engineering designers, in particular for design optimization problems under design code provisions and discrete design variables encountered in engineering practice. However, the efficiency of meta-heuristic algorithm remains to be further improved. It is often seen 5000 calls of structural analysis is carried out for an optimum solution by the meta-heuristic algorithm. It is interesting to remember that structural optimality criterion people strived for obtaining optimum design by 10 calls of structural analysis in 1980s.

CONTINUUM STRUCTURAL TOPOLOGY OPTIMIZATION AND BUILDABILITY

Classical structural topology optimization originates from the study of minimum weight design of truss structure under stress constraints (Michell 1904). The classical Michell truss theory was then further elaborated and a set of elegant analytic solutions was obtained under various boundary and external load conditions (Rozvany 1989). One important result is that under single static load case and symmetric stress constraints (i.e., the strength limit for tension and compression are the same), the corresponding optimal truss structure is statically determined. It is also found that if the parameters involved in the optimization problems being scaled appropriately, this optimal design also coincides with the optimal design for minimum compliance and the optimal design of rigid-plastic truss structures under available volume constraint. When this classical truss topology optimization under stress constraints and multiple load cases is solved by ground approach (Sved and Ginos 1968), however, it is surprising to discover that global optimal topology cannot be reached by continuous gradient-based optimization algorithms. This so-called singular optimum was now understood as caused by the possible discontinuity of the stress constraint function when topology change occurs (Cheng and Jiang 1992) and could be solved by relaxing the stress constraint in mathematically rational ways (Cheng and Guo 1997).

Modern continuum structural topology optimization was initiated by Bendsoe and Kikuchi in 1988. Since topology optimization provides an effective approach for finding optimum connection of continuum structure, topology optimization techniques are quickly becoming recognized as a powerful tool for conceptual design in various engineering areas. Several methods of structural topology optimization are available. Homogenization method (Bendsoe and Kikuchi 1988) assumes the structure to be optimized consists of material with microstructure of given configuration, in which microstructure parameters are chosen as the design variable. Meanwhile, size optimization techniques are applied to obtain optimum microstructural parameter, which determines material distribution and structural topology. The macrostructure effective coefficients corresponding to the material microstructure is obtained by mathematical asymptotic homogenization method. Many research work focuses on minimum structural compliance design under the given material volume constraints, which

generates the most efficient force transmission path. Though this method results in structural topology in which the intermediate density can be related to porous material, the method is time consuming. SIMP (solid isotropic material with penalty) (Zhou and Rozvany 1991) is the most popular method to speed up and simplify this general approach. In SIMP, an artificial relation between material density and Young modulus is assumed instead, and a penalty is imposed on the artificial relation to push the element density either zero or one. Since the implementation of this approach is straightforward, the method is widely applied to multiphysical topology design problems. Other feasible methods include the Evolution method (Xie and Steven 1993) and the level set method (Wang et al. 2003).

Even with the great success of SIMP, numerical implementation of topology optimization has encountered many problems. Most common ones are treatment of grey elements, checkerboard design, and mesh-dependent solution in minimum structural compliance design. Appearance of hinge and disconnect design in optimum compliant mechanism design is also difficult. Similarly, singular optimum needs to be treated carefully in stress-constrained and frequency-constrained optimum topology design. Furthermore, many 3D topology optimization results are simply difficult to visualize, let alone manufacture. From the viewpoint of engineering application, these problems all are part of the manufacturability or buildability, critical to turn topology optimization results into reality application. A solution with many grey elements or checkerboard areas is difficult to use for extracting manufacturable design. Therefore, linear density filter and sensitivity filter were developed to reduce the checkerboard solution but led to higher number of grey element. The nonlinear Heaviside filter removes the grey element and yields black-white final design. Moreover, the parametric nonlinear Heaviside filter (Xu et al. 2010) further stabilizes the iteration history. To control the minimum and maximum length or special feature in the final topology design, the projection method and robust design approach was also studied. Recently, Guo and his co-workers (2014) proposed morphable component method that has great potential to control structural features and addresses constructability, extending further the level-set based concepts. Nevertheless, manufacturability is still a great challenge that is further complicated by the requirement of special manufacturing process or new manufacturing techniques.

In the field of civil engineering, topology optimization already finds good usage in conceptual high-rise building design by systematically exploring the structural design space for efficient, novel structural layouts (Bobby et al. 2015). The lateral bracing systems are under study for its optimum topology (Stromberg et al. 2012). Manufacturing constraints such as pattern gradation and repetition are studied to facilitate the conceptual design for buildings, i.e. layout optimization (Stromberg 2011). There are also the growing interests in the architectural community to make topology optimization as a means of generating aesthetic and efficient structural forms (Beghini et al. 2014), as well as searching for design methodologies that facilitate weight reduction of concrete structures while maintaining the required load-carrying capacity. Overall, expansion of structural topology optimization is necessary for its wider application in civil engineering. For example, the existing structural topology optimization formulation mostly addresses the linear elastic and deterministic problem. However, topology optimization problem with consideration of uncertainty, structural non-linear and dynamic response needs further study.

RELIABILITY-BASED STRUCTURAL OPTIMIZATION AND SEQUENTIAL APPROXIMATE APPROACH

Traditional structural optimization commonly deals with deterministic optimization. However, there are many

inherent uncertainties in the real-world environment of civil engineering structures. If uncertainties are neglected there is a possibility that the final optimum designs may perform unsatisfactorily. Commonly referred to as RBDO (reliability-based design optimization) in structural optimum design, it has several formulations to address inherent uncertainty (Cheng et al. 1998). When the reliability index is applied to describe the probabilistic constraint, the so-called RIA (reliability index approach) for RBDO is stated as:

$$\begin{aligned} &\min \quad \text{cost}(\mathbf{X}) \\ &\text{s.t.} \quad \beta_j^{accept} \le \beta_j(\mathbf{X}) \quad (j = 1,\ldots,N_p) \\ &\qquad \mathbf{X}^L \le \mathbf{X} \le \mathbf{X}^U \end{aligned} \tag{1}$$

In the following, we take one formulation as an example to review these approaches. In general, the solution of this formulation needs the simultaneous solution of an optimization problem and calculation of the reliability index, which involves another optimization problem. Many solution approaches have been developed in the literature. In general, RBDO approaches are divided into three categories: double loop approaches, single loop approaches and decoupled approaches based on how the two optimization problems are handled. Methods based on decoupling the optimization loops for the reliability analysis allow the adoption of efficient deterministic optimization algorithms to be applied after results of the reliability analysis being available. This kind of decoupling method has received considerable discussion (Royset et al. 2001; Du and Chen 2004). Instead of introducing them in details, here we concentrate on the sequential approximate programming approach.

Sequential approximate programming (SAP) approach in structural optimization developed in 1980s' and solved the general nonlinear mathematical programming. For simplicity of discussion, we show the approach by optimization problem with only one inequality constraint,

$$\begin{aligned} &\text{To find } \mathbf{X} \\ &\min f(\mathbf{X}) \\ &\text{s.t.} \quad g(\mathbf{X}) \le 0 \end{aligned} \tag{2}$$

The sequential approximate programming solves the problem by solving a sequence of sub-optimization problems, that is,

$$\begin{aligned} &\text{for } k=1,2,... \\ &\text{To find } \mathbf{X}^k \\ &\min f^k(\mathbf{X}) \\ &\text{s.t.} \quad g^k(\mathbf{X}) \le 0 \end{aligned} \tag{3}$$

The objective and constraint function in Eq. 3 is the approximation of their corresponding one in Eq. 2 and their approximation should be improved with the iterations. For example, $f^k(\mathbf{X})$ is chosen as the linear approximation in the vicinity of $\mathbf{X}^{k-1}$ obtained in the previous (k-1)th iteration. Quadratic approximation and diagonal quadratic approximation are examples. By introducing the carefully constructed transformation of design variable and objective or constraint function, many variant algorithms were developed in the literature, and some of them are very efficient. For example, the method of moving asymptotic (MMA) is mostly often applied in structural topology optimization.

The success of SAP drives us to propose a sequential approximate programming for RBDO, which solves a sequence of approximate programming as

$$
\begin{aligned}
&\text{for } k = 1,2,\ldots \\
&\min \quad \text{cost}^k\left(\mathbf{X}\right) \\
&\text{s.t.} \quad \beta_j^{accept} \le \beta_j^k\left(\mathbf{X}\right) \quad \left(j = 1,\ldots,N_p\right) \\
&\qquad \mathbf{X}^{\mathrm{L}} \le \mathbf{X}^{\mathrm{L}k} \le \mathbf{X} \le \mathbf{X}^{\mathrm{U}k} \le \mathbf{X}^{\mathrm{U}}
\end{aligned} \tag{4}
$$

The question here is how to construct the approximate functions of the reliability index constraint function in RDBO. The commonly-used linear approximation requires reliability index value and its sensitivity at the (k-1)th iteration, which is difficult to obtain. Instead, we use approximate reliability index and its sensitivity at (k-1)th iteration to construct the approximate reliability index constraint function.

$$
\beta^k\left(\mathbf{X}\right) \approx \hat{\beta}\left(\mathbf{X}^{k-1}\right) + \left(\nabla_{\mathbf{u}}\hat{\beta}\left(\mathbf{X}^{k-1}\right)\right)^T\left(\mathbf{X} - \mathbf{X}^{k-1}\right) \tag{5}
$$

$$
\hat{\beta}\left(\mathbf{X}^{k-1}\right) = \frac{g\left(\mathbf{X}^{k-1},\mathbf{u}^{k-1}\right) - \left(\nabla_{\mathbf{u}}g\left(\mathbf{X}^{k-1},\mathbf{u}^{k-1}\right)\right)^T\mathbf{u}^{k-1}}{\left\|\nabla_{\mathbf{u}}g\left(\mathbf{X}^{k-1},\mathbf{u}^{k-1}\right)\right\|} \tag{6}
$$

where $\mathbf{u}$ is the most probable failure point (MPFP) of the limit state surface in u-space. The (k-1)th estimation of MPFP $\mathbf{u}^{k-1}$ for the design $\mathbf{X}^{k-1}$ is reserved and substituted into Eq. 6 to obtain a updated estimation $\mathbf{u}^k$ for the design $\mathbf{X}^k$, which will be used in the next iteration.

$$
\mathbf{u}^k = -\hat{\beta}\left(\mathbf{X}^{k-1}\right)\frac{\nabla_{\mathbf{u}}g\left(\mathbf{X}^{k-1},\mathbf{u}^{k-1}\right)}{\left\|\nabla_{\mathbf{u}}g\left(\mathbf{X}^{k-1},\mathbf{u}^{k-1}\right)\right\|} \tag{7}
$$

$$
\nabla_{\mathbf{u}}\hat{\beta}\left(\mathbf{X}^{k-1}\right) = \frac{\nabla_{\mathbf{u}}g\left(\mathbf{X}^{k-1},\mathbf{u}^{k-1}\right)}{\left\|\nabla_{\mathbf{u}}g\left(\mathbf{X}^{k-1},\mathbf{u}^{k-1}\right)\right\|} \tag{8}
$$

Due to the space limitation, more detailed description is referred to (Cheng et al. 2006; Yi and Cheng 2008). The above method can be applied to performance measure approach (PMA), in which the performance measure is applied to describe the probabilistic constraint. From numerical tests of several structural examples, its efficiency were reported in literatures such as Aoues and Chateauneuf (2010). The basic idea of SAP is also applied to solve size and topology optimization with reliability constraints based on probablity and multi-ellipsoid convex model hybrid model (Kang and Luo 2010). to minimize the economic cost under many ncertainty factors in an efficient manner. Here, the multi-ellipsoid convex modeling technique is developed as a powerful tool to cope with bounded uncertainty arising from different sources (Kang and Luo 2009). When the random parameters are known for engineering system, the reliability-based design optimization based on classic probability theory performs well for this type of problem (Liu et al. 2014). The performance of these algorithms, including accuracy, efficiency and robustness, are the key of the RBDO. It is worthy to note that Yang and his colleagues (Yi and Yang 2009; Yang and Xiao 2013) investigated the essential reasons of iterative failure of some widely used algorithms in reliability analysis and design optimization and so on, such as FORM (first order reliability method), PMA, SAP with PMA based probabilistic optimization, SORA (sequential optimization and reliability assessment) based on the theory of nonlinear dynamics, and discovered the chaotic dynamics mechanism of period oscillation, bifurcation and chaos of iterative solutions. Further, they suggested the stability transformation method (STM) of convergence control for these iterative algorithms from the new perspective of chaotic control. To enhance the efficiency and performance of RBDO with STM for convergence

control, Li and Meng *et al*. developed the modified STM through relaxing the iterative step size of radial direction and adaptively determining the control factor of STM with respect to PMA for probabilistic constraint estimation in RBDO (Li et al. 2015).

PERFORMANCE BASED STRUCTURAL DESIGN AND DAMAGE-REDUCTION DESIGN

In later 1990's, I learned the concept of performance-based seismic engineering and its importance to the future engineering design. Performance-based engineering (PBE) is a general methodology that allows designers to conceive and assess the performance of complex structural systems subject to various hazards by rigorously taking into account the pertinent uncertainties (Cornell et al. 2002; Bozorgnia and Bertero 2004; Fischinger 2014). With the PBE approach, the designer can define the performance objective for the structural system during its desired/expected design life, and take advantage of specific criteria and methods for verifying that the agreed performance objectives are met. To realize performance-based structural design the optimization methodology is one of the most important ingredients from the concept formulation of PBE to numerical algorithm. Many works have been accomplished in performance-based earthquake engineering over the past two decades. The related processes have been established that facilitate probabilistic seismic hazard analysis, evaluation of relevant engineering demand parameters through advanced modeling and nonlinear response history analysis, quantification of damage measures and associated repair/replacement costs at the component level, and aggregation of losses for structural and nonstructural systems. The outcome of performance-based earthquake engineering is a probabilistic assessment of direct economic loss and collapse failure due to earthquake action.

There are two different formulations for optimization considering the balance of cost and benefit. One formulation is written as (Cheng and Li 2000)

$$\begin{aligned} &\text{Find } \mathbf{X} \\ &\min\ W(\mathbf{X}) = C(\mathbf{X}) + P_{f_s}(\mathbf{X})C_{f_s} \\ &\text{s.t. } P_{f_s}(\mathbf{X}) \le \left[P_{f_s}\right] \\ &\quad g_j(\mathbf{X}) \le 0,\ j=1,2,...,m \end{aligned} \tag{9}$$

System reliability in this formulation introduces additional computational complexity to RBDO, especially when the limit-states have statistical dependence. To apply this formulation, we need to know the system reliability and the system failure cost, which are difficult to obtain. Many researchers (Royset et al. 2001; Liang et al. 2007) made important contribution for the numerical algorithms of RBDO with system reliability. Furthermore, minimizing the system reliability often leads to simultaneous failure design, i.e. all failure modes have the same failure probability, or, a uniform strength design. However, in a system life cycle, various hazard and various limit state caused different damage and different economic loss. Therefore, in many cases, it is more rational to solve the following optimization formulation,

$$\begin{aligned} &\text{Find } \mathbf{X} \\ &\min\ W(\mathbf{X}) = C(\mathbf{X}) + \sum_{i=1}^{n_p} P_{f_i}(\mathbf{X})C_{f_i} \\ &\text{s.t. } P_{f_i}(\mathbf{X}) \le \left[P_{f_i}\right],\quad i=1,2,...,n_p \\ &\quad g_j(\mathbf{X}) \le 0,\ j=1,2,...,m \end{aligned} \tag{10}$$

It is interesting to note that under this formulation, the optimum design of Eq. 10 has different failure probability for different failure modes. For low failure cost component or limit state, we could allow high failure probability. This observation leads to the concept of damage-reduction-based seismic design, or fuse design of structural system. Here, the structural system is either physically or functionally designed as two parts, the main-function part and the damage reduction part (Li and Cheng 1998). The main-function part satisfies the serviceability requirements of the structural system. The damage-reduction part composes of several damage reduction elements, which work under hazard loads to ensure the safety of the main-function part, and further maintain the serviceability of the structural system by specific damage-reduction techniques or even by failure of damage-reduction elements. The formulation of damage-reduction optimum design for seismic high-rise structures is presented in (Li and Cheng 2003), in which damage-reduction design examples of RC frames are examined. The optimal design results show that several measures of structural seismic performance, including the life-cycle cost, severe earthquake action and the story-drift reliability index of the weakest story, can be improved by damage-reduction design compared with conventional design. Finally, it is pointed out that, the idea of damage-reduction structure with sacrificing the secondary damage-reduction part or components such as energy dissipated damper, supporting or link beam is fairly similar to that of earthquake resilient structure (Fischinger 2014). Optimum design of resilient structure is a promising direction to performance based structural engineering.

FINAL REMARKS

Performance based and life-cycle based structural engineering covers a broad area of research activities and technical advancement. Structural optimization provides theory and algorithm from concept development, numerical algorithm to practical solution in PLSE. Abundant publications on these topics are available, and author is sorry for being not able to cover many other important works herein.

SUSTAINABILITY - A BRIDGE ENGINEER'S VIEWPOINT

Man-Chung Tang*

ABSTRACT

Engineering uses natural resources to fulfill the fundamental needs of society. For the building of a bridge, steel, stone, and other raw construction materials are used. The results are bridges that cross rivers, valleys, and the like. Besides bridges, our built world consists of buildings, highways, and all manufactured goods needed in daily life. Ideally, improvements in engineering should improve our economy; a better economy improves our living standards, which, in turn, should provide the capability to improve the environment we live in, thus making it possible to achieve sustainability. But a better economy can also spur consumption and deplete the world's resources even faster. Currently, it appears that the latter is more likely to happen. The Brundtland Commission defined "sustainable development" as such: "Sustainable development is development that meets the needs of the present without compromising the ability of future generations to meet their own needs." (United Nations General Assembly 1987) But how do we know what and how much future generations need to live? As bridge engineers, how can we help making this possible?

KEYWORDS

Sustainability, sustainable development, bridge engineering, durability, natural resources, non-renewable resources.

INTRODUCTION

The formation of the planet occurred billions of years ago, well before the onset of human civilization, which began tens of thousands of years ago. The evolution of any organism can be described as a biological process taking place over many generations. However, with the appearance of humans, the natural state and resources of our planet have been impacted dramatically in a very short time.

No matter how we define the length of human civilization on this planet, be it 5,000 years old, 10,000 years old or 100,000 years old, it is still a very short period of time compared to the age of the planet itself, which is believed to have developed over several billions of years. Nevertheless, the impact that human beings have had on Earth is unmistakable. Many habitats have been destroyed as a result of population growth and our insatiable demand for natural resources. Human consumption of those resources have forever altered natural landscapes, destroyed countless ecosystems and, along with it, brought the mass extinction of many animal and plant species, leading to the inevitable loss of Earth's biodiversity. Ultimately, this process affects our own very survival.

SUSTAINABILITY

Sustainability can be defined as "the ability to continue." The total resources of the planet is finite. In order to be able to continue, we must produce at least as much as we consume, and create at least as much as we destroy. As a simple example, if we cut more trees than we plant, sooner or later we will run out of wood.

Engineering is the application of some knowledge for the purposes of designing and building a structure for modern comfort. Engineers change many aspects of the way we live. The results of their work can also impact our natural environment. Indeed, engineers have changed and continue to change the world dramatically. While we would like to think that we only improve our surroundings through engineering, we can also destroy the environment at the same time. Sustainable engineering can be described as a process in which the output or work product is offset by some means to compensate for the consumption of natural resources. From an economic standpoint, if the relative value of a thing is equal to or more than the relative cost it took to make, then that product can be viewed as having been engineered sustainably.

BRIDGE ENGINEERING

Sustainability is a global issue that affects our present-day society as well as future generations. Can the planet continue to support all of the human beings living on it? How can we, as engineers, and to a larger extent, as responsible citizens, understand our role in the sustainable development of our built environment?

One may consider a bridge to be one small element in a highway system. Bridge engineering is a niche in the field of civil engineering; civil engineering is one discipline in the group of engineering disciplines. Engineering is merely one example of human activity impacting our natural environment. Bridge engineering may appear to be rather trivial as it relates to sustainable design. But the following considerations may be quite interesting!

ENGINEERING

Engineering uses natural resources to fulfill the most fundamental needs of society. For the building of a bridge, steel, stone, and other raw construction materials are used. The results are bridges that cross rivers, valleys, and the like. Besides bridges, our built world consists of buildings, highways, and all manufactured goods needed in daily life. Ideally, improvements in engineering should improve our economy; a better economy improves our living standards, which, in turn, should have the capability to improve the environment we live in, thus making it possible to achieve sustainable engineering. At the same time, a better economy can also spur consumption and deplete the world's resources. Currently, it appears that the latter is more likely to happen. A wealthy country like the United States, per capita consumption, is much higher than less developed countries.

DEFINITION OF SUSTAINABLE DEVELOPMENT

Sustainable development was defined in the 1987 Brundtland Commission Report of the United Nations as such: "Sustainable development is development that meets the needs of the present without compromising the ability of future generations to meet their own needs." (United Nations General Assembly 1987)

This statement is very simple and concise but full of unknowns and spurs obvious discussion. How much do we know about the needs of future generations? Given our history, it is clear that people of past generations, say, in 1915, could never have dreamed of how we live today. Back then, there were no freeways, commercial airlines, high speed rails, cell phones, computers, and so on. It may be equally impossible for us, in 2015, to predict how people in 2115 will live, even though a hundred years is a very short period of time in human history. The world is changing at an incredible pace, and we can barely keep up or even imagine what future generations may need to improve their quality of life!

From a resource point of view, we can quantify a supply and demand equation where the balance (B) is the difference between demand (D) and supply (S):

$$B = S - D \tag{1}$$

If supply is more than demand, B is positive and the needs of future generations can be satisfied. If supply is less than demand, then B is negative and their needs cannot be satisfied. This seemingly simple equation is very difficult to solve because both S and D are unknowns.

To take a very simple micro approach to this problem, we can ask how many bridges we should maintain over the East River in New York City: Or, how many bridges are required (which is the demand, D) and how many bridges can we build and maintain (which is the supply, S). Judging from the average daily traffic, it appears that the number of existing bridges is far from sufficient. But how many are sufficient? The same question can be asked of the Han River in Seoul. There are more than 20 bridges over the Han River in Seoul already, but traffic jams still persist. If we cannot determine what we need today, it may certainly be difficult to project how many bridges would suffice 100 years from now, let alone in the distant future. On the other hand, people may not need as many bridges in 100 years because people may not have to drive, working remotely instead. Goods may be delivered via pipelines or some other delivery system than highways. Furthermore, bridge maintenance technology may advance to a point where new bridges are not necessary. Therefore, the demand D for future bridges may be negligible, reducing impacts to the environment. In this case, sustainable development goes hand in hand with the technology to design, build, and maintain high-quality bridges.

As we can see, sustainability in bridge engineering for a city depends on the size of the population, our standard of living in the future, as well as the quality and maintainability of existing bridges. As engineers, we are not in a position to influence population control. Nor can we predict how people may live in the future. But we can address issues of quality and maintainability of all existing bridges and work toward developing sustainable solutions for new bridges to be built in the future.

GREEN

The word "green" has been introduced to describe anything that makes the world more sustainable. There are green cities, green transportation, and so on. Similarly, we may also have "green bridges." The term, "greening" represents reducing consumption and encouraging the replacement of conventional fuels with renewable energy. Even though greening may help us to be more environmentally responsible, it cannot solve the fundamental problem of sustainability. As long as the Balance B in Eq. 1 is negative, we cannot achieve sustainability.

For example, 1,500 years ago, in the fifth century, we would not have had to worry about wood supplies because trees were plentiful. The world's population was only about 300 million. Today, a world population of only 300 million would allow the use of wood for construction, furniture, energy, paper making and many other applications. The world would remain "green," because we would be able to plant a sufficient number of tress to replace the wood we use! We would have minimum air pollution and CO_2 emissions. If this were the case, refurnishing wood supplies with new trees would be more than enough to offset our consumption. So, the balance B in Eq. 1 would always be positive. In this scenario, wood is a sustainable product. However, this is certainly not the case today as we have over seven billion people in the world and growing; this is 23 times the population of the fifth century. If the required consumption per capita remains the same, we now need 23 times more supply to satisfy Eq.1. Nature will never be able to restore the trees we need to supply such a world population.

Another example can be found in our water supply. Water is a commodity that is an increasingly important concern for society. As our living standards improve, we consume more water. As populations increase, more water is consumed. Together, these two conditions drive up water demand exponentially. And, this is happening today! Green design promotes the recycling of water which means to use the same water more than once before discharging it into the soil, river or lakes. Conservation efforts such as these help but don't solve problems of sustainability.

In sum, green practices are good for sustainability, but they are not the final solution.

SUSTAINABLE DEVELOPMENT

"Sustainable development is development that meets the needs of the present without compromising the ability of future generations to meet their own needs." (United Nations General Assembly 1987)

If we are to ascertain that future generations must have sufficient resources to satisfy their needs, we must define what "sufficient" means. Sufficient has a quantitative meaning and a qualitative meaning. If we take a very simplified approach and assume that, at some point in the future, there will be n people in the world and each of them, on average, needs a quantity of q to live, the total demand, D, of the entire population will be

$$D = n \times q \tag{2}$$

Equation 2 would be very simple to solve if we knew the value of n and q. But both n and q are variables, the prediction of which is not only difficult, but basically impossible.

Let us start with the number n, which represents the world's population. Figure 1 shows the global population in the last 12,000 years, while Figure 2 shows the world's population in the last 2,000 years (US Census Bureau 2015). The size of our world's population is important because when the population increases, the consumption of resources will proportionally increase, as denoted in Eq. 2. Figure 2 shows clearly that the world's population increased exponentially around year 1800. At that time, the total world population was about 750 million, while by the end of 2014, the world population had increased to over seven billion, which is a 900% increase within about 200 years. But when we look at the average rate of increase per year that corresponds to such an expansion, it is a very modest value of 1.11% per year, a figure most politicians and sociologists would believe to be acceptable. By extrapolation, with a 1.11% increase per year, the world population will expand to 1,800 billion by year 2515 from today's 7.14 billion. This is only 500 years from now and it would be a 25,000%

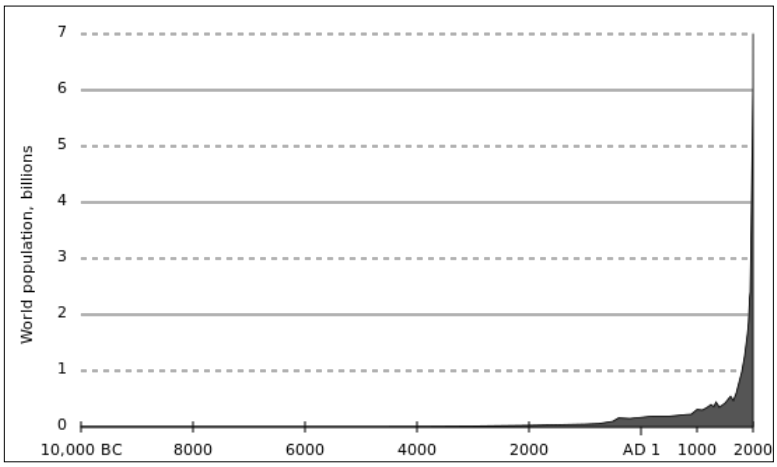

Figure 1 World population from 10,000 BC

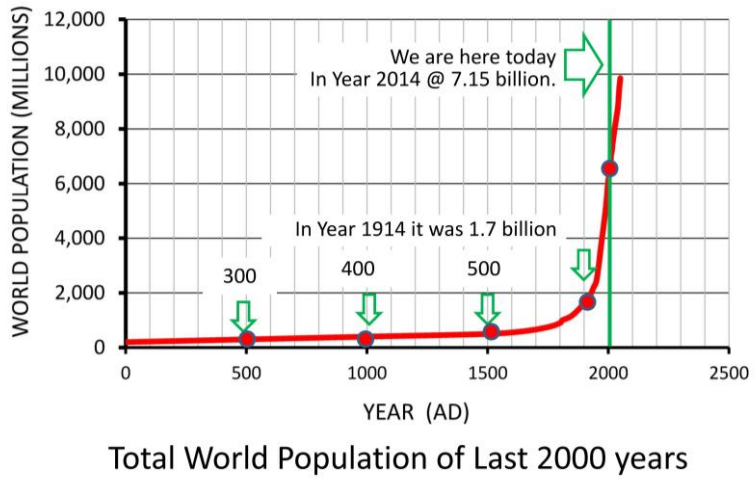

Figure 2 World population from 0 AD

increase. If we are talking about the sustainability of our planet, 500 years is not a long time. Can this planet support a population of 1,800 billion in any way that we can imagine? For bridge engineers, 1,800 billion people would need a huge infrastructure system, which certainly includes a large number of bridges!

Currently, there are about 630,000 bridges in the United States for a population of 320 million, and about 750,000 bridges in China for a population of about 1.4 billion. China is still building a large number of new bridges. How many bridges will be necessary for a population of 1,800 billion? Let us use the US numbers as an example because the US is a more developed country. By extrapolation, for a population of 1,800 billion, there should be about 3.50 billion bridges in the world. The total deck area of 3.50 billion bridges would probably be covering all the rivers in the world.

In 2014, the United Nations reported that the world population is increasing at a rate of 1.20% per year; with United States at 0.74%, China at 0.49%, and India at 1.46%. If this trend continues, with a 1.20% rate increase, the world population would be 2,780 billion in 2515, 500 years from now. No matter how people live in the future, this planet will not be able to support a population of 2,780 billion. Something has to happen! But, if n is not 2,780 billion in the future, what should it be? Again, 500 years is a relatively short period of time in the history of the planet.

Fortunately, as our living standards increase, the world's population is in decline. In some countries, it has even dipped into the negative. Most forecasts predict that the world's population will top out at about 10 to 11 billion by 2050. But human behavior is hard to predict. Political and social forces can have a huge influence too.

RESOURCES

Now let us look at the second number, q, which represents the average amount of resources each person needs to pursue a reasonably happy life. Certainly, happiness is important because life might lose its meaning if it is an unhappy one. What will we need to be happy in the future?

Back in the 1950s when I was young, life was much simpler. We had no money to learn piano, play tennis, golf, ice skate, or do any other sport that required equipment. Today's youth can do many of these things whenever they want. But are they happier than the youths of my time? I'm not so sure.

Cell phones, personal computers, and many gadgets have appeared only in the last 20 years or so. At the time when the United Nations formulated the above definition of "sustainability" in 1987, most of these things were not popular nor were they available. If we had worked on Eq. 2 in 1987, we would have assumed these things to be non-essential. But today, can you imagine a world without cell phones? This means that "q" varies with time; hence, we will not be able to predict "q" for the future!

To simplify the process, let's use today's population as a start. To provide for today's population with an average quantity of life, q, we must quantify the resources we will need to satisfy our needs.

We can divide the world's resources into two categories: renewable resources and depletable resources. Wind energy, solar energy, water (rain) and hydro power, plants, and vegetation are examples of renewable resources because those commodities can be made available assuming we employ the right strategies to sustain these resources. However, renewable resources are still limited for any given period of time. Thus, abiding by sustainable principles means we cannot use more than what is available to us. On the other hand, crude oil, coal, minerals, and other kinds of fossil fuels are all examples of depletable or nonrenewable resources. This means that once they are gone, they are gone forever. For example, oil is in limited supply and cannot be replaced after we have used it. One day when we use up all of the oil, there will be none left. Then, what will happen? Developing alternatives to replace the use of this nonrenewable energy resource would mean investing in research, development, and deployment of clean energy before our natural reserves of oil run out. We have to attack this problem from two sides: reduce consumption so the known reserve we have will last long enough to find a suitable replacement and discover an alternative that can replace oil before it runs out.

The development of green technologies is the step we take to reduce consumption of natural resources and to protect the environment. In green bridge engineering, durability appears to be the most important topic. We can use low carbon products and materials that will release little to no carbon emissions during construction and throughout the life of the structure. We can actively select construction procedures that create less waste and leave less of a carbon footprint. But in my opinion, the most important is designing for durability. That is, if a bridge can last 300 years instead of the average life of less than 100 years today, this is equivalent to a reduction in consumption of natural resources and in carbon emissions of at least 66%. In other words, the materials used in construction can last up to three times as long, mitigating the need to source more materials. In this respect, today's standard design life of 75 to100 years for a bridge is probably too short. With today's technology, we should be able to design bridges that last much more than 100 years!

THE IPAT FORMULA

Social, economic and environment have been defined as the three pillars of sustainability. The relationships of these three pillars can be expressed by means of a Venn diagram as shown in Figure 3. (Adams 2006)

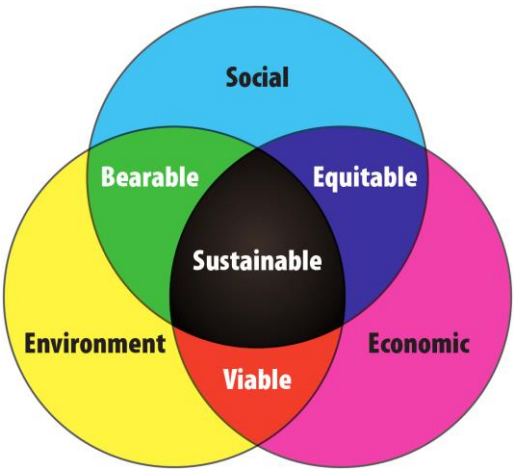

Figure 3 The three pillars of sustainability

Sustainability is achieved where the three circles overlap, which means that all three elements have been satisfied. In the past and even today in many developing countries, people tend to emphasize economic growth and neglect its impact on the environment. In many developed countries, people tend to emphasize the social ills of a society. All three pillars must be addressed before we can have a balanced world that can satisfy the needs of both present and future generations.

In the end, we must preserve the environment. We have only one world. Technological advancements have not only changed the way we live, but they have also had drastic effects on the environment. While engineering has and continues to consume natural resources, it has also increased our standard of living. Good engineering has improved transportation, changing the way that we move. As mentioned above, an optimistic way of thinking would be to expect that engineered commodities will improve our economy; a better economy will improve our society, and, in turn, that should offer ways to improve our environment, making it possible to achieve sustainability. However, as noted earlier, a better economy can also spur consumption and destroy the environment. This idea is expressed in the IPAT formula (Ehrlich, P.R. and Holden, 1971, Ehrlich, P.R. and Holden, 1974, and Adams, W.M. 2006) as

$$I = P \times A \times T \tag{3}$$

Where, I is the impact on environment, P is the world population, A is affluence of our society, which is meant to represent the level of consumption, and T is technology, which denotes the impact per unit of resource used, a quantity the advancement of technology can change.

We may compare this formula to Eq. 2 above. The product A x T is similar to the quantity q in Eq. 2. Technology affects the affluence of society. Both technology and affluence affect the impact on the environment. While the total sum of demand, D, is what we have to take from the environment, the impact, I, can be interpreted as the effect of human activity on the environment. They have very similar meaning!

LIFE CYCLE COST

A life cycle cost is usually defined as “the sum of the initial cost, construction costs, maintenance cost, rehabilitation cost or replacement cost, and demolition cost.” We can also divide the total life cycle cost by the number of years of service life to obtain the unit life cycle cost per year. This reflects more accurately the actual cost of the project. The costs included in the above definition are all monetary costs. They vary from place to place and from time to time.

Missing in the discussion are two major, non-monetary items: social costs and environmental costs. These two costs could be huge as compared to other costs in the equation. Thus, a project with the least life cycle costs as defined above could actually be more expensive than a project that has less of an impact on society and the environment.

SUMMARY

The task of engineering is to modify our natural environment, to improve human living conditions. As a result, engineers consume natural resources, while creating commodities such as bridges, highways, buildings, and other useful facilities. Better infrastructure improves functionality and facilitates a good economy. A better economy should offer ways to improve our environment, thus achieving sustainability. However, a better economy can also spur consumption and negatively impact sustainable development. The future is an unknown. We do not know what we will need to satisfy future generations because we do not know how they will live. For example, a bridge engineer would want to know how many bridges would be needed by future generations. Unfortunately, nobody knows! Because we do not know, conservation seems to be the best approach.

Currently, we are building bridges with steel and concrete. The effects on the environment in producing these structures with these materials, such as carbon emissions is great. But the potential to improve is rather limited. It appears that the best way to reduce impacts to the environment is to extend the service life of bridges. A bridge that lasts 300 years instead of 100 years is equivalent to a reduction in environmental impacts by 66%.

But, real sustainability is only possible if we can also control the size of the population. Currently, population growth in many if not most developed countries is very slow or even decreasing. By contrast, populations in developing countries are increasing at an alarming rate, with China being the only exception. Statistically, if the world's population increased at a rate equal to the same rate as in the last 200 years, 1.11% per year, we would have 1,800 billion people in the world in 2515, 500 years from now. Fortunately, most researchers believe that the total world population will top out between 10 and 11 billion by 2050 as poorer countries become industrialized and have fewer children. But, most researchers also predict that the world can only sustain a population between 600 million and two billion. It appears that the earlier we tackle the problem of overpopulation, the better. Thus, issues of population control are still the nemesis of sustainable development. Unfortunately, population control is a politically incorrect topic and not a subject that politicians are likely to discuss!

EVALUATING AND IMPROVING THE SEISMIC PERFORMANCE OF OLDER TALL BUILDINGS

Stephen Mahin[1*], Juin Wei Lai[2], Shanshan Wang[1] and Matthew Schoettler[1]

ABSTRACT

The seismic performance of new tall buildings located in regions of high seismic hazard has been recently investigated by Pacific Earthquake Engineering Research (PEER) Center under its Tall Buildings Initiative (TBI) program. The Tall Building Initiative has now expanded to assess the seismic performance of existing tall buildings. Buildings being considered are 20 stories or more in height, and constructed on the West Coast of the U.S. between about 1960 and 1990. During this period, several hundred tall buildings were constructed in California, but earthquake-resistant design procedures had not yet been fully developed. From these structures, a 35-story steel building, designed in 1968, and having representative details from that period, was selected for evaluation. In this paper, results of three-dimensional nonlinear analysis models developed to assess the seismic performance of this structure are presented. Two earthquake hazard levels are used for the evaluation. Structural analysis results are interpreted to assess the impact of suspected deficiencies on seismic response, and the ability of different evaluation guidelines, numerical models and analysis methods to identify seismic vulnerabilities. A feasible retrofit strategy was identified. Recommendations are offered for further research and guideline evaluation.

INTRODUCTION

With the resurgence of tall building construction at the beginning of the 21st century, PEER embarked on a program of investigation to assess the seismic performance accounting for changes in architectural styles, height and configuration, structural and foundation systems, seismic hazards, and acceptance criteria that occurred since the previous generation of tall structures was constructed. The TBI program culminated in a set of background documents and design guidelines, intended to provide designers, public officials and occupants with high confidence that these structures would achieve the targeted seismic performance (PEER, 2010a, 2010b and 2011; Stewart et al. 2010). Additional refinement of these guidelines is underway. Additional guidelines are used in performance based design of tall buildings (SFDBI, 2014; LATBSDC, 2014) However, it was noted that many buildings taller than 20 stories were constructed in California the 1960's, 1970's and 1980's (Figure 1), when understanding of earthquake hazards and structural behavior were not as advanced as now. These buildings formed the focus of phase 2 of the TBI. This paper describes the results for one of the case study buildings being considered as part of the Phase 2 investigations. Several evaluation procedures were used to assess the performance of this case study building.

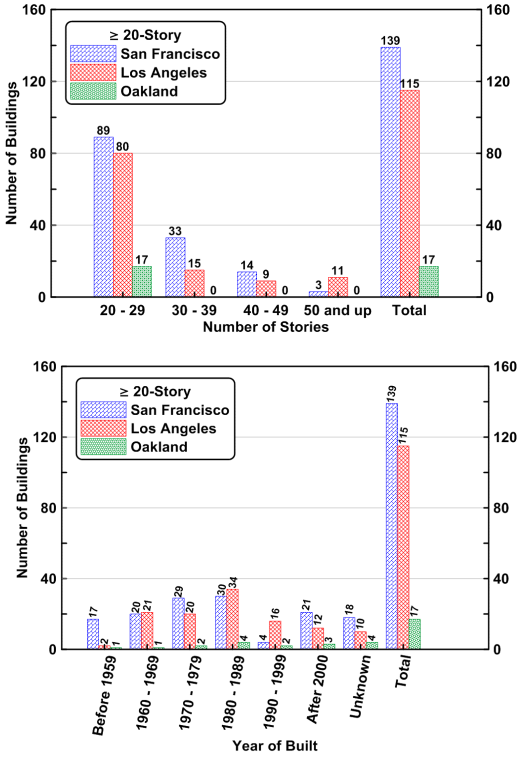

Figure 1 Inventory of tall buildings in three major cities in California

After establishing performance criteria, defining seismic hazards at the site, and constructing a simulation model, results of nonlinear

time history analyses are presented for two seismic hazard levels. These analyses identify significant potential structural deficiencies at the higher hazard level. As a result, several potential retrofit strategies are identified. Results for several alternative retrofits based on the use of fluid viscous dampers (FVD) are examined. Additional research and guideline refinement and validation are recommended to reduce the uncertainty with regards to modeling and analyzing existing tall buildings, and to establish appropriate design criteria. More detailed information about the study reported herein can be found in Lai *et al*. 2015.

EVALUATION OF EXISTING TALL BUILDINGS

Many tall buildings have performed satisfactorily during moderate to strong ground shaking. In some parts of the world, such as the West Coast of the U.S., numerous tall buildings were designed and constructed when building codes were not as advanced as now. A casual inspection of actual buildings, and codes used prior to about 1990, indicate that for the western U.S. many tall buildings have features vulnerable to strong earthquake excitation. Problematic geometric features include vertical irregularities, especially at the base of the building where partial mezzanines, tall first story columns (compared to typical story heights), discontinuous columns, sudden changes in framing systems, etc. Similarly, challenges arise due to irregularities in plan, such as when L, T or other floor layouts are used or when elements of the lateral load resisting system are asymmetrically placed in the structure. While engineering methods exist today to address some of these issues, and some of the features may be proscribed, this was not the case two or more decades ago.

Similarly, many of these buildings were designed for lateral design forces much smaller than used today, and many were not designed to limit lateral drifts due to seismic excitations. For steel moment frame buildings, a very common form of early high-rise construction in the Western U.S., building codes for these early designs did not require columns to be stronger than the adjacent beams, beam-column panel zones were not required to develop the capacity of the members framing into them, and pre-Northridge connections were used to attach the beams to the columns. Capacity design concepts were not used during the period of interest here, so that plastic hinge yielding may not dominate inelastic response. Moreover, the low design lateral forces, the low use of dynamic analysis methods, and the absence of capacity design concepts resulted in column splices that are not able to develop the capacity of the members being attached. Thus, there are many features of older steel (and other) tall buildings that raise concern.

The vulnerability of older welded steel moment-resisting frame structures was addressed as part of the SAC Steel Project following the 1994 Northridge earthquake. The State-of-the-Art Report on Performance Prediction and Evaluation of Steel Moment-Frame Structures (FEMA 355F (FEMA 2000)) examined the behavior of 3, 9 and 20 story welded steel moment frame structures designed according to different codes. For the case of a 20-story building designed in the Los Angeles Area according to the 1973 Uniform Building Code (ICBO 1973), the confidence that the collapse prevention limit state can be achieved for maximum considered level excitations is less than 50%. Moreover, there is more than a 70% confidence that at least one beam column connection will exceed its deformation capacity and fracture in a brittle manner. Even for similar designs based on the 1994 Uniform Building Code (ICBO 1994), FEMA 355F suggests that there is more than an 80% probability of seeing brittle connection fractures. However, the imposition of a strong column-weak girder design philosophy in that code increases the confidence of avoiding global collapse to about 75%. Similar findings were obtained by others (e.g. Krishnan and Muto 2011).

The seismic performance evaluation presented in this paper follows ASCE 41-13, "Seismic Evaluation and Retrofit of Existing Buildings" (ASCE 2013). ASCE 41 has been adopted by the California Building Code (CBSC 2013) for seismic rehabilitation of existing buildings. Performance objectives for the building are selected to conform to the Basic Performance Objective for Existing Buildings (BPOE) described in ASCE 41.

ASCE 41 outlines a three-tiered approach to evaluation. For a complex high-rise structure, like the case study building, the ASCE 41 Tier 1 simplified screening evaluation is not required. Instead, the Tier 3 systematic evaluation procedure is automatically required. However, to identify potential seismic deficiencies, the Tier 1 screening evaluation was performed. Tier 2 "deficiency-based" procedure was also not required, and is not included herein as part of the evaluation. Thus, the principal seismic performance evaluation utilizes the Tier 3, dynamic analysis approach. These analyses were based on the available existing as-built drawings and engineering judgment regarding the likely behaviour of pre-Northridge era steel construction.

Nonetheless, the Tier 1 procedure was used to identify deficiencies in the structural system. This tier utilizes checklists to evaluate the adequacy of a building's lateral force-resisting system. The "Basic Configuration Checklist", which is applicable to all building types, was followed. ASCE 41 also has additional checklists for both Life Safety (LS) and Immediate Occupancy (IO) performance levels. The basic performance objective for

existing building (BPOE) recommended by ASCE 41 requires the prototype building to meet the Life Safety (S-3) performance level. Therefore, the Checklists for the Life Safety performance level were also completed. For a more complete evaluation, considering the cost of repair, downtime, business interruption costs associated with disruption or loss of occupancy, see Porter (2009), FEMA (2012) and Terzic et al. (2015).

THE CASE STUDY BUILDING

The existing building considered in this paper is a 35-story tall (about 490-ft in height), approximately 185 ft. by 135 ft. in plan (Figure 2). It was built in San Francisco starting in 1968. The typical story height is 13-ft. The building is constructed over three basement levels. The structural system consists of complete, three-dimensional, welded steel, moment-resisting space frames. These steel frames consist primarily of built-up box (single-cell or two-cell) or wide flange columns welded to beams (either built-up or hot-rolled sections). A typical 6-in.-thick concrete slab on metal deck is provided at each floor. The perimeter precast concrete façade and other non-structural elements were not simulated in the analytical model.

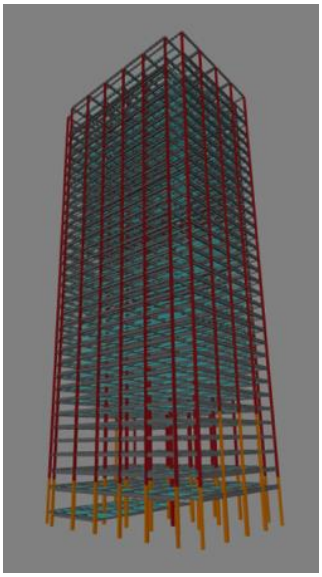

Figure 2 Perspective View of Case Study Building

The building's foundation consists of a 7-ft-thick foundation mat located 40-ft below grade and supported by more than 2,500 concrete piles that extended to 60-ft below the mat. The foundation mat is connected to a 3-ft-thick retaining wall running around the entire site. Member sizes, structural detail drawings, foundation details and other information were collected from the building owner and the department of building inspection, San Francisco (DBI 2013).

Beam-to-column moment connections incorporate typical pre-Northridge details. Partial joint penetration (PJP) weld column splice details are used. Based on research following the Northridge earthquake, these types of connections are expected to be relatively brittle. Column slices use partial penetration welds, located about 4 ft. from the lower floor level, and these are relatively brittle if overloaded.

Performance objectives and ground motion selection

The Basic Performance Objectives (BPOE) in ASCE 41 depend on the risk category (occupancy) of the building and the evaluation procedure used. Here, the risk category of the prototype building was selected to be III, based on ASCE 7-10 (ASCE 2010). The BPOE criteria for structural elements are "Damage Control" at the BSE-1E seismic hazard level (20% probability of exceedence in 50 years; 225 year mean return interval), and "Limited Safety" at the BSE-2E level (5% probability of exceedence in 50 years; 975 year return interval).

Numerous sets of ground motions were developed based on various code requirements and probability of exceedence levels (Baker 2014). Each set consisted of 20 three-component records. Ground motions were extracted from the PEER NGA West2 database, and no more than five ground motions were taken from any single event. For this paper, results for two different hazard levels, BSE-1E and BSE-2E, are presented Ground motions were scaled so the square root sum of square (SRSS) of their two horizontal response spectrum matched the associated target spectrum between 0.5 and 10 seconds for each hazard level. Ground motions were selected such that the distance to rupture was less than 50 km, the magnitude of event was 6.5 or larger, and the scale factor needed was less than 9. Figure 3 shows the horizontal response spectra of the ground motions for the BSE-1E and BSE-2E hazard levels.

Mathematical Modeling

A three-dimensional computer model was constructed in OpenSees (McKenna and Fenves 2010). All above ground main framing members contributing to the seismic lateral force resisting systems are included in the model (see Figure 2). A fixed-base boundary condition is used at the column bases at the ground level. Concrete floor slabs are not included in the numerical model, but rigid in-plane diaphragm constraints are introduced. Dead loads and 25% of design live loads are included in the seismic analyses. The first three elastic modal periods of the structure are: 4.33 s (x-translation), 4.18 s (y-translation), and 3.58 s (rotation about the z-axis).

Columns are modeled using displacement-based nonlinear beam-column elements with fiber sections at five integration points along the length of element. Each fiber section has 4 layers in the width (or depth) direction and 4 layers in the thickness direction of any part of a section. A Giuffré-Menegotto-Pinto material model with isotropic strain hardening (Steel02) is used to define the fiber sections. Structural materials are modeled per ASCE 41, Section 9.2.2. The expected steel material strength is estimated as the multiplication of lower bound strength and modification factor for each material class. Column splices are modeled and assumed to be either fully ductile (no failure) or brittle. To capture the brittle behavior, a maximum permitted tension fiber strain for each column splice location is derived and assigned to the corresponding fiber section within the zerolengthsection element (Kanvinde 2012).

Beams are modeled using force-based nonlinear beam-column elements with finite-length plastic hinges at both ends as proposed by Ribeiro et al. (Ribeiro 2015), and the hysteresis uniaxial material in OpenSees is used to model the moment-curvature behavior of plastic hinge locations and used with the fatigue material wrapper to account for low cycle fatigue. Plastic hinge length was selected as 1/6 of beam length such that no correction of moment of inertia (for the elastic portion of the beam element) is required for this special case (Ribeiro 2015). ASCE 41 modeling parameters for welded unreinforced flange (WUF) beam-to-column connections are used as default input to simulate the connection behavior. Figure 4 illustrates one example of simulated beam-to-column assembly responses for a wide flange beam (W33X118) to box column connection. Another set of modeling parameter for an ideally ductile connection. Panel zones are not explicitly modeled. Instead, as permitted by FEMA 451(10), center-to-center elements models are used.

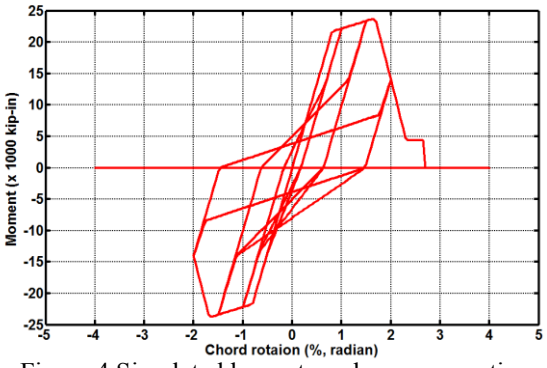

Figure 4 Simulated beam-to-column connection response based on ASCE 41 recommended modeling parameters

An important limitation of the modeling of the mechanical characteristics of member and connection behavior is that many of the built-up column and beam sections used do not have sufficient welds to develop the full flexural capacity of the members. This issue is addressed elsewhere (Liu *et al*. 2015).

Rayleigh viscous damping coefficients were derived assuming the 1st and the 24th mode critical damping values both equal to 1.71 % (α/N = 60/35). This damping value was determined according to the Equation 2-10 in PEER (2010b). Inertial and kinematic soil-structure interaction effects are not considered in this paper because of the building's long fundamental period (NIST 2012).

Table 1 lists the numerical models used for the current studies (Models 1a*, 1a, 1b*, 1b, 1c*, 1c, 1d* and 1d). The four models that include an * symbol in their designation include the full weight of the relatively heavy perimeter cladding. These panels cumulatively represented about 20% of the total mass of the structure. Model 1c was selected as baseline model to be presented in this paper. In this case, the building is presumed partially retrofit, with the as-built cladding replaced by a lightweight curtain wall, and the column splices retrofit to avoid premature brittle at these locations. In addition to the ASCE 41-13 evaluations, estimates of behavior were performed using FEMA 352 and FEMA P-58. These results are not presented herein for the sake of brevity.

Table 1 List of Numerical Models

Model ID	Beam-to-column connection behavior	Column splice behavior
1a, 1a*	fully ductile (bilinear)	fully ductile
1b, 1b*	fully ductile (bilinear)	brittle
1c, 1c*	per ASCE 41 (WUF)	fully ductile
1d, 1d*	per ASCE 41 (WUF)	brittle

ANALYSIS RESULTS AND DISCUSSION

ASCE 41 stipulates a number of specific evaluations. For the case study building, a series of nonlinear analyses are to be carried out. However, to better understand the behavior of the structure, the simplified Tier 1 checklist approach is used to identify the types of deficiencies that need to be modeled carefully. In addition, series of nonlinear analysis procedures (static pushover analyses) were undertaken to help identify vulnerable regions of the structure.

Seismic Deficiencies Identified From Tier 1 Screening

The simplified Tier 1, checklist based structural evaluations are not required for this type of structure according to ASCE 41. However, these simple checks identified a number of possible deficiencies, including a potential soft story at the mezzanine level. Several other deficiencies are also identified, such as high column stress levels, pre-Northridge beam-to-column connection details, panel zone details, not passing the strong-column weak-beam (SCWB) check, column bases not anchored to the foundation, diaphragm openings at mezzanine level and metal decks are connected to steel frames with only puddle welds (no shear studs were used). In some cases, welds used to fabricate built-up sections are insufficient to develop member flexural capacities. Detail checklists are presented in the appendix of the project report (Lai et al. 2015).

Nonlinear Static Pushover Curves

Nonlinear static pushover analysis typically is not permitted for tall buildings, since higher mode effects are not realistically taken into account. However, such analyses provide basic comparative information on post-yield behavior. Figure 5 shows pushover curves and deformed shapes at selected roof displacements of the four models with loads applied in the Y direction. The lateral load pattern used was the same as the first mode shape. The shear capacity in both directions is about 13,700 kips (equivalent to about 10% of building weight). Significant P-Δ effects can be inferred from the structure's negative post-yield tangent lateral stiffness for models 1a and 1b. Note that the design base shear (2,993 kips) per 1967 Uniform Building Code (ICBO, 1964) for the prototype building is only 2.2% of building weight; about 45% of the required design base shear (6,650 kips) per the current edition of ASCE 7 (ASCE, 2010).

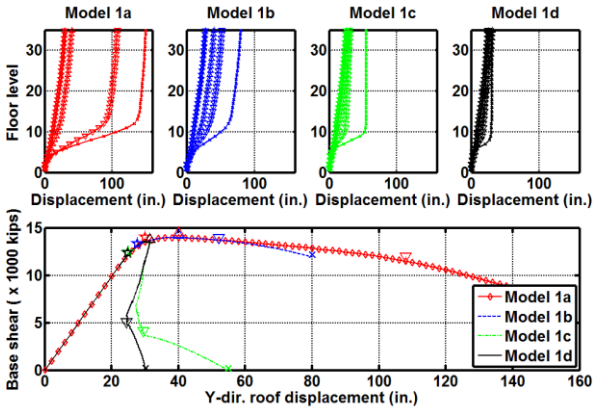

Figure 5 Static pushover curves and deformed shapes of four models (Y-Direction)

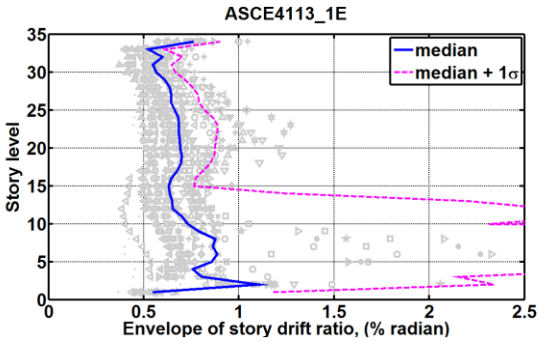
The star symbol markers on the pushover curves indicate roof displacements corresponding either to first significant yielding or first column splice failure. Upward-pointing triangle makers indicate the roof displacements at peak base shear. Cross markers indicate the roof displacements when simulation terminated or numerical model became unstable. Clearly, story drifts concentrate between floor levels five and ten in all models. However, the mechanical behavior of the beam-to-column connection has a significant effect on the degree of concentration and system deformability. For example, Models 1c or 1d both exhibit substantial loss in lateral load resistance at a roof lateral displacement of about 30 in. While the column splice behavior has an important influence on overall lateral force-displacement behavior, this is secondary to the deterioration and failure of the beam-to-column connections.

Tier 3 Evaluation (Nonlinear Dynamic Analysis)

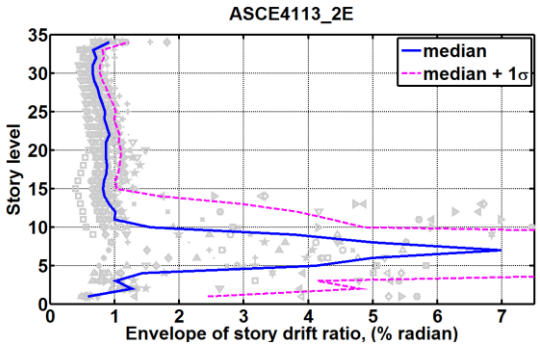
Nonlinear response history analyses were performed in OpenSees using BSE-1E and BSE-2E hazard level ground motions. Each hazard level ground motion set contained 20 records and each record contains three components (two-horizontal and one vertical). Only the results of models 1c (baseline model) and global responses are presented in this paper. Complete results for all eight models, and a comparison of cases with and without consideration of the vertical component of motion, can be found in Lai et al. 2015.

Figure 6 displays the average story drift envelope distribution under BSE-1E and BSE-2E hazard level events. Median peak drifts are all less than 1.2% under BSE-1E events but rise to about 7.0% under BSE-2E events. Computed peak story drift ratios are as large as 46% under BSE-1E events and 55% under BSE-2E events,

significantly larger than the peak 4.5% limit permitted by several criteria (e.g., LATBSDC (2014)). Note that Figure 6 only shows the story drift up to 2.5% and 7.5% for each hazard level. Drifts in some stories exceed these values. Obviously, results show a tendency towards soft story behavior in the bottom third of the structure.



a. Model 1c, BSE-1E hazard level



b. Model 1c, BSE-2E hazard level

Figure 6 Story drift envelops (Y-Direction)

Maximum story shear demands for the BSE-1E and BSE-2E level events are both about 15,000 kips; similar to the value predicted by the static pushover analysis. Median peak beam end total rotation demands for BSE-1E and BSE-2E events are as large as 1.2% and 9%, and follow the trend for story drift, concentrating in the bottom one third of the building (Figure 7). In terms of percentage of beam-to-column connections at a floor level that lose their moment capacities (beam ends rotation demands larger than collapse prevention criteria per ASCE 41), the median percentage can be as high as 30% under BSE-2E events (Figure 8). Even for the BSE-1E level excitation, some ground motion records would be expected to fracture a significant number of connections in the lower half of the structure

Observations Regarding Evaluation

The computed response of the prototype building does not satisfy the targeted performance objectives according to ASCE 41 (damage control state under BSE-1E events or limited safety state under BSE-2E events). Several specific seismic deficiencies were identified during the evaluation procedure. It is found that the case study building has a tendency to form weak story regions in its lower third. Pre-Northridge beam-to-column connection details result in a high percentage of connection failure under BES-2E events. High column stress demands, fracture vulnerable column splice details, beams and columns not conforming to the strong-column weak-beam criterion and no anchorage between column bases to foundation were also found during the Tier 1 screening. Although results presented herein do not consider column splice failures, they are considered in the

overall evaluation of the building. From a review of the seismic evaluation results, it is suggested to retrofit the building. The feasibility of such a retrofit remains a question that is addressed in the next section.

RETROFIT FEASIBILITY ASSESSMENT

A number of different approaches are possible for retrofit. One approach is to increase the inelastic deformation capacity of the existing connections. However, while Model 1a described previously with ideally ductile beam-to-column connections and ductile column splices was able to develop the full capacity of the columns but resulted in very large story drift demands between levels 5 and 10, and substantial residual displacements. Even if the analytical results (not shown) suggested acceptable seismic response, the large number of difficult to access, beam-to-column connections needing retrofit would likely make this approach economically prohibitive. Thus, it appears that an approach that would reduce story drift deformation demands, beam ends rotational demands, and the tendency of the structure to form a weak story mechanism should be explored.

The lack of column attachment at the foundation and the fragility of the columns, pose significant challenges to stiffening the building by adding strong centralized bracing or wall elements. Retrofit schemes such as adding distributed velocity- or displacement-dependent bracing devices (Wang et al. 2015) to the current lateral force resisting frames or implementing mid-level isolation systems might be considered.

To provide the required lateral stiffness and energy dissipation needed to reduce lateral displacements, while not increasing the strength of the structure, is a challenge. Common approaches in the U.S. would be to consider the addition of buckling restrained braces or fluid viscous dampers. Because of the fragility of the columns in compression and tension, an approach using fluid viscous dampers has been explored in some detail. In this approach, the ability of the fluid viscous dampers to result in peak force resistance that is out of phase with the forces acting in structural elements may provide a way to limit drifts but not create excessive demands on the columns and other structural elements. Several other alternatives that might be considered including reducing the force demands on the system by reducing the weight of the structure. For instance, the heavy cladding used on the building could be replaced with a much lighter curtain wall system. Similarly, an isolation system might be added to the building above the mezzanine level. This option introduces substantial changes in the architecture components, elevators, stairs, utilities and structure near the base of the structure. Thus, the initial focus is placed on fluid viscous dampers.

A Fluid Viscous Damper (FVD) is a velocity-dependent energy dissipation device. Numerical and experimental investigations have both shown merits of such devices (Reinhorn et al. 1995; Symans et al. 1998; Miyamoto et al. 1971). More recently, probabilistic risk assessments have been made of steel moment frames with FVD (Miyamoto 2010). One of the largest advantages of FVD is its forces tend to be out-of-phase with forces in elastic structural members. This avoids the peak damper force occurring concurrently with forces in other elements, thus limiting the maximum force developed by the structure.

Considerable research in the 1990s resulted at least five code-oriented procedures for designing passive energy dissipation systems (Ramirez et al. 2001). Those guidelines and codes such as ASCE 41-13 and ASCE 7-10 provide methods to account for the supplemental damping effects of these devices by modifying the design spectrum. In this way, damper characteristics can be selected to achieve basic performance goals. However, they do not prescribe specific methods for optimally placing dampers in a building, and damper placement could have large impacts on both structural behavior and the cost of using dampers. A wide variety of methods have been suggested to identify optimal damper placement (e.g. Apostolakis and Dargush 2010; Balling and Pister 1983; Garcia and Soong 2002; Gluck et al. 1996; Lavan and Dargush 2009; Lee et al. 2004; Levy and Lavan 2006; Singh and Moreschi 2001, 2002; Takewaki 2000; Yang et al. 2002; Zhang and Soong 1992).

Most of the aforementioned methods focus on FVD in low- to median-rise buildings. Intensive computation is needed to optimize the distribution of dampers and their properties, even for these structures. Whittle et al. (2012) compared two conventional design methods and three advanced optimizations methods and showed that even for computationally efficient optimization algorithms the total computation time required for a ten-story building was 10-50 times that for a conventional design method. For a far taller building, having complex, three-dimensional, nonlinear dynamic behavior, typical optimization algorithms are not expected to be computationally efficient.

Thus, in this paper, selecting potential FVD configurations and properties starts by examining three conventional schemes, and then assessing their advantages and limitations. Improved designs are then proposed based on the findings for these initial schemes.

Modeling of Retrofit Alternatives

For the feasibility study, the retrofit design focuses primarily on a hazard level corresponding to the Basic Safety Earthquake, Level 2 for existing buildings (BSE-2E). The intent of the retrofit is to reduce the concentration of drifts in the lower levels (stories 5-10) compared to other stories, and to reduce the overall drifts of the structure to a level where brittle fracture of the beam to column connections are limited to the point where they do not seriously jeopardize the overall stability of the structure under the BSE-2E excitations. It is assumed that the columns splices will need to be retrofit in multiple places in the structure to prevent this undesirable failure mode. Similarly, it is assumed that the heavy perimeter cladding will be replaced with lighter weight curtain walls. As a consequence, the basic numerical model for the building used for the retrofit studies is Model 1c (Table 1) that has "brittle" beam-to-column connections, and ductile column splices.

To streamline the analysis process during preliminary feasibility studies, only three three-component ground motion sets are used. As stipulated by ASCE 41, the largest response value computed for a parameter of interest is used to assess the performance of the system. The ground motions used were selected based on the closeness of their pseudo-acceleration spectra to the target spectrum at the fundamental period of the as-built structure.

Selection of Initial VFDs

Figure 9 shows a sketch of the plan view of a typical floor, where the black boxes indicate column locations. The interior frames are usually adjacent to stairs and elevator locations, and putting dampers there would interfere with office space and egress. Therefore, dampers were added only to the perimeter frames.

As a first trial, dampers were stacked above one another within single bays, as indicated by the cross lines in the plan view. However, this resulted in a significant accumulation of damper forces in the adjacent columns and this approach was discarded. As such, the dampers were distributed diagonally across the structure, Figure 9. It is assumed here that the heavy precast cladding panels in the actual building are removed to reduce the weight of the structure, and facilitate damper installation.

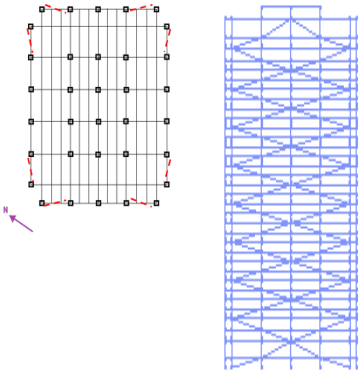

Figure 9 Plan view and exterior elevations of case study building showing trial placement of dampers

As a first trial, dampers were stacked above one another within single bays, which is indicated by the cross lines in the plan view. However, this resulted in a significant accumulation of damper forces in the adjacent columns and this approach was discarded. As such, the dampers were distributed across the structure, as seen in Figure 2, to minimize this accumulation. The odd number of bays in the longitudinal direction of the building resulted in a skewed distribution of dampers.

Effective damping needed. -- Estimating the overall effective damping (including the intrinsic damping and supplemental damping from the FVDs) needed to reduce the overall drifts and drift concentrations to acceptable levels is a crucial first step in selecting the appropriate number and size of dampers. For this preliminary study, a simple and direct approach is used. Several guidelines and codes provide damping coefficients to modify the design response spectrum to account for damping values other than 5%. The values are typically derived based on responses of simple structural systems to a limited selection of ground motions, not including records on soft soil sites and from near-fault sites (Ramirez 2001). In this paper, a spectrum modification approach developed by Rezaeian (2012) is used. In this approach a Damping Scale Factor (DSF) was developed to adjust 5% damped spectral ordinates to damping ratio ranges between 0.5 to 30%. These factors are based on analyses using the entire NGA West2 earthquake record set.

Here, the target acceptance criterion is based on the roof drift at which the as-built structure suddenly loses significant strength. This was simply done by examining Figure 5. For Model 1c, the roof displacement at which the structure exhibits a sudden loss of capacity was identified. For the X-Direction, this was about 38 in. Simplified methods in FEMA 41-13 were then used to assess the expected roof displacement for the BSE-2E excitation. This resulted in an estimated roof displacement in the X-Direction of 48 in. As a result a DSF of (38/49=) 0.79 is needed in this direction. The value of required damping to achieve this DSF was estimated from the regression analysis equation proposed by Rezaeian (Rezaeian et al. 2012).

Following this procedure, no additional damping is required for the BSE-1E level earthquake. However, for the BSE-2E hazard level, an effective damping ratio of 10% and 15% for the X-direction and Y-direction,

respectively, are required. For comparison, damping tables contained in ASCE 7-10 suggest 12% and 18% effective damping for the same BSE-2E level target roof displacement for the X- and Y-directions, respectively. Thus, the method presented here requires a bit less damping that estimated using standard code requirements. However, the method used selects the performance target from the pushover curve of the specific building and uses improved DSF that considers variations of magnitude, source-to-site distance, local site conditions; also, this method designed the two horizontal directions separately. The validity of this method will be demonstrated below using the results of nonlinear dynamic analyses of the retrofit building models.

The effective damping ratio relates to designing the damping constants C of the FVDs, a parameter related to the damper force by the equation: $F = CV^{\alpha}$. The set of C values are calculated based on the strain energy method in ASCE 41-13, considering both linear dampers and nonlinear dampers:

$$\xi_{eff} = \xi_0 + \frac{\sum_j \lambda C_j \phi_{ij}^{1+\alpha} cos^{1+\alpha}\theta}{2\pi A^{1-\alpha}\omega^{2-\alpha}\sum_j m_i \phi_i^2}$$

The structure's first mode frequency and mode shape were used in conjunction with the desired effective damping ratio to identify the C coefficients for linear FVDs (with α=1). Three distributions of C over the height of the building were considered: I) Uniform damping constant; II) Damper force proportional to story shear demand; and III) Damping constant proportional to story stiffness. The in-line brace used to drive the brace was given stiffness equal to twice the story stiffness. The braces were arranged as shown in Figure 9.

Structural Response. -- Peak story drift, floor displacement and floor acceleration envelopes are examined to check the effectiveness of the three damping systems. The maximum value for the three time history analyses is used to compare the different systems. Only X direction responses are presented in this paper.

Figures 10 and 11 show envelops of maximum story displacement and maximum story drift. All three design schemes help reduce the story drift ratio by about 20%-30%, and by a much larger amount in stories 5 through 9. Scheme II is the least effective. Schemes I and III are more effective with Scheme III being slightly more effective in reducing the peak story drift ratio. In this later case the maximum peak story drift is about 1.3%, which is acceptable under the BSE-2E level earthquake (LATBSDC 2014; ASCE 41-13).

Figure 15 shows that the average peak roof displacement is about 38 in. for all three cases, validating the method used to calculate the effective damping ratio for the initial retrofit.

Figure 16 shows the maximum peak floor acceleration envelope. All of the FVDs reduce the floor accelerations, especially those that appear to be associated with higher mode effects. The peak accelerations in the structures with supplemental damping are about 0.7g, which represents about a 30% reduction. Another benefit of FVDs is that it results in a rapid decay of structural vibrations at the end of the earthquake. The reduction of both story drifts and floor accelerations could help reduce both structural and non-structural damage, and reduce the fear and discomfort of occupants.

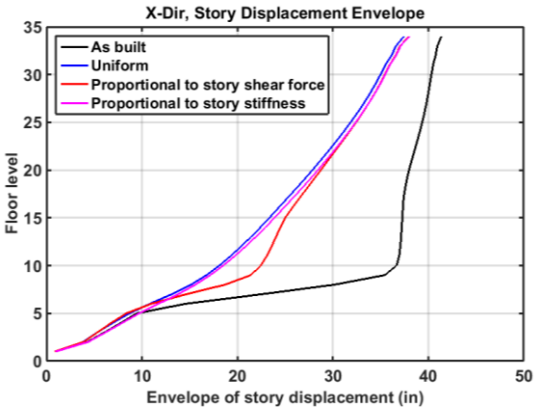

Figure 10 Peak floor displacement in X-direction (BSE-2E)

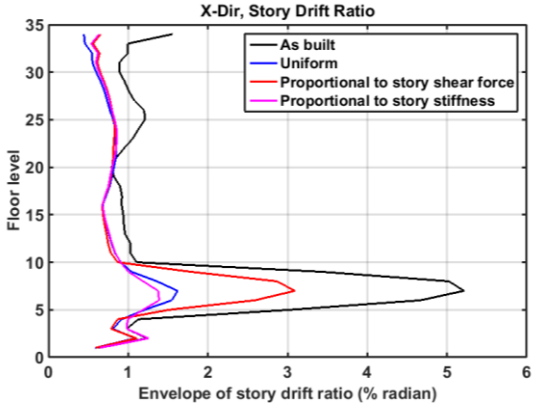

Figure 11 Peak Story Drift in X-direction (BSE-2E)

Damper response. -- The damper force demand envelopes are shown in Figure 12. All cases give fairly large damper forces, with the maxima ranging from 1600 kips to 2300 kips, at the lower stories. While such large

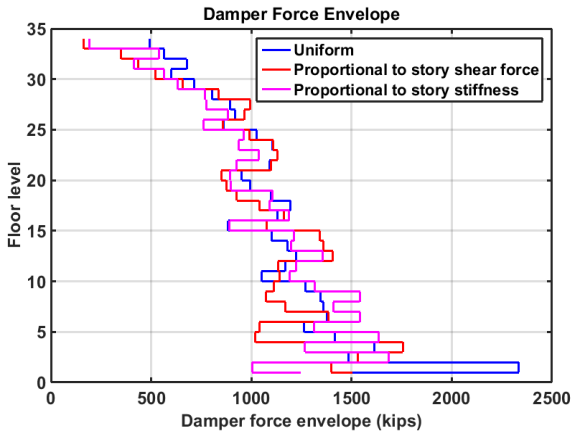

Figure 12 Peak damper forces (BSE-2E)

dampers are possible to achieve, more typically dampers with capacities up to 1300 kips are used in engineering practice (Taylor and Katz 2004). It should be noted that Scheme III, which produced the most effective reduction in story drift has the least damping force demand (1600 kips).

Alternatives using two dampers per driver (for example, installed in parallel), more damped bays at selected stories, or utilizing toggle-brace mechanisms to magnify the effective force of a damping device (Constantinou et al. 2001), might be considered.

Observations. -- Comparing three schemes studied, sizing dampers uniformly provides reasonable results. However, it results in using larger dampers than needed at the upper stories, and large damping forces particularly near the base of the structure. Scheme II, where dampers are sized in order to achieve damper force distribution proportional to story shear, failed to suppress fully the soft story in stories 5 to 9. This is mainly due to the relative small damping capacity assigned in those levels. The last scheme (III), with damping constant sized proportional to story stiffness, provides the best results and introduces smallest damper force demands, and thus it is selected as an initial scheme towards further refinement.

Improved Retrofit Design

The results of the preliminary study show that under a given effective damping ratio, it would be more effective to put a larger portion of the damping in the lower levels. Starting with Scheme III, an improved scheme is proposed with a 30% increase of C values assigned in the lower level floors, 30% reduction and 70% reduction of C values assigned to the middle and upper levels, respectively. Those values are quantitatively obtained using a performance index and cost index. The performance index was defined as a weighted function of story drift ratios, residual story drift ratios and floor accelerations. The cost index is defined as a function of the sum of the individual damper capacities. The selection of damper C values was based on balancing the performance index with the cost index. Details of this process are described in the final project report (Lai et al. 2015).

Envelopes of story drift ratio and the damper force demands are plotted in Figures 13 and 14. The story drift ratios in the lower levels are further reduced by this improved distribution where heavier damping is used in those levels, while drifts in upper levels are increased a little due to the reduction in supplemental damping in these stories. Such a redistribution of dampers also results in larger damper forces for lower levels and smaller damper forces in middle and upper levels. The benefits of the improved scheme mainly lie in reducing the peak drift values in the most deformed stories. Following such a procedure, the design could be further improved by comparing the cost of using more small dampers or fewer large dampers at these levels, and refining the design accounting for the axial forces in the columns and other structural members.

Additional Retrofit Studies

Additional research has or is being undertaken to identify and assess the feasibility and cost effectiveness of different retrofit strategies. This includes examining other configurations and properties of supplemental damping systems, use of buckling restrained braces alone or in combination with FVDs, and the use of seismic isolation.

CONCLUSIONS

This paper examines the possible seismic performance of a representative steel moment frame building constructed in San Francisco during the later half of the 20th century. Primary structural evaluations were carried out using ASCE 41-13. While not required for this type of buildings, the ASCE 41-13 Tier 1 checklists were able to identify most, but not all of the vulnerabilities that exist with this particular structure. Tier 3 nonlinear dynamic analyses showed that these vulnerabilities were not necessarily critical on average from the collapse prevention viewpoint for significant earthquakes represented by the BSE-1E level of shaking (RT=225 years). However, significant damage to displacement and acceleration sensitive non-structural elements, and fracture of some beam-to-column connections is likely for some excitations. Story drifts while not on average excessive, show concentrations especially for some records at the irregular mezzanine level, between floors 5 and 9 and around level 22. Moreover, it is clear from the BSE-1E simulations that significant numbers of beam to column fractures would be expected for some ground motions at this level of shaking, raising the possibility of time consuming inspections and repairs to structural elements as well.

As the intensity of the excitation increases to the BSE-2E (RT = 975 years) level, drifts concentrate at the stories between floors 5 to 10. These drifts in many cases exceed the deformation capacity of the beam-to-column connections, leading to sudden reduction of lateral load capacity, and large lateral displacements. Not shown here is the tendency of the welded column splices at this level of shaking to partially or completely rupture. Even without considering these splice failures, more than 30% of the beam to column connections at some stories are expected on average to loose nearly all of their load resisting capacity, and in some cases more than 70% of the connections on a level fracture. Clearly, a more refined assessment of the building is still needed to assess more realistic models of the connections and splices, validated by representative test results if possible, and to account for possibly beneficial effects of the basement region of the structure, soil-structure interaction, partial composite action of the slabs with the beams, stiffening and damping effects of cladding and some substantial non-structural components, and to more realistically assess the effect of uncertainties in various modeling assumptions. The cost of expected repairs and the business and other losses associated with loss or disruption of occupancy remain to be assessed.

Additionally, the costs and benefits of alternative retrofit strategies should be explored. In the preliminary study presented herein fluid viscous dampers were quite useful in improving the performance under both levels of excitation considered herein. They could reduce the peak drift ratio by up to 30%, and decrease the residual drift ratio by a similar amount. FVDs also help suppress floor accelerations and lead to more rapid decay of vibrations, so that damage to structural and non-structural elements and discomfort to occupants would be expected, especially for small and moderate earthquakes. For the BSE-2E level of excitation, some localized connection fractures may still be expected. The analysis results indicate the large damper forces are needed to achieve the desired responses, especially in the most deformed stories. Moreover, extensive upgrading of column splices and other existing features of the building is needed. The results to date show that significant benefit and cost may be possible through more extensive assessment of damper configuration within the building, and selection of damper properties.

Thus, it would be prudent to investigate other strategies to improve seismic performance, such as strengthening existing structural elements/connections, using other types of energy dissipation devices alone or in combination with FVDs, or adding lateral load resisting elements such as steel or reinforced concrete structural walls. Seismic isolation above the base of the structure may also be a viable strategy. A key question for owners, occupants and public officials is what performance criteria should be used to make final assessments of this and other potentially vulnerable tall buildings containing large number of occupants, that provide substantial economic benefit for the occupants and neighboring community, and that raise risks for nearby buildings.

TREATING ROBUSTNESS AS A PERFORMANCE BASED STRUCTURAL DESIGN REQUIREMENT

ABSTRACT

The basis for current design provisions intended to ensure adequate Robustness in building structures e.g. those of the Eurocode and similar North American documents, is discussed and their limitations identified. In particular, the often tenuous link between the concepts employed and behaviour observed in actual incidents is highlighted. It is contended that research in the subject - particularly that completed within the past few years - provides sufficient understanding that - at least for some forms of construction - a scientifically more soundly based approach is now appropriate. Such an approach would fit naturally within the ethos of Performance Based.

KEYWORDS

Buildings, disproportionate collapse, performance based, progressive collapse, robustness, structural design.

INTRODUCTION

Structural design seeks to ensure that before a structure is built an assessment has been made to check that it can be expected to perform adequately. Over time the basis for how this is done has changed significantly: from mimicking nature, trial and error and observing precedent through increasingly more scientifically based thinking to our latest conceptual framework of Performance Based. At the highest level this is a delightfully but deceptively simple concept: define what is required and then engineer the structure so that it delivers this performance. But defining acceptable performance and specifying how it should be demonstrated are hard challenges, particularly if every structure is required to be treated individually within its own context.

It is for this reason, as well as because of concerns over public safety and legal liability, that our present generation of Structural Codes based on Limit States principles essentially define the conditions that should be met and provide (in more or less detail) procedures for checking and demonstrating that this is the case. Where departures from this practice have occurred e.g. the original thinking that the Structural Eurocodes (Breitschaft, Oestlund and Kersken-Bradley 1992) should focus on Principles with limited concern for Application Rules or the treatment of serviceability defections for portal frames in the first version of the British Code for Steel Buildings, BS 5950 (BSI 1990) as a matter to be agreed with the client on the basis of the particular arrangements, the situation has subsequently changed e.g. the current focus for the Evolution of the second generation of Structural Eurocodes is on usability whilst the first revision to BS 5950 saw the inclusion of specific default deflection limits.

Largely as a result of public concern arising from a few spectacular and widely publicised collapses, the provision of sufficient resilience that, should a structure suffer an incident that has not been allowed for explicitly in its design its functionality should not be unduly impaired, now features more prominently in the thinking of clients, insurers, regulatory authorities and construction professionals. But how should this be treated? With prescriptive rules or general principles? Should Codes provide the means to demonstrate adequacy or just set out the requirements to be met? How should these be framed - as general objectives or in terms of specific limits? What is the scientific and evidential basis for making specific provisions? Noting that the most significant event in this field, the progressive collapse due to a localised gas explosion of one corner of the 22 storey Ronan Point apartment building, occurred almost 50 years ago (Griffiths, Pugsley and Saunders 1968) it is considered appropriate to review the subject with the aim of assessing the adequacy of current provisions, the information and understanding currently available on which something different might be based and the possibilities for improved treatments. This is done herein from the particular perspective of Robustness, a property that is defined and explained below, focussing on the performance of multi-storey steel and composite

frame building structures subject to an initial incident with the potential to trigger a Progressive Collapse form of failure (Staroussek 2009).

THE CONCEPT OF ROBUSTNESS

Robustness is an inherent feature of a structure. It has been defined in many places; (Haberland and Starossek 2009); that used herein is:

Robustness in a structure ensures that the consequences of sustaining some limited damage will not be disproportionate to the event that caused the initial damage.

Thus it can be associated with a specific event e.g. accommodating the failure of one or more cables in a cable stayed bridge, or it can be used as a more generic indication of adequacy e.g. better response to an unforeseen event. A particularly simple definition is: the ability of the structure to 'take a knock'.

Disproportionate collapse - the condition that the possession of adequate robustness is intended to prevent - occurs when a local failure spreads throughout the structure in such a way that a partial or complete collapse occurs. Well known incidents include the collapse of the Twin Towers of the World Trade Centre (FEMA 2002) illustrated in Figure 1 as a result of aircraft impact and the collapse of one corner of the Ronan Point apartment building (Griffiths, Pugsley and Saunders 1968) shown in Figure 2 as a result of a gas explosion. In both cases an event occurred essentially on a single floor yet its influence spread in such a way that the consequences could be said to be disproportionate to the initial incident.

Figure 1 WTC

Figure 2 Ronan Point

Derivation of a suitable design approach to Robustness or to lessen the likelihood of Disproportionate Collapse or to reduce the possibility of a Progressive Collapse (the particular form of spectacular collapse witnessed in full or partial form respectively for the WTC towers and for Ronan Point, in which the structure collapses under its own weight in a pancake mode) is complicated by its being a low probability but high consequences type of event i.e. there will be few instances of actual progressive collapses and, thus relatively little observed behaviour from which to develop an understanding of the governing features and still less to use in any statistically based approach.

As a result a series of somewhat indirect design approaches have emerged e.g. key elements, tying capacity and alternate load path as illustrated in Figures. 3-5. Although the mechanics of implementation have changed and some research data directly related to the subject area has emerged, the essence of these approaches is not very different from that which resulted from the findings of the Report into the Ronan Point collapse (Griffiths, Pugsley and Saunders 1968) that was published almost 50 years ago. Given the developments in Structural Engineering over that period e.g. the widespread use of computer analysis, emergence of the Finite Element Method, adoption of the Limit States Design philosophy etc., it is surprising that more scientific approaches to Robustness have not been embraced.

The reality is, of course, that there have been developments and there have been proposals but these have not really resulted in much change in design practice. Why is this? Partly, because the topic is inherently very complex and designers prefer simple, straightforward tools. Partly, because of concerns that complex and time

consuming procedures should not be imposed on the profession unless the need can be clearly demonstrated - even post Ronan Point few countries had any national provisions addressing Robustness, although the publicity associated with the high profile WTC collapses certainly prompted some change of attitude. Partly, because researchers have not been able to distill their findings into suitably attractive design methods.

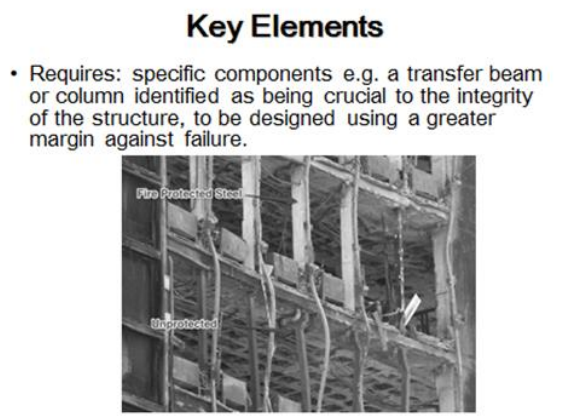

Figure 3 Key Elements

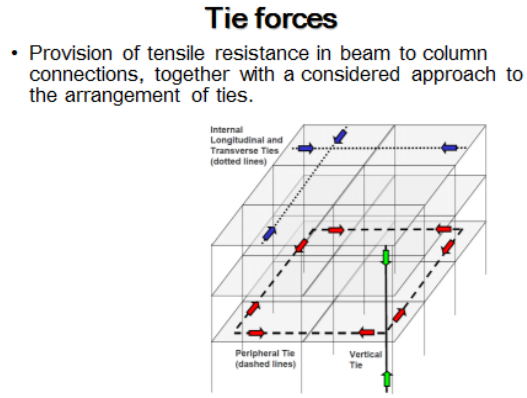

Figure 4 Tying Capacity

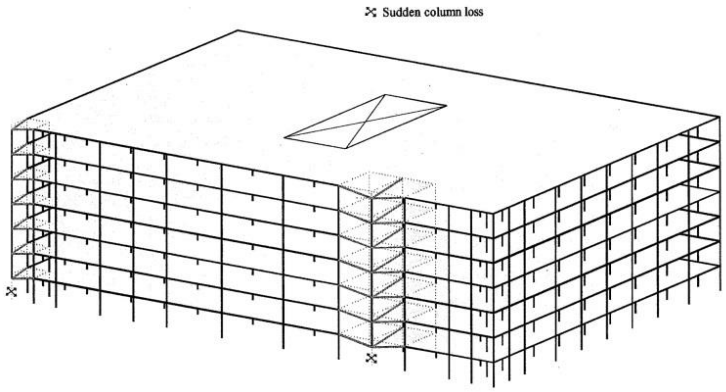

Figure 5 Alternate load path

It is argued herein that the subject is now sufficiently mature, with adequate understanding of the controlling features, that it is time for a more scientific approach. This is not to say that complex calculation methods should become the norm, nor that every structure should be required to include Progressive Collapse in its design requirements. Rather it is about recognising an imbalance in our present arrangements, with an inevitable tendency to focus on that with which we are comfortable and for which we have plenty of tools available, whilst continuing to treat Robustness as something of an afterthought. There is an interesting and highly relevant precedent here: the move from fire protection to fire engineering for steel and composite buildings. As a result of actual incidents that suggested that the performance of unprotected steelwork might be significantly better than that indicated by standard fire tests on individual components, the concept of assessing the fire loading and then checking in a quantitative fashion the ability of the complete structure to behave in an acceptable fashion for a suitable time has now become established to the extent that 'Fire design' is often an integral part of the overall structural consideration - in much the same way that design for wind loading and foundation design are treated.

ROBUSTNESS AS A STRUCTURAL DESIGN PROPERTY

Robustness is most often regarded as a property of the structure, with typical questions being: 'Has robustness been checked?' or 'Does the structure possess sufficient robustness?' When posing such questions an important aspect is whether they need to be answered within the context of their being threat dependant or threat independent. For the former it is presumed that the specific design requirement can be defined in terms that would permit a customised design approach to be devised e.g. an explosion caused by a specific type of device

placed at a specific location, with the design requirement being that only limited damage be caused and the resulting modified structure be able to deliver a specific level of performance in its new condition. Such a situation is not the main concern of this paper. Threat independent means that the specific triggering action is not known but that the client wishes their structure to have some degree of inherent resilience should an unforeseen event occur. Specification of particular tying capabilities in connections intended to ensure that they could facilitate the development of catenary action or designating certain components as 'key elements' and then proportioning them to have a greater margin against conventional failure come within this category. Their inherent weakness is that they are not linked to the behaviour of the structure should it suffer a triggering event in the sense that a statement of the form: 'As a result of doing x this arrangement will be y times safer than the original scheme', cannot be made. Nor is it possible to make quantitative comparisons in terms of outcome between alternative possible solutions. Thus the important skill of a structural designer viz. to use their judgement based on the combination of experience and understanding informed by calculation to make decisions on satisfying the problem constraints, cannot be properly exercised. Essentially, the approaches are of the pass/fail type using arbitrary criteria.

When dealing with Robustness it is helpful to recall the often stated (or, more likely, implied) questions that designers should ask of their clients:

How safe do you want to be?

How confident do you want to be that you have achieved this level of safety?

Full answers do, of course, require consideration of what individuals and society will tolerate as well as some recourse to statistical treatments. The former is complicated by the subjective and emotive element, whilst the latter is made difficult by the nature of the data available for low probability but high consequences events. For example, Table 1, which was prepared some years ago for the UK's Standing Committee on Structural Safety (a body formed in the aftermath of Ronan Point, whose role is to identify features and developments in Construction with the potential to have adverse effects on the safety of structures) contrasts the extremely low chance of death by structural collapse compared with many everyday or hazardous activities. Given that a disproportionate collapse caused by insufficient robustness would also involve an unusual triggering event, what level should be adopted? It is a question that I shall leave to others.

Table 1 Relative cost of death in UK by activity

	Activity	Risk of death x 10^{-8}/h: FAR

RESEARCH INTO STRUCTURAL ROBUSTNESS

As is the case for any topic, identifying the first pieces of research is difficult - partly because later work often illustrates how something done earlier in a different context actually has relevance to the topic in hand. Based on the presumption that those responsible for compiling the Ronan Point Report will have made strenuous efforts to identify anything that might have been helpful to them, it would appear that very little existed back in the 1960s. Interestingly, in a paper presented at the first Structural Engineers World Congress (SEWC), that took place in San Francisco in 1997, Bruce Ellingwood stated: 'There is currently a virtual absence of research activity or interest in the United States in the topic'. This situation contrasts sharply with the position today when each of the main structural journals e.g. Engineering Structures, Journal of Constructional Steel Research, ASCE Journal of Structural Engineering etc., regularly contain papers with Robustness, Progressive Collapse or Disproportionate Collapse in their titles. Figure 6 charts the growth in these papers across the whole publication database; 50% of these papers have been published in the past 5 years.

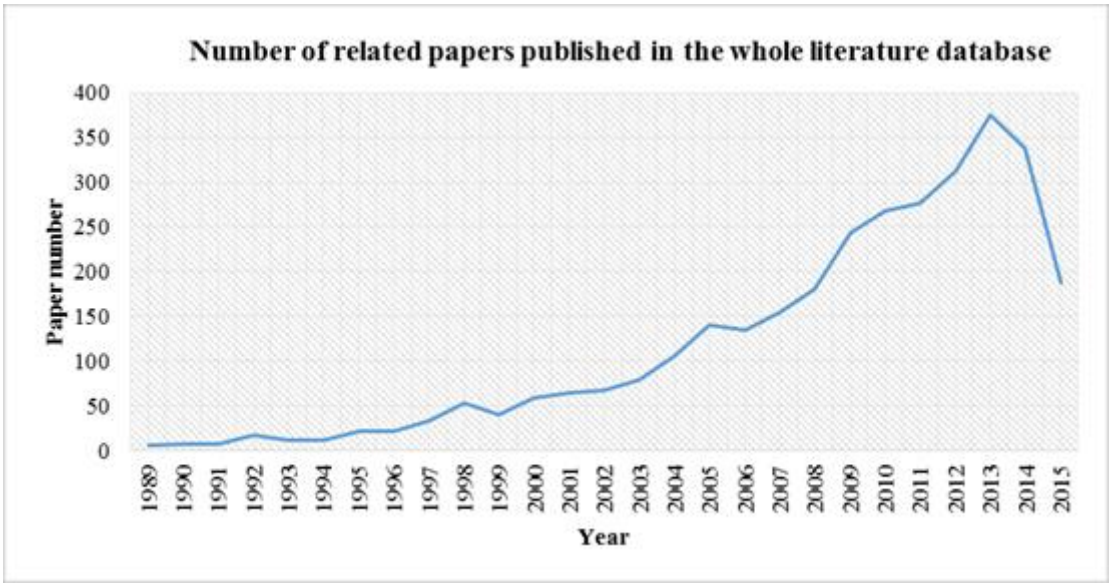

Figure 6 Growth of papers on robustness

Research in the subject area has taken several different forms:

1. Conceptual or philosophical studies on the Vulnerability of structures.
2. Risk and probability studies aimed at deciding how the topic should be treated.
3. FE studies using sophisticated modelling to try to replicate the physically important features of a progressive collapse.
4. Experimental work on connections to assess their ability to perform adequately under the conditions experienced during a progressive collapse.
5. Modelling of connection behaviour for inclusion in analyses of overall response.
6. Experimental work designed to replicate the behaviour of part of a structure as progressive collapse is induced.
7. Simplified analysis intended to cover all the main features but without the explicit modelling of each.

Unsurprisingly, coverage of the subject is patchy with considerable progress having been made in certain areas e.g. large scale FE simulations, and comparatively little real progress in others e.g. laboratory tests to investigate connection response under the specific conditions experienced during progressive collapse. Equally unsurprisingly the actual value of the contributions varies, with some being focussed on providing clear insight into an important feature and others being somewhat superficial e.g. FE analyses with no clear idea of what constitutes failure. However, taken together there is no doubt that far more is known about the mechanics of the subject, the relative importance of different physical features and which parameters to address in order to effect improvements than was the case 25 years ago. Complications arise because certain effects only become significant for particular combinations of circumstances e.g. whilst catenary action is clearly a potentially important resistance mechanism it cannot be achieved unless the structure - particularly its connections - possesses sufficient ductility that this phase can be mobilised. In some cases it has been found that practices adopted to address other concerns actually have a negative impact on robustness e.g. structurally isolating corner columns in frames designed to withstand seismic action. Thus, although behaviour is governed by the 'eternal

truths' of Structural Engineering of strength, stiffness and ductility, because of the complex interplay of these properties in any given situation it has not been possible to provide simple yet generally applicable guidance.

BASIC FEATURES OF PROGRESSIVE COLLAPSE AND POTENTIAL DESIGN APPROACHES

When dealing with the particular case of providing Robustness in a multi-storey frame building so as to limit the likelihood of a progressive collapse should a local triggering event occur, identification of the basic mechanics is the first requirement. Careful examination of actual occurrences (Starossek 2009; FEMA 2002) together with consideration of related situations e.g. bomb damaged buildings from World War Two (ICE 1948), aircraft impact on the Empire State Building (Levy and Salvadori 1992) performance in earthquakes (Scawthorn and Chen 2002) as well as fundamental structural thinking has led to the identification of the key features as:

- The actual collapse occurs rapidly and is, therefore, a dynamic event.
- It involves the structure undergoing gross deformations.
- Inelastic behaviour of the material of the components will occur.
- Key to the containment of the triggering incident is the avoidance of separation.
- Members and connections directly involved in the damaged regions will be subject to very different loading demands from those experienced under normal loading cases.

Thus neither the concept of 'key elements', in which certain structural members, whose involvement in the structural system is judged to be particularly important, are proportioned more conservatively, nor that of 'tying forces', in which tensile resistance is provided in the beam to column connections so that beams can act in a catenary fashion, directly address the actual mechanics of Progressive Collapse. The former is only really a 'comfort mechanism' since there is no link between the increased resistance provided in certain members and improved capability to resist Progressive Collapse. Although catenary action can contribute to resisting a Progressive Collapse it can only be mobilised after very large beam deformations - typically of the order of one to two times the beam depth - have developed, something that is unlikely to occur in many cases due to there being insufficient ductility available in the beam to column connections. Thus neither approach links directly to the concept of the performance of the structure in the actual situation being addressed.

The other design concept to emerge in the aftermath of the Ronan Point Investigation was 'alternate load path', in which one or more elements of the structure are removed and the ability of the damaged structure to redistribute loads, to adopt a new equilibrium position and to remain stable is assessed in a quantitative fashion. In their description of the aircraft impact on the Empire State Building, Levy and Salvadori (Levy and Salvadori 1992) liken this to a centipede losing a couple of legs but being able to adjust and compensate for the loss, the opposite would be the flamingo standing on one leg!

Since its emergence the 'alternate load path' concept has been subject to considerable study and development and features explicitly in both the most recent North American (GSA 2003; GSA 2013; DOD 2013) and European (BSI 2014) Code provisions. However, guidance on exactly how it should be implemented is, at best, unclear and, in places unhelpful. Central to this is the need to define the criterion of failure or the actual level of performance to be designed for. Having note to the characteristics of Progressive Collapse identified in the above list, it should be clear that stress limitations or deflection limits cannot represent the true objective. This can only be defined as separation of the elements such that the collapse can propagate. Since the most likely location for such separation is the connections, the ability of the beam to column connections to resist the conditions imposed by the grossly deformed damaged structure becomes the crucial consideration.

Another important consideration is the nature of the initial triggering event. This can either be defined e.g. a specific charge detonated at a specific location within the structure, or unknown as in the need to 'provide sufficient robustness'. These two cases are normally referred to as 'threat dependant' and 'threat independent' respectively. In the threat dependant case the designer should treat the issue as an additional load case and make suitable provision. By its nature 'threat independent' does not prescribe the actual triggering incident so, for design purposes, something has to be defined. The situation is, therefore, similar to the 'three second gust' or the 'standard fire' in that a representative (some might say arbitrary or even artificial) case is specified. For robustness and progressive collapse this is the 'column removal' scenario, in which a single column is assumed to be instantaneously removed and the ability of the remaining structure to bridge over the gap, as illustrated in Figure 7, examined.

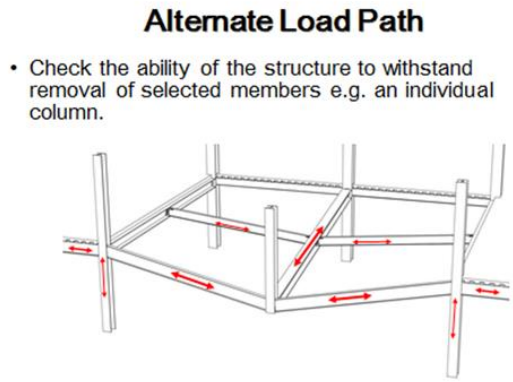

Figure 7 Column removal

THE ALTERNATE LOAD PATH APPROACH

Figure 8 shows how the alternate load path concept may be employed at the structure, substructure, floor, floor grillage or beam level. A single column is selected for removal and the response of the remaining structure is then analysed. It is essential that this analysis is capable of representing all important physical features and that it includes a realistic criterion of failure. Clearly a nonlinear dynamic Finite Element analysis that incorporates connection behaviour should be capable of doing this but such an approach requires both an understanding of all the complexities involved and the necessarily large computing facilities needed to run very big analyses.

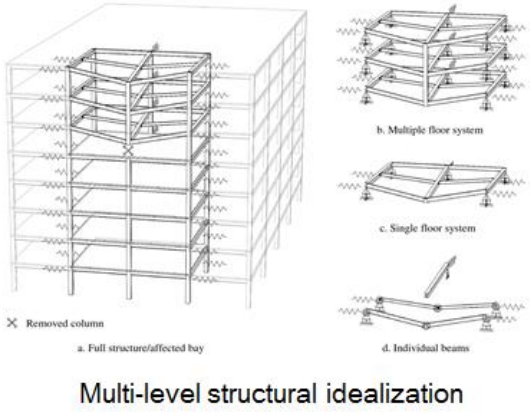

Figure 8 Frame to beam substructuring

Thus it can hardly be regarded as an approach suitable for routine use. It is for this reason that the group at Imperial College London has spent many years developing its Robustness Assessment Framework, in which all important features are allowed for but without the need for their explicit and computationally very demanding fundamental treatment. Key features of the Framework are:

- Only static analysis is required, dynamics being incorporated through the concept of energy balance.
- The actual analysis may be conducted using any suitable software, alternatively an enhanced slope deflection method that permits very rapid calculation using a spreadsheet may be used.
- Quantitative comparisons between alternatives may readily be made.
- The steps involved are very similar to those used for conventional structural design.
- Failure is defined in terms of the available connection ductility under the loading experienced at gross deformation.
- If suitable analysis software is available then potentially beneficial features such as the influence of floor slabs and cladding can be incorporated.

Full details are available in a series of PhD theses, of which the most significant for design are:

- Vlassis 2007 - basic framework and methodology (Vlassis 2007).
- Styllianidis 2011 - simplified calculation method and examination of importance of different features (Styllianidis 2011).

- Vidalis 2014 - design strategy, including consideration of frames designed for seismic conditions (Vidalis 2014).

Figures 9-11 illustrate three important features of the approach: the 'conversion' of the results from a static analysis into a pseudo static analysis, the stages through which a beam undergoing gross deformation passes and the loading experienced by a beam to column connection during the development of these gross deformations. The first considerably simplifies the approach, whilst the other two provide the key to understanding the mechanics. Using this knowledge and based on the appraisal of many hundreds of different examples a strategy for addressing design to resist progressive collapse has been devised (Vidalis and Nethercot 2014). This respects the practical limitations associated with the reality that this aspect of the design will normally be undertaken once the majority of the 'conventional design' has been completed so that only certain options will be open e.g. whilst modifications to connection details remain possible, altering the grid spacing is unlikely to be feasible.

PERFORMANCE BASED DESIGN

Adopting a Performance Based approach to design for Robustness first requires that the required level of performance be defined. For Robustness within the context of the avoidance of Progressive Collapse this should be the ability of the damaged structure to assume a new stable equilibrium position. This is most readily characterised by the avoidance of separation at the connections. This may, in turn, be defined in terms of the deformation limits for key connection components based on the realistic appraisal of connection behaviour under the conditions experienced during a progressive collapse. The demands on the connections should be assessed by a suitable analysis of the damaged structure. Given that the general requirement is that this be conducted for the threat independent condition, the well established conventional 'test' is removal of a single column; this may be implemented using a variety of different column positions since response in the case of (say) removal of a corner column will be different from that for an edge or internal column removal. The analysis may use any approach that allows for all the key effects and should also make allowance for the dynamic nature of the event. By adopting an energy balance approach the need to conduct a dynamic analysis may be replaced by a much simpler static analysis. Whilst any other method of converting the results from a static analysis into their dynamic equivalent could, in principle, be used, some others such as the popular Dynamic Amplification Factor approach, whilst appealingly simple in concept and application, have been shown (Izzuddin and Nethercot 2009) to produce inconsistent results. Whilst not the only possible procedure, the Imperial College Robustness Assessment Framework, whether it is implemented using the explicit spreadsheet approach or by employing suitable analysis software, does meet all the requirements and is available in a comprehensive form.

It is, therefore, contended that moving design for Robustness from its current largely prescriptive based approach to a performance based approach is now feasible. At least for some aspects the underlying logic and methodology is available. Moreover, this has been provided in a form that closely mirrors the approach used for design in other situations e.g. gravity and wind loading, fire design, seismic design etc. What is currently missing is a concerted effort to convert the research knowledge and understanding into a comprehensive design document, something that must involve collaboration between knowledgeable researchers and experienced practitioners.

Taking this proposition a stage further, a strong case could be made for the funds awarded to the next research project in the area aimed at investigating one particular feature or promising an even more all embracing statistical framework to be used instead to produce a Performance Based design guide that would both cover those aspects for which sufficient is currently known and would identify exactly what would be needed to place areas for which some gaps in knowledge exist in a similar position. Such work is, of course, often derided as being insufficiently novel or not fundamental; it is, arguably, at least as intellectually challenging as conventional laboratory or numerical research, is actually the type of work that can only be conducted by a very limited number of individuals and would yield considerable benefits.

CONCLUSIONS

Important features of the Robustness of structures have been reviewed. It is contended that, whilst design provisions introduced in the aftermath of the 1968 Ronan Point collapse ensure that the situation is better than would be the case if no such provisions existed, the combination of expectation on the part of the public and understanding developed through a sustained programme of research means that better provision can and should now be made. Because of the nature of the subject setting this within the Performance Based concept is the obvious approach. Thus the profession should divert resources from traditional narrowly focussed investigative research projects into a concerted effort to make the best use of that which is currently available, to identify the important limitations that prevent every aspect from being treated in the same way as can be done for the most advanced and to ensure that properly focussed study of the missing items is conducted.

MAINTENANCE AND SAFETY OF DETERIORATING SYSTEMS: A LIFE-CYCLE PERSPECTIVE

Dan M. Frangopol *, Samantha Sabatino, and Mohamed Soliman
Department of Civil and Environmental Engineering, ATLSS Engineering Research Center,
Lehigh University, 117 ATLSS Drive, Bethlehem, PA 18015-4729, USA. *E-mail: dan.frangopol@lehigh.edu

ABSTRACT

This paper reviews the key aspects associated with maintenance and safety of deteriorating infrastructure systems from a life-cycle perspective. The main conceptual aspects related to probabilistic optimization of maintenance and rehabilitation of structural systems are discussed. These aspects include life-cycle risk and sustainability assessment, risk-informed and utility-based decision making, and multi-objective optimization of interventions. In general, sustainability assessment is performed by quantifying economic, social, and environmental impacts associated with infrastructure management activities. This keynote paper also reviews various methods for determining optimum life-cycle maintenance, repair, and rehabilitation types and times, as well as the impact of such activities on the total life-cycle cost. The role of probabilistic performance indicators including reliability and risk, the sustainability assessment of deteriorating infrastructure systems, and risk- and utility-informed decision making are highlighted herein.

KEYWORDS

Deteriorating infrastructure systems, life-cycle engineering, risk, sustainability, decision making, optimal management of infrastructure.

INTRODUCTION

Improving the condition and safety of deteriorating infrastructure systems is a key concern worldwide. For example, in 2013, the American Society of Civil Engineers reported, within the 2013 Report Card for America's Infrastructure, that the average age of the United States' 607, 380 bridges was 42 years (ASCE 2013). Additionally, nearly a quarter of these highway bridges were classified as either structurally deficient or functionally obsolete (FHWA 2013). These statistics highlight the dire need to implement rational management strategies that maintain structural performance within acceptable levels through the life-cycle of deteriorating civil infrastructure. Managers of infrastructure systems are usually in charge of allocating limited financial resources in a cost-effective manner to maintain adequate functionality of their systems (Liu and Frangopol 2005a). Life-cycle management is well recognized as an effective tool for maximizing the cost-effectiveness of implementing intervention actions that improve condition, safety, and extend the service life.

This paper presents the general concepts pertaining to maintenance and safety of deteriorating infrastructure systems, through a life-cycle perspective, with emphasis on bridges. In order to predict structural performance for life-cycle analysis under uncertainty, critical deterioration mechanisms for the investigated structural systems (e.g. corrosion and fatigue for bridges) must be accounted for. Furthermore, the effects of maintenance, repair, and rehabilitation on structural life-cycle performance must be well understood. The deterioration effects, as well as the influence of maintenance and repairs on structural performance, can be incorporated in a generalized framework for multi-criteria optimization of the life-cycle management of infrastructure systems (Frangopol 2011). In such a framework, specific random variables associated with the load effects and structural resistances of a structural system's components are identified. Component, as well as system reliability can be computed for the investigated infrastructure considering that failure of a single component or a combination of individual components may initiate the failure of the system. In addition to identifying the structural reliability against failure, it is also possible to consider various functionality aspects that affect infrastructure systems such as serviceability limit states.

In this paper, risk and sustainability are also investigated as rational performance indicators for the life-cycle behavior modeling of infrastructure systems. In general, approaches for the life-cycle management of infrastructure involving reliability performance indicators consider uncertainties associated with loads and resistance, but are not able to account for the consequences incurred from structural failure. Risk-based performance metrics provide the means to combine the probability of structural failure with the consequences

corresponding to this event (Ang and De Leon 2005; Ellingwood 2007). Within this keynote paper, approaches which incorporate risk within the generalized life-cycle management framework are presented. Furthermore, methodologies considering sustainability as a performance indicator are discussed. The incorporation of sustainability in the life-cycle performance assessment and management procedures allows for the effective integration of indirect (e.g. environmental and social impacts), as well as, direct (e.g. economic impacts) losses. In general, within the field of life-cycle engineering, two definitions are usually referred to when developing appropriate sustainability metrics. The first representation of sustainability defines it as: "meeting the needs of the present without comprising the ability of future generations to meet their own needs" (Adams 2006). The second definition complements the first one by emphasizing that economic, environmental, and social objectives must be simultaneously satisfied within a sustainable design or plan (Elkington 2004). Accordingly, a sustainability performance indicator, that incorporates economic, environmental, and social risks of structural failure, is presented in this paper. This novel sustainability performance metric is established considering multi-attribute utility theory, which facilitates the combination of several risks (i.e., risk attributes) while incorporating the risk attitude of the decision maker. This sustainability performance indicator incorporating multi-attribute utility theory has been applied to the life-cycle management of bridges (Sabatino et al. 2015) and bridge networks (Dong et al. 2015).

As infrastructure systems deteriorate with time, maintenance, repair, and rehabilitation interventions may be carried out to improve and/or sustain the structural performance above acceptable levels. In general, essential maintenance actions are typically applied when a performance indicator reaches a predefined threshold, leading to a substantial improvement in the structural performance. For instance, replacement of bridge superstructure components, such as the deck and girders, is considered as essential maintenance intervention. Figure 1 shows, conceptually, the effect of essential maintenance on the life-cycle structural performance and cost; also shown are the probability density functions of the initial performance index, deterioration initiation, rate of deterioration, and service life without and with maintenance. Another category of maintenance actions include preventive measures that normally repair smaller defects or decrease the rate of deterioration for a period of time. Examples of preventive maintenance include recoating a bridge deck and repainting the steel girders. Although maintenance and other types of interventions (e.g. rehabilitation) have the ability to maintain structural performance within prescribed levels, the cost of carrying out such actions must also be considered when developing life-cycle management plans. Thus, a comprehensive framework for the life-cycle management of aging structures considering risk, sustainability, and life-cycle cost is required in order to maintain structural performance and mitigate economic, environmental, and social consequences (Frangopol and Soliman 2015).

The application of utility-based decision making in the optimal lifetime intervention on civil structures is a topic of paramount importance and is experiencing growing interest within the field of life-cycle infrastructure engineering. In general, utility is defined as a measure of value (or desirability) to the decision maker. Utility theory provides a framework that can measure, combine, and consistently compare these relative values (Ang and Tang 1984). Utility theory is utilized herein in order to depict the relative desirability of optimal lifetime maintenance strategies to the decision maker. Multi-attribute utility theory may be used to transfer the marginal utility of each attribute involved in the performance assessment (e.g. economic, social, and environmental risks) into one utility value that effectively combines the effects of all risks investigated (e.g. risk attributes) in order to facilitate decision making.

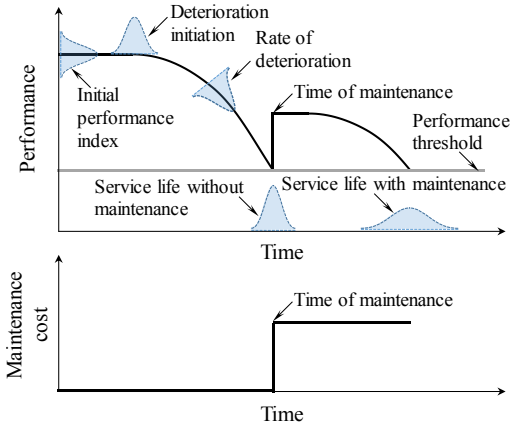

Figure 1 Effect of gradual deterioration and essential maintenance on structural performance and cost

Summarily, this keynote paper reviews the key aspects associated with maintenance and safety of deteriorating infrastructure systems from a life-cycle perspective. Life-cycle risk and sustainability assessment, risk-informed

and utility-based decision making, and multi-objective optimization of interventions are discussed. Various methods for determining optimum life-cycle maintenance, repair, and rehabilitation types and times, as well as the impact of such activities on the total life-cycle cost are investigated. The role of probabilistic performance indicators including reliability and risk, the sustainability assessment of civil structures, and risk- and utility-informed decision making are emphasized via illustrative examples.

PERFORMANCE INDICATORS

Condition and Safety Indices

To date, most condition assessment activities associated with civil infrastructure rely on visual inspections results. For bridges, visual inspection results are typically used to establish a condition rating index to measure the bridge's remaining load-carrying capacity. Currently in-use bridge management systems characterize the performance of structural elements by discrete condition states which incorporate predefined degrees of damage (Thompson *et al*. 1998; Hawk and Small 1998). For example, reinforced concrete elements subject to an aggressive corrosive environment can be classified, based on visual inspection results, into one of four discrete condition levels. The bridge element under investigation may be categorized as condition state 0, 1, 2 or 3, which represent (a) no chloride contamination, (b) onset of corrosion, (c) onset of cracking, and (d) loose concrete/significant delamination, respectively (Liu and Frangopol 2005b). Based on the identified condition states, maintenance interventions may be prioritized among all inspected structural components.

Several research efforts have integrated these discrete condition states within the life-cycle management and intervention optimization associated with deteriorating infrastructure systems. Most of these approaches incorporate Markov chain models to depict the structural deterioration process. In a Markov chain model, the current condition states of the investigated system are considered to be dependent only on a finite number of previous states. The main element of a Markov chain model is the transition matrix that specifies the probability that the state of a component changes to another state within a specified period of time. In the United States, bridge management systems, such as Pontis (Thompson *et al*. 1998) and BRIDGIT (Hawk and Small 1998), which are used by state departments of transportation, are established considering visual-inspection-based discrete condition states and Markovian deterioration modeling using stationary transition probabilities. A safety index can also be defined to model the life-cycle performance of deteriorating systems. In the United Kingdom, the safety index is defined as the ratio of available to required live load capacity (HA 2001). In this case, the performance is considered unacceptable if the value of safety index drops below 0.91. Note that the condition index is a subjective measure which may not realistically reflect the true load-carrying capacity of structural members (Liu and Frangopol 2005b). Accordingly, other performance indicators capable of properly modeling the structural performance, while considering various uncertainties associated with resistance and load effects, have been developed and adopted in the life-cycle management of deteriorating infrastructure systems.

Reliability

This section introduces the concept of reliability and its application in quantitatively incorporating uncertainty in structural performance prediction. Structural reliability can be defined as the probability that a component or a system will adequately perform its specified purpose for a specified period of time under specified conditions (Leemis 1995; Frangopol and Kim 2011). In reality, the reliability problem of engineering systems can be expressed as a problem of supply and demand which is modeled by means of random variables. For instance, if R and S represent the resistance and the load effect, respectively, probability density functions (PDFs), f_R and f_S, characterizing these respective random variables may be established. The probability that S will not exceed R, $P(R > S)$, represents the reliability of the structural system. As a general case, the time-variant probability of failure $p_F(t)$ can be expressed in terms of joint PDF of the random variables $R(t)$ and $S(t)$, $f_{R,S}(t)$, as:

$$p_F(t) = \int_0^\infty \left(\int_0^s f_{R,S}(t)\, dr \right) ds \tag{1}$$

Furthermore, the reliability index can be expressed as:

$$\beta(t) = \Phi^{-1}\left(1 - p_F(t)\right) \tag{2}$$

where $\Phi^{-1}(\cdot)$ is the inverse of the standard normal cumulative distribution function (CDF).

A wide variety of research has been conducted that includes reliability analyses of infrastructure systems or networks of civil structures. Hendawi and Frangopol (1994) developed rational system redundancy- and reliability-based structural design and evaluation approaches. Within Hendawi and Frangopol (1994), the effects

of material behavior, correlations between random variables, variability of resistances and loads, resistance sharing, structural damage, and number of members on the redundancy and reliability of a parallel system were investigated. Stewart (2001) demonstrated that the initial stage of performance based assessment techniques is to estimate the reliability of an existing infrastructure system. Cesare *et al*. (1993) calculated the reliability index for each structural element of a bridge using first-order reliability methods. The overall system reliability index of the bridge was calculated by combining the individual reliability of the components in a series system. Decò and Frangopol (2011) provided a rational methodology for reliability and risk analysis of existing highway bridges under a multi-hazard exposure and illustrated their approach on the I-39 Bridge crossing the Wisconsin River in Wausau, WI, USA.

In addition to bridges, reliability analyses have been performed on naval vessels and offshore structures. More specifically, Moan (2005) established an approach for reliability-based management of inspection, maintenance and repair of offshore structures and demonstrated how the interrelation between design, inspection, maintenance and repair requirements can be rationally dealt with. An approach for structural life-cycle management of ships under uncertainty was presented by Frangopol and Soliman (2015), and Kim *et al*. (2013) presented a generalized probabilistic framework for optimum inspection and maintenance planning of deteriorating structures. Decò *et al*. (2011) have used advanced statistical techniques such as Latin Hypercube Sampling (McKay *et al*. 1979) and second order reliability methods (Melchers 1999) to determine the probability of failure of ship hulls. Also Decò *et al*. (2012) proposed a framework for the assessment of structural reliability and redundancy of a Joint High Speed Sealift (JHSS) under different operational conditions. Polar representations of system reliability for different sea states and heading angles were presented. Additionally, an approach to account for the time-dependent corrosion and fatigue effects on the reliability of ship hull structures was provided in Kwon and Frangopol (2012).

Risk

Risk is quantified by combining the probability of occurrence and the consequences of events generated by hazards. In general, the instantaneous total risk R of a structural system can be formulated as (CIB 2001):

$$R = \int\int\cdots\int \kappa(x_1, x_2, \ldots, x_m) \cdot f_{\mathbf{X}}(x_1, x_2, \ldots, x_m) \cdot dx_1 \cdot dx_2 \cdots dx_m \tag{3}$$

where $\kappa(\mathbf{x})$ denotes the consequences associated with events resulting from certain hazards $\mathbf{x}$ and $f_{\mathbf{X}}(\mathbf{x})$ is the joint PDF describing the probabilistic behavior of the random variables $\mathbf{X} = \{ X_1, X_2, \ldots, X_m \}$. Typically, the consequences associated with events resulting from hazards are quantified in terms of monetary values. The m-fold integral within Eq. 3 is difficult to assess and often cannot be solved. Therefore, assumptions are established in order to obtain a simpler expression for total risk. If the hazards are considered mutually exclusive and collectively exhaustive, a more simplistic approach for calculating instantaneous total risk R is:

$$R = \sum_{i=1}^{n} C_m \cdot P[F \mid H_i] \cdot P[H_i] \tag{4}$$

where C_m represents the consequences of failure, $P[H_i]$ describes the probability of occurrence of a hazard, $P[F|H_i]$ is the conditional failure probability given the occurrence of a hazard, and n is the total number of hazards considered within the analysis. An even simpler formulation of time-variant risk was proposed by Ang and De Leon (2005) as:

$$R(t) = p(t) \cdot \chi(t) \tag{5}$$

where $p(t)$ denotes the probability of occurrence of an adverse event and $\chi(t)$ represents the consequences of the event at time t.

Several research efforts have been conducted involving the risk assessment of bridge structures. Decò and Frangopol (2011) developed a rational framework for the quantitative risk assessment of highway bridges under multiple hazards. Time-dependent profiles of risk, accounting for direct and indirect consequences, were calculated for an existing highway bridge considering abnormal traffic loads, environmental attacks, scour, and earthquakes. Similarly, Saydam *et al*. (2013b) proposed a methodology for quantifying lifetime risk of bridge superstructures based on the condition index. Within Saydam *et al*. (2013b), an illustrative example was presented to demonstrate the capabilities of this methodology; the time-variant expected losses associated with the flexural failure of girders and the risk-based robustness index were determined for an existing bridge located in Wisconsin, USA. Additionally, Cesare *et al*. (1993) calculated the total risk associated with a bridge using the reliability and consequence of closure of the bridge. Stein *et al*. (1999) developed an approach for assessing the

risk associated with scour of bridge foundations. The risk of scour failure was determined by multiplying the cost associated with failure and the probability of scour occurrence. Similarly, Stein and Sedmera (2006) proposed a risk-based approach for managing bridges in the absence of foundation information.

Furthermore, risk analysis was utilized to assess the performance of networks of infrastructure systems. For example, the time-dependent expected losses of deteriorated highway bridge networks were investigated within Saydam *et al*. (2013a). Additionally, Decò and Frangopol (2013) proposed a computational framework for the quantitative assessment of life-cycle risk of multiple bridges within a transportation network including the effects of seismic and abnormal traffic hazards. Overall, risk, as a performance indicator, can offer valuable information regarding the performance of individual structures or spatially distributed systems, such as buildings, bridges, and bridge networks.

Sustainability and Utility as Performance Indicators

Within a robust risk assessment, it is crucial to consider the economic, social, and environmental impacts of structural failure. Sustainability assessment involves the integration of these various risk values into a convenient index used to measure performance. In general, it is important to measure the performance of infrastructure systems and networks of structural systems whose functionality is vital for economic and social purposes (Saydam *et al*. 2013a). Recent research efforts have considered a wide variety of risks in order to effectively quantify sustainability. For instance, the time-dependent expected losses of deteriorated highway bridge networks were investigated within Saydam *et al*. (2013a). A five-state Markov model was proposed to predict the time-dependent performance of bridges within a network. The probabilistic variation of direct, indirect, and total expected losses in time was computed. The proposed approach was illustrated on an existing highway bridge network in the lower San Francisco Bay Area, California. Additionally, Dong *et al*. (2013) presented a framework for assessing the time-variant sustainability of bridges associated with multiple hazards considering the effects of structural deterioration. The proposed approach was illustrated on a reinforced concrete bridge and the consequences considered within the risk assessment were the expected downtime and number of fatalities, expected energy waste and carbon dioxide emissions, and the expected loss. Overall, the inclusions of societal and environmental impacts along with economic consequences effectively encompass the concept of sustainability within the risk analysis framework. Combining the economic, societal, and environmental, risk metrics allows engineers and decision makers to make informed decisions based on sustainability by providing them with a complete picture of system performance.

In general, utility-based decision making may be divided into five separate stages: the pre-analysis, problem set-up, uncertainty quantification, utility assignment, and optimization, as shown in Figure 2 (Keeney and Raiffa 1993). In this process, it is usually assumed that there is a single decision maker who possesses a predetermined risk attitude with respect to a specific structural system. Next, all possible solution alternatives are identified and the uncertainties associated with the investigated decision making problem are accounted for by using a probabilistic approach. Since technical and economic uncertainties are both expected and unavoidable in the life-cycle assessment of civil infrastructure, decisions regarding life-cycle management must consider all relevant uncertainties associated with the probability of structural failure and its corresponding consequences (Ang 2011). For instance, life-cycle management problems involving deteriorating highway bridges have uncertainties that are present within modeling the structural resistance (e.g. material properties and element dimensions), the occurrence and magnitude of hazards that may impact the structure (e.g. corrosion, fatigue, earthquakes, floods, and hurricanes), operating conditions, and loading cases (Stewart 2001), in addition to those associated with the cost of interventions performed during the service life.

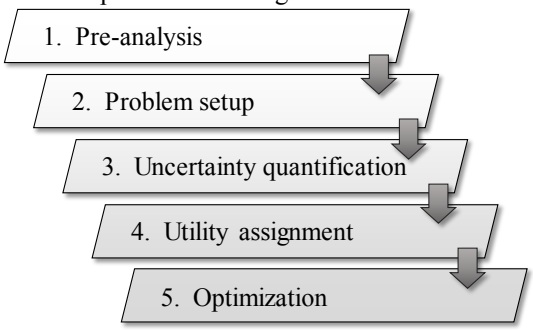

Figure 2 Utility-based decision making steps

After effectively incorporating the appropriate uncertainties, the decision maker may assign utility values to the investigated attributes (e.g. risk attributes) associated with each alternative considering his/her risk attitude.

Utility theory is applied in order to normalize each attribute value corresponding to solution alternatives to a number between 0 and 1; this ensures that all attributes are directly comparable to each other. The formulation of the utility function corresponding to each attribute depends on the knowledge, preferential characteristics, and risk attitude of the decision maker. Within the last step of the utility-based decision making framework an optimization procedure is carried out in order to find the alternative that maximizes the utility value.

Once the time-variant risks affecting a deteriorating system are calculated (e.g. using Eq. 5), the decision maker may assign utility values to the attributes associated with each alternative considering his/her risk attitude. As an example, the computational procedure for the multi-attribute utility assessment of a highway bridge subjected to a corrosive environment and time-increasing traffic loading is shown in Figure 3, where u_i and k_i, respectively, are the utility function and associated weighting factor corresponding to the ith risk attribute. A multi-attribute utility value is established that effectively represents sustainability performance by consolidating economic, social, and environmental risks.

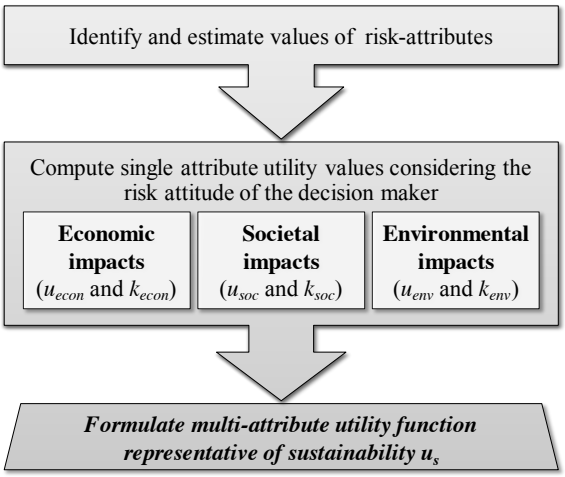

Figure 3 Flowchart describing the multi-attribute utility performance assessment.

For the risk attributes analyzed, each of the corresponding utility functions may be formulated as monotonically decreasing functions. Considering an exponential formulation, the utility associated with a single attribute (e.g. economic, social, and environmental risks) can be expressed as (Ang and Tang 1984):

$$u_{RA} = \frac{1}{1-\exp(-\gamma)}\left[1-\exp\left(-\gamma\frac{RA_{max}-RA}{RA_{max}-RA_{min}}\right)\right] \tag{6}$$

where RA is the mean of the risk attribute value under investigation, RA_{max} and RA_{min} denote the maximum and minimum value of the risk attribute, respectively, and γ is the risk attitude of the decision maker (i.e., $\gamma > 0$ indicates risk-aversion and $\gamma < 0$ denotes risk-acceptance). A monotonically decreasing function that has bounds of 0 and 1 must be utilized within the utility assignment procedure in order to accurately depict the relative utility of detrimental consequences.

Qualitative plots of the utility function corresponding to a single risk attribute with variable risk attitude, considering the exponential formulation, are provided in Figure 4. As indicated by Keeney and Raiffa (1993), for a single risk attribute, $u_{RA} = 1$ corresponds to the lowest possible loss while $u_{RA} = 0$ is associated with the largest possible loss. Alternatives associated with high utility values are usually preferred to those associated with small utility values (Howard and Matheson 1989). The concavity of these utility functions is highly dependent on the risk attitude of the decision maker. Risk averse and risk accepting attitudes yield concave and convex utility functions, respectively.

After the utility function associated with each risk attribute is appropriately established, multi-attribute utility theory may be employed to combine them into a single utility value that effectively represents a sustainability performance metric. Although there are various established types of multi-attribute utility functions, the additive formulation is utilized herein. Within the additive formulation for the multi-attribute utility function, marginal utility values associated with each attribute are multiplied by weighting factors and summed over all attributes investigated (Stewart 1996). Considering an additive formulation, the multi-attribute utility function is computed as (Jiménez et al. 2003)

$$u_s = k_{econ}u_{econ} + k_{soc}u_{soc} + k_{env}u_{env} \tag{7}$$

where u_s is the multi-attribute utility function associated with the sustainability performance metric; u_{econ}, u_{soc}, and u_{env} represent the marginal utility values associated with economic, social, and environmental risk attributes, respectively; and k_{econ}, k_{soc}, and k_{env} are the weighting factors corresponding to the three metrics considered in the sustainability assessment such that $k_{econ} + k_{soc} + k_{env} = 1$. Typically, these weighting factors are not known or are difficult to assess for certain decision makers. Therefore, it is advantageous to perform a sensitivity study concerning these weighting factors.

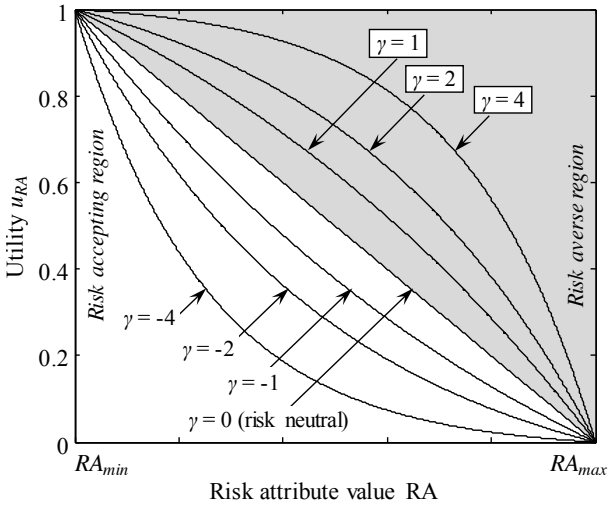

Figure 4 Qualitative representations of typical exponential utility functions that are monotonically decreasing as the expected value of the risk attribute value increases

UTILITY-BASED DECISION MAKING

Once the appropriate multi-attribute utility-based sustainability metric is established, it may be utilized within a life-cycle optimization to find the best intervention strategies for the investigated structure. In general, the presented generalized decision–support approach may be used to determine optimal repair, rehabilitation, and monitoring interventions. Accordingly, the effect of interventions on the sustainability performance must be examined. Within the generalized decision making methodology presented, two objectives, represented in terms of utility, can be simultaneously maximized: (a) the relative value of investment costs considering the risk attitude of the decision maker u_c, and (b) the sustainability of each alternative expressed in terms of the utility u_s. The cost associated with implementing optimal lifetime maintenance actions may be expressed in terms of utility by employing Eq. 6. Given the maximum cost investment that the decision maker can tolerate, a utility function representative of cost considering the attitude of the decision maker may be established. The formulation of the cost utility u_c effectively captures the decision maker's preference to investing money in the face of risk.

The cost u_c and sustainability u_s utilities are used within a multi-criteria optimization process as the objective functions to be maximized. More specifically, this optimization maximizes the minimum annual utility associated with sustainability while simultaneously maximizing the utility associated with the total maintenance cost. Generally, if the utility values of all the alternatives are available, the solution with the highest utility value is always preferred (Howard and Matheson 1989); thus, the two utility objectives are maximized within the presented optimization procedure. The main output of this bi-objective optimization, often carried out by using genetic algorithms (Davis 1991) in MATLAB (MathWorks 2013), comes in the form of a Pareto-optimal solution set that depicts optimal solutions outlining lifetime maintenance schedules. A solution is Pareto-optimal if there does not exist another solution that improves at least one objective without worsening another one. A plot depicting Pareto fronts for the lifetime maintenance planning of a bridge, considering a varying risk attitude, is shown in Figure 5. Within this example, the weighting factors associated with marginal economic, social, and environmental utilities are all assumed to be equal to 1/3; essentially, the decision maker weighs all three risks equally within the sustainability assessment.

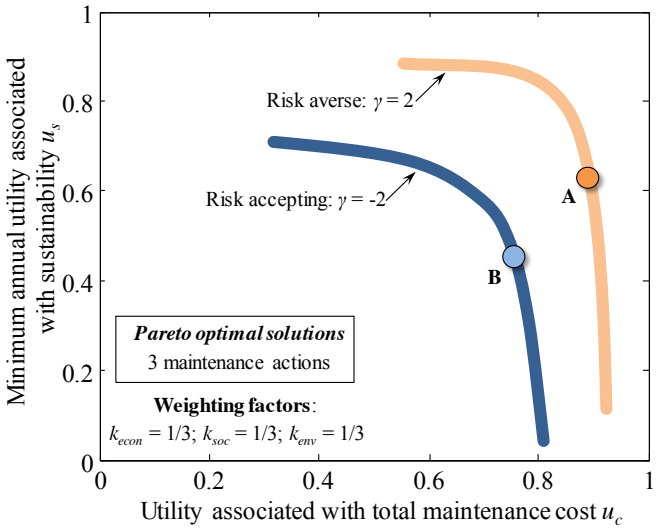

Figure 5 Effect of risk attitude on the optimal solutions for lifetime maintenance considering weighting factors equal to one third

Embedded within each Pareto solution contained in Figure 5 are the optimum maintenance plans that detail which structural components should be maintained and the optimum maintenance time. In this case, the investigated bridge has a predetermined lifetime of T_L years and three maintenance actions may be implemented throughout its life-cycle. Representative solutions A and B, denoting typical optimum maintenance plans resulting from a risk averse and risk accepting decision maker, respectively, are shown in Figure 5. The time-variant multi-attribute utilities associated with sustainability corresponding to representative solutions A and B are shown in Figure 6a. Similarly, the economic risk profiles associated with solutions A and B are depicted in Figure 6b. In general, these plots show that the multi-attribute utility assessment of sustainability is highly dependent upon the risk attitude of the decision maker.

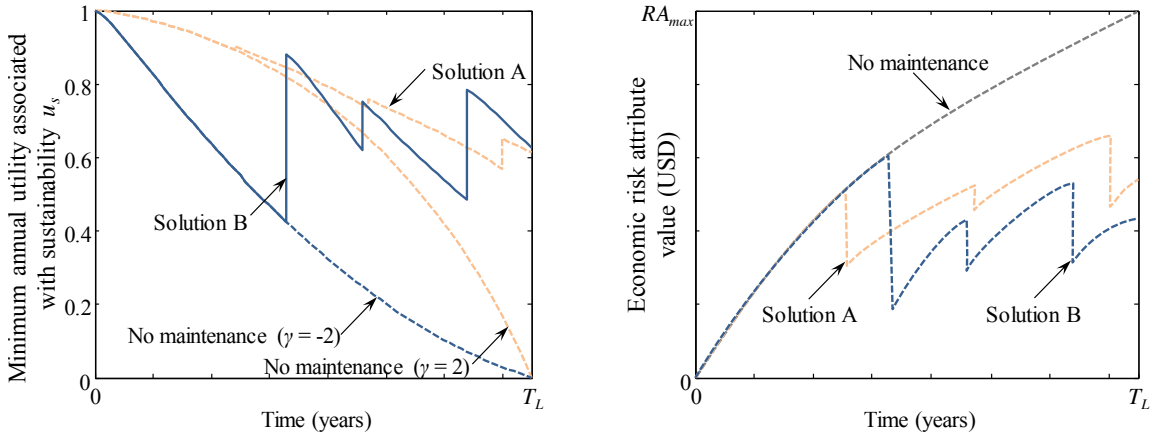

Figure 6 Time-variant profiles of (a) utility associated with sustainability and (b) economic risk for representative solutions A and B in Figure 5

The presented methodology can be used to assist decision making regarding intervention and operational actions. Depending on the maintenance cost, level of sustainability, and in turn, maximum annual risk attribute values desired, a decision maker can choose a Pareto optimal alternative that best satisfies his/her needs.

CONCLUSIONS

This keynote paper discussed various aspects pertaining to maintenance and safety of deteriorating infrastructure systems, from a life-cycle perspective. A utility and sustainability-based methodology to carry out probabilistic optimization of lifetime intervention actions of deteriorating structural systems was presented. The role of probabilistic performance indicators including reliability and risk, sustainability assessment of civil structures, and risk- and utility-informed decision making were highlighted. Furthermore, utility theory was introduced and a multi-attribute utility value representative of sustainability, established in order to effectively combine the effect of economic, social, and environmental of risks, was discussed. Multi-objective optimization procedures,

with utility values as the objectives to be maximized, were used to determine the best maintenance plan for a highway bridge in the presented illustrative example. Accordingly, the decision maker will be able to make sustainability-informed decisions based on his/her particular preferences and the decision support system provided.

Overall, the methods presented herein can be utilized to facilitate informed decision making regarding the lifetime intervention scheduling of deteriorating infrastructure. Multi-attribute utility theory can be used to formulate a utility-based sustainability index which offers a measure of desirability of a given management alternative to the decision maker. An approach that incorporates multi-attribute utility theory provides a framework which can measure, combine, and consistently compare the relative values of different alternatives while taking into account the decision maker's attitude. However, sensitivity studies aimed to quantify the weighing factors which represent the effect of the decision maker's particular preference to which aspect of sustainability is most important are still needed.

ABSTRACT

Concrete is the most widely used construction material due to its impressive resistance to compressive load. The major weaknesses of concrete are its brittleness and poor resistance to tensile forces. Intensive number of studies has been conducted to add various types of short discrete fibres into concrete mix to enhance its ductility and post-peak load-bearing capacity. A spiral-shaped steel fibre was recently proposed for reinforcing concrete material with 3D bond components. A series of laboratory tests have been conducted for a comprehensive investigation of the performances of spiral-shaped steel fibre reinforced concrete materials and structures. A fundamental understanding of the bond-slip behaviour of spiral fibres and its mechanism of reinforcing the matrix was achieved by conducting pull-out tests. Compressive and direct tensile tests on Ø100-200 mm concrete specimens with spiral fibres of different geometries were conducted for properly determining fibre geometries to reinforce concrete materials. Split Hopkinson pressure bar (SHPB) tests were carried out to study the dynamic behaviour of spiral steel fibre reinforced concrete (SFRC) with various volume fractions under compression and splitting tension. The corresponding relations of dynamic increase factor (DIF) vs. strain rate were proposed based on test data. Repeated drop-weight impact tests on SFRC beams reinforced with the commonly-used hook-end fibres and spiral fibres were performed. Test results demonstrated the superiority of spiral fibres in bonding and enhancing concrete structural elements in resisting impact loads. The even distributions of spiral fibres in comparison with crimped fibres in concrete matrix were justified by physical examinations. Mesoscale simulations with distinctive consideration of mortar matrix, coarse aggregates and spiral fibres were conducted for statistical derivation of dynamic properties of spiral SFRC. While having demonstrated the promising performances of concrete reinforced with spiral fibres, further studies are also suggested based on the observations and results obtained.

Spiral fibre, steel fibre reinforced concrete, pull-out, distribution, dynamic properties, structural responses, blast and impact.

INTRODUCTION

Throughout the ages, concrete has always been and continues to be one of the most impressive construction materials. Concrete exhibits excellent resistance to compressive loads, corrosion, and heat etc. The wide availability of materials used to manufacture concrete and the price at which these materials can be obtained make it even more appealing for using concrete as the primary source of construction. Despite the beneficial properties of concrete there is a major flaw in the capacity of concrete, i.e., the brittleness due to low resistance to tensile loading. Tension crack development and propagation is one of the major issues of application of concrete in construction. Moreover, the increased possibility of being subjected to blast and impact loads requires the concrete material possessing increased ductility and energy dissipation capability. Besides the reinforcing bars entrenched within the concrete matrix, the addition of discrete fibres to brittle materials to increase their strength and ductility has been used since ancient times, with mud huts manufactured with baked clay reinforced with straw and masonry mortar reinforced with animal hair. The most common of these small fibres in today's ready-mix concrete industry include glass, steel, natural and synthetic fibres, each with their own special ability to enhance the properties of concrete in one way or another. Unfortunately, the ideal fibre for reinforcement has not yet been industrialised, with the properties for this "perfect" fibre requiring high strength and modulus of elasticity, ease of dosing and distribution, and high bonding strength and frictional resistance that do not exceed the strength of fibres (Johnston 2001).

Among all types of fibres commercially available in industry, those made of steel have occupied the majority of the industrial market to be used for reinforcing concrete material. For analysis of behaviours of steel fibre

reinforced cementitious or concrete (SFRC) material and structural elements subjected to different loading conditions, it is critical to characterise the bonding strength and pull-out behaviour of steel fibres from cementitious matrix. The past four decades have seen several researchers making predictions and developing models for the pull-out behaviour of steel fibres with various geometries in SFRC (Brandt 2008). It is generally acknowledged that the geometry of steel fibres influences the combined action of bond components such as adhesion between fibre and matrix, frictional bond component, and the mechanical characteristics of concrete reinforced with steel fibres (Naaman and Najm 1991). Various attempts have been made to improve the bond-slip characteristics of steel fibres, with the most effective method utilising mechanical deformation such as hook-end fibres, crimped fibres, undulated fibres, twisted fibres and flat end fibres etc. which have become available in construction industries (Hsueh 1990). It has been noted that anchorage bond and frictional bond are only able to be provided by these commercial steel fibres in a two-dimensional plane along one or two directions. Steel fibre that is able to provide bond components tri-dimensionally is believed to more effectively improve the mechanical properties of SFRC materials. In a pilot study conducted by Xu et al. (2012b), 6 types of fibres, namely hook-end fibres, flattened fibres, cold rolled fibres, undulated fibres, synthetic fibres, and spiral fibres were considered to reinforce concrete specimens and their effectiveness of reinforcement was evaluated by conducting compressive tests under static and drop-weight impact loads. Two types of spiral fibres, one with relatively small coil pitch (spiral I) and the other with relatively large coil pitch (spiral II) allowing coarse aggregates to fit in laterally, were considered as shown in Figure 1. Ø100-100 mm specimens were impacted by the impactor weighing 96.7 kg dropping from heights of 2 m and 3.8 m, respectively. In the study it was found that spiral II fibres outperformed the other types of fibres in reinforcing concrete matrix in terms of compressive strength, toughness and sensitivity to strain rate as illustrated by Figure 2.

(a) Stress-strain curves under 3.8 m impact (b) Toughness vs. strain rate

Figure 2 Comparison of properties of concrete reinforced with different types of fibres (Xu et al. 2012b)

A follow-up study (Xu et al. 2012a) focused on comparing the splitting tensile properties of concrete reinforced with spiral II fibres and hook-end fibres. Notched cylindrical specimens with load adaptor (Figure 3) were prepared for static and drop-weight tests. It was found that spiral fibres performed better in terms of ductility, toughness, crack controllability and rate sensitivity as illustrated in Figs. 4 and 5. The authors attributed the superiority of spiral fibres to their three-dimensional bond components and confinement to concrete matrix.

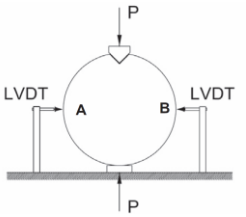

Figure 3 Schematic of notched specimen with load adaptor (Xu et al. 2012a)

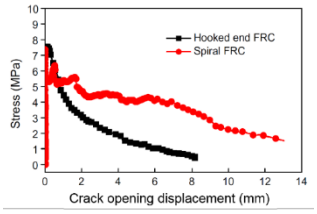

Figure 4 Comparison of splitting tensile stress-COD curves under quasi-static loading (Xu et al. 2012a)

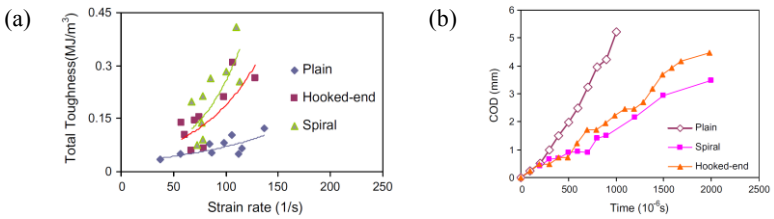

Figure 5 Comparison of a) toughness and b) COD histories of SFRC under impact loading (Xu et al. 2012a)

Based on the observations from (Xu et al. 2012a; Xu et al. 2012b), a series of experimental and numerical studies have been conducted for a more comprehensive understanding of properties of concrete reinforced with spiral-shaped steel fibres under static and dynamic loadings. To explore the reasons that explain the superiority of spiral fibres, pull-out tests on 2D fibres (straight and hook-end fibres) and 3D spiral fibres were carried out for distinct comparison and fundamental understanding of the mechanism of spiral fibres reinforcing the concrete matrix. Because changing the fibre geometry might result in different bond-slip performance of individual fibres, hence the mechanical properties of SFRC, parametric studies were conducted to systematically investigate the influences of spiral fibre geometries on performances of SFRC under compression and direct tension. Suggestion was given to select geometrical parameters according to the test results, followed by split Hopkinson pressure bar (SHPB) tests on specimens with different volume fractions of spiral fibres to investigate dynamic material properties of SFRC under compression and splitting tension. Based on the understanding of dynamic properties of spiral SFRC, drop-weight impact tests were performed to evaluate the effectiveness of spiral fibres in enhancing deformability and energy absorption capacity of concrete structural elements under impact loads. Mesoscale numerical models with distinctive consideration of mortar matrix, aggregates and spiral fibres were developed predict behaviours of spiral-fibre reinforced concrete specimens under impact loads. Finally, to investigate the distribution of spiral fibres in concrete structure prepared under normal mixing and vibrating procedure, beam specimens were prepared and internal examination of fibre distributions were conducted by cutting the specimens into pieces. These studies are summarised in the present paper. Discussions on the effectiveness of spiral fibres in reinforcing concrete matrix are made. Further studies are also suggested.

GEOMETRICAL CHARACTERISTICS OF SPIRAL FIBRES

The three-dimensional characteristics of spiral fibres can be represented by nominal length, wire diameter, coil diameter and coil pitch as shown in Figure 6. In all tests reported in this study the wire diameter is 0.56 mm. The nominal aspect (length-to-diameter) ratio is determined by the nominal length and diameter of the wire. Complications arise with the number of different geometries a spiral can have, varying the coil pitch and coil diameter to create optimum toughness while maintaining a viable steel/concrete ratio. More importantly, as mentioned in the study by Xu *et al*. (2012b), the spiral fibre with relatively small coil pitch did not perform well. This is primarily because coarse aggregates were expelled from the volume inside the spiral fibres, making the specimens more heterogeneous with more defects such as micro cracks and air voids. Laboratory study of the influence of spiral fibre geometries on mechanical properties of SFRC is introduced in the following section.

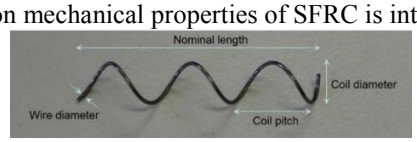

Figure 6 Parameters representing spiral fibre characteristics

PULL-OUT TESTS

The study of steel fibre pull-out behaviour from concrete is fundamental to understand the behaviour of SFRC as a composite when it is incorporated in structures. Numerous attempts have been made to better understand the effects of geometry of hook-end fibres on the mechanical behaviour of pull-out in SFRC (Alwan et al. 1999; Laranjeira et al. 2010b; Naaman and Shah 1976; Zīle and Zīle 2013). Despite the valuable understanding gained from these models, there have been no investigations into spiral shaped steel fibres in SFRC and no attempts to model the pull-out behaviour of a spiral fibre. To bridge this gap, laboratory tests were conducted to study the pull-out behaviour of spiral fibres from concrete matrix. In addition, straight fibres and hook-end fibres were also tested for comparison. The embedment depths of all fibres were 30 mm. It should be noted that the mixing constituents and proportions of concrete matrix given in Table 1 are consistent throughout the laboratory tests presented in this paper. The test setup is schematically given in Figure 7 below. The compressive strength of concrete in pull-out tests is 44 MPa.

Table 1 Mixing constituents and proportions of concrete matrix

Water	Cement	Sand	<4mm aggregates	4-7mm aggregates	7-10mm aggregates
205 kg/m^3	426 kg/m^3	843 kg/m^3	130 kg/m^3	306 kg/m^3	444 kg/m^3

The general shapes of the force-slip curves observed in pull-out tests are given in Figure 8. It can be seen that straight fibre gave the least bonding strength among all types of fibres. Hooking the ends was able to effectively enhance the bonding strength and frictional bond component. Unlike the behaviours of 2D steel fibres, the pull-out force on spiral fibres from concrete matrix increased with a series of peaks before a final maximum peak force followed by the complete drop marking the end of the test. As the pull-out process progressed, an increasing force was needed for debonding. This may be attributed to the pull-out procedure applied whereby the fibre was pulled out from the central axis of the spiral rather than pulling in a circular manner following the coil diameter of the spiral as schematically illustrated in Figure 9. As the pull-out process progressed deeper into the concrete, the fibre was progressively pulled out at a decreasing angle, θ, to the central axis. An increasing force was needed to pull out fibre deeper in the concrete matrix because the fibre needed to overcome an increasingly larger volume of concrete. This is in agreement with previous experimental works by Laranjeira et al. (2010) who showed that the load at which fibres failed decreases at increasing inclination angles. Although the latter paper was addressing the condition of an inclined hook-end fibre, the results may be applied to the spiral fibres since spiral fibres can be viewed as a fibre that is inclined at every point.

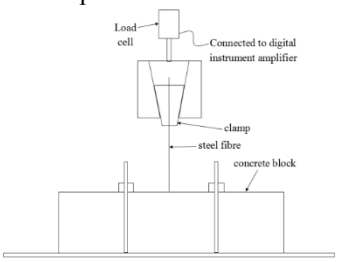

Figure 7 Schematic diagram of pull-out test setup

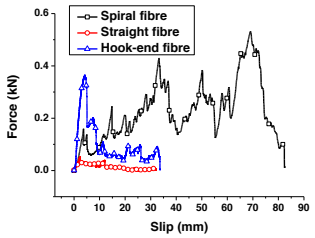

Figure 8 Typical force-slip curve in pull-out tests

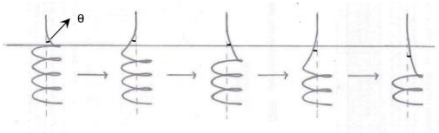

Figure 9 Spiral fibre pull-out process

From the pull-out curve, peaks were observed between the starting point of the pull-out process and the final peak. The peaks may be indicative of the bond strengths at various depths of the fibre as the fibre was pulled out. It was also observed that concrete spalling occurred at intervals corresponding to the peaks. For each peak, the pull-out force increased gradually until the force exceeds the matrix strength at that point. Once the pull-out force reached this value, a fragment of the concrete was spalled off and the pull-out force drops. This increase-decrease trend of the pull-out force continued throughout the pull-out process, resulting in the numerous peaks observed in Figure 8. Research by Leung and Li (1992) showed that spalling-compressive strength is higher than the conventional compressive strength of concrete which is due to the very small region of concrete that is involved in bearing the locally induced stresses. Concrete spalling occurs when that region of the concrete reaches a pressure equal to concrete compressive strength. The final peak (which was the maximum peak in most cases) is indicative of the ultimate bond strength after which a complete drop was observed which marked the end of the test where the fibre was pulled out completely. From the comparison in Figure 8, with the same embedment depth, spiral fibres had the highest slip capacity, and more importantly the highest energy dissipation (area under force-slip curves) per single fibre's complete pull-out. As the integration of pull-out behaviour of individual fibres is the dominant factor that determines the mechanical properties of SFRC, the observations in Figure 8 clearly demonstrated why spiral fibres outperformed other types of fibres in terms of enhancing ductility, toughness and energy absorption capability of the concrete matrix.

SENSITIVITY OF MECHANICAL PROPERTIES TO FIBRE GEOMETRIES

As is mentioned above, the geometry of spiral fibres has important influences on the workability, homogeneity and mechanical properties of SFRC materials. Laboratory tests were carried out to investigate the influences of fibre geometries on compressive and tensile properties of SFRC materials reinforced with 1% fibres by volume. The wire diameter was 0.56 mm. Spiral fibres with different nominal lengths (17mm, 25mm and 34mm) (equivalent to nominal aspect ratios of 30, 45 and 60), coil pitches (5mm, 10mm and 15mm), and coil diameters (3mm, 6mm and 9mm) were considered, as shown in Figure 10 and summarised in Table 2. Compressive and

direct tensile tests were conducted on Ø100-200mm specimens. 6 samples from each batch were tested with 3 samples under compression and 3 under tension. Individual fibres were carefully dosed into concrete mix to prevent from getting balled.

Table 2 List of geometries of spiral fibres corresponding to the batches

Batch	1	2	3	4	5	6	7
Nominal length	17	34	25	25	25	25	25
Nominal aspect ratio	30	60	45	45	45	45	45
Coil diameter (mm)	6	6	6	6	3	9	6
Coil pitch (mm)	10	10	5	15	10	10	10

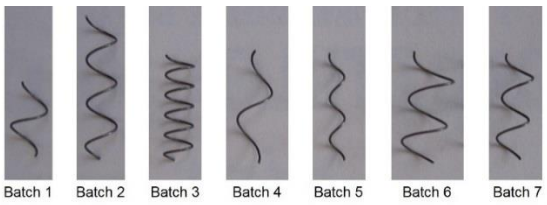

Figure 10 Spiral fibres with different geometries mixed in different batches

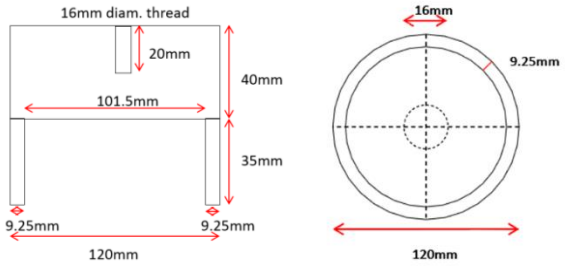
Due to the difficulty of testing concrete in direct tension, steel caps with dimensions illustrated in Figure 11 were fabricated for direct tensile testing. The inside of the steel caps and the ends of concrete samples were blast cleaned for better adhering concrete to the caps using Sikadur epoxy. Steel rods were screwed into each end of the samples and then assembled into the hydraulic testing machine. An angle meter with magnetic base was used to ensure that all samples were tested as vertical, concentric to the direction of the tensile force applied, as can be seen in Figure 12. Concentrically loading the samples under tensile loading ensures that the failure mechanism occurs horizontally through the middle half of the sample. A tensile load was continuously applied to the steel rods until the sample had been completely pulled apart into two pieces and no fibres were still bridging the gap between the two halves of the sample.



Front view Plan view

Figure 11 Schematic of steel cap design for direct tensile testing (not to scale)

Figure 12 A sample in direct tensile test

From the compressive and direct tensile tests, specimens from Batches 2 and 3 were found to have quite inconsistent mechanical properties. For Batch 2 specimens, the large aspect ratio of 60 significantly reduced the workability and the even distribution of spiral fibres in the concrete matrix. Moreover, the fibres were more likely to get balled. Examinations before and after tests confirmed large air voids existed both on surface and inside the specimens. On the other hand, the inconsistent behaviours of Batch 3 specimens were expected as the coil pitch of spiral fibres was only 5 mm, which is smaller than most of the coarse aggregates as indicated in Table 1. As discussed above, the small coil pitch expels coarse aggregates from the volume occupied by spirals, making the specimens more heterogeneous with more defects during casting and curing. Due to the significant inconsistencies of specimens from Batches 2 and 3, their stress-strain curves are not used. Typical stress-strain curves of specimens from other batches, i.e., Batches 1 and 4-7, under compression and direct tension are compared in Figure 13. As can be seen, the stress-strain curves in Figure 13 do not show significant differences within limited strain range. Specimens reinforced with spiral fibres of longer full length had higher deformability as the fibre pull-out process is dependent on its full length embedded in the matrix. However, as the post-peak resistance is relatively low and this range is of less interest, the data are not shown in this paper. The observations from Figure 13 demonstrate that as long as the nominal aspect ratio and coil pitch are properly determined to prevent from fibre balling and inconsistency, selection of other geometrical parameters can be relatively flexible.

Figure 13 Typical stress-strain curves of concrete specimens reinforced with spiral fibres with different geometries

SHPB TESTING OF DYNAMIC COMPRESSIVE AND SPLITTING TENSILE PROPERTIES

Split Hopkinson pressure bar (SHPB) tests were conducted to understand the dynamic behaviours and properties of SFRC with spiral fibres under compression and splitting tension. Ø75-37.5mm SFRC specimens containing different volume fractions of spiral fibres from 0% (plain concrete) to 1.5% with interval of 0.5% were prepared for SHPB tests. The nominal length, wire diameter, aspect ratio, coil diameter and coil pitch are 15mm, 0.5mm, 30, 5mm and 10mm, respectively. The SHPB test setup is illustrated in Figure 14 while examples of recorded incident and transmitted stress histories from compressive and splitting tensile tests are given in Figure 15. Formulae to calculate stress, strain and strain rate of tested specimens, and verification of stress equilibrium are presented in (Hao and Hao 2013).

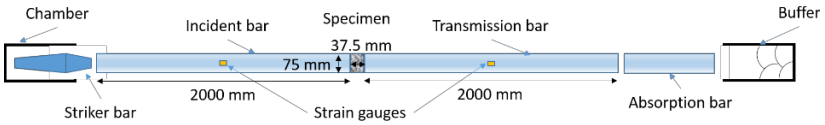

Figure 14 Schematic of SHPB test setup

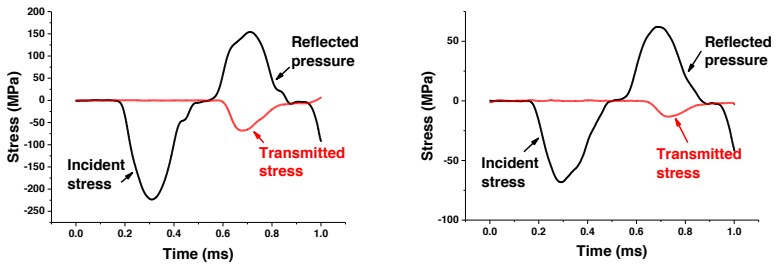

(a) SHPB compression (b) SHPB splitting tension

Figure 15 Typical stress waves recorded in SHPB tests

In SHPB compressive tests, besides the observations that the number of cracks and fragments was markedly reduced with the increase of fibre additions (Figure 16), it was also indicated by the test results that when the strain rate is below 100 s^{-1}, 1.0% seemed to be the optimal volume fraction of spiral fibres in terms of ductility and energy dissipation capability. Under higher strain rate, the energy absorption capability of spiral SFRC can be further improved by adding more fibres in the matrix as shown in Figure 17.

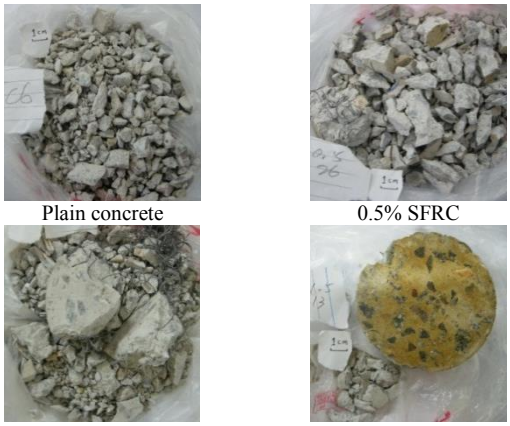

Figure 16 Comparison of failure patterns under the same impact

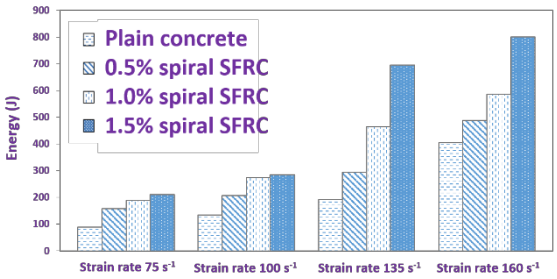

Figure 17 Comparison of energy absorption (Hao and Hao 2013)

In SHPB splitting tension tests, the dynamic splitting tensile strength, deformability, crack controllability and energy absorption capability of spiral SFRC were found to increase with the fibre content. Failure processes were recorded by high speed camera for detailed investigation and image analysis of splitting crack widths. It should be noted that for reaching higher rate of framing, the resolution of photos was sacrificed, and the crack widths could only be estimated as 0.5 mm (size of one pixel) multiplied with integers. The crack widths of SFRC specimens with different volume fractions of spiral fibres with respect to time under stress rate of 150 GPa/s are given and compared in Figure 18 where the time instant corresponding to the first appearance of crack is set to zero.

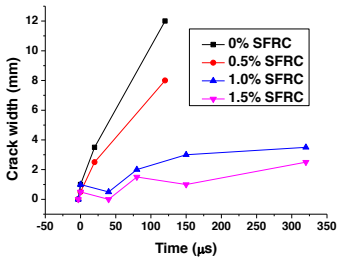

Figure 18 Comparison of crack widths under stress rate of 150 GPa/s

Figure 18 shows significant differences among specimens reinforced with different dosages of spiral fibres. Compared to plain concrete specimen, termed as 0% SFRC in the figure, the width and opening velocity of crack in the specimen with 0.5% spiral fibre reinforcement are effectively reduced. It is very interesting to note that at 40 μs, the crack widths in both 1.0% and 1.5% SFRC specimens were reduced as compared to those at 0 μs, indicating the cracks in the two specimens were recovered, or in other words, pulled back by spiral fibres. Another reduction in crack width can be observed at 150 μs in 1.5% SFRC specimen. Overall the crack widths of 1.0% and 1.5% spiral SFRC specimens developed with much slower rates, demonstrating the excellent crack controllability is further enhanced by adding more fibres.

Both compressive and splitting tensile strengths of the tested specimens were found to be sensitive to strain rate as shown in Figure 19 where the dynamic increase factor (DIF), the ratio of dynamic to static strengths, are used to represent the strength increment. Plain concrete is the least sensitive to strain rate among all materials. The sensitivity increases with the volume fraction of spiral fibres, and the 1.5% SFRC material exhibits the most significant rate sensitivity. This is consistent with the findings by Banthia et al. (1994) that SFRC specimens with higher dosage of fibres were stronger and tougher under impact. The curves in Figure 19 are best-fit relations according to scattered data of specimens containing different dosages of spiral fibres. The fitted DIF versus strain rate relations are formulated by equations below where the subscripts C, 0.5%, 1.0% and 1.5% denote materials of concrete, 0.5%, 1.0%, and 1.5% spiral SFRC, respectively. They can be used to model spiral SFRC materials in numerical prediction of SFRC structural responses to high-rate loadings.

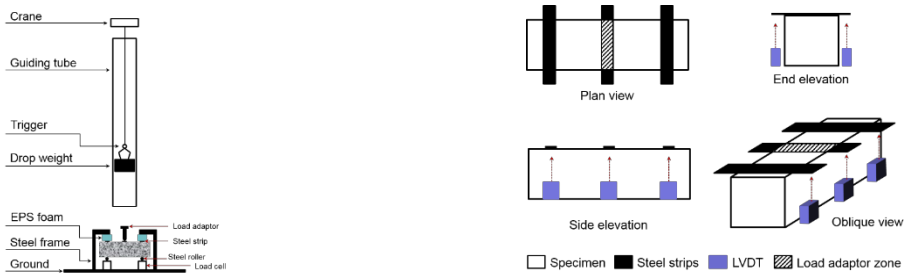
DROP-WEIGHT IMPACT TESTS ON SFRC BEAMS

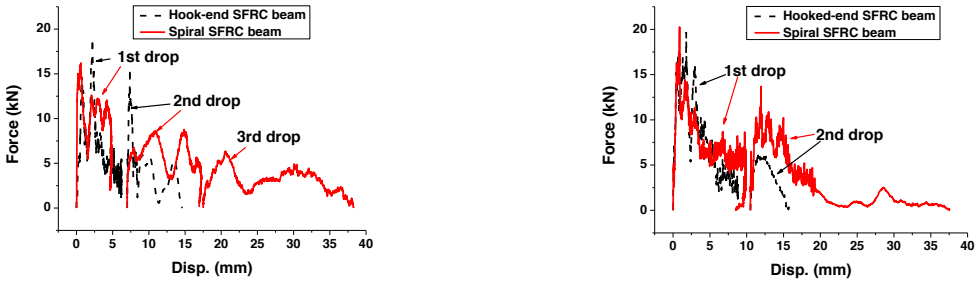
To study the structural responses of spiral SFRC beams under impact loads, laboratory impact tests were conducted. Concrete beams reinforced with hook-end fibres were also prepared and tested for comparison. Both spiral and hook-end fibres had the same nominal aspect ratio of 50. 100×100×350 mm SFRC beam specimens with 0.5% and 1.0% fibre fractions by volume were prepared for impact tests using instrumented drop-weight system. Repeated impact tests with impactor weighing 15.2 kg were carried out with 0.5 m and 1.0 m drop heights. The boundary conditions, test setup and measurement of load and deflection are illustrated in Figure 20.

0.5% SFRC beams with spiral fibres and hook-end fibres exhibited similar performances under impact loads, therefore the related results are not given in this paper. When the volume fraction was increased to 1%, spiral SFRC beams significantly outperformed hook-end SFRC beams in terms of deformability and energy dissipation capability as illustrated in Figure 21. This is consistent with the findings from SHPB tests where the change of spiral fibre volume fraction from 0.5% to 1% resulted in significant improvement in strength, crack controllability and energy absorption capability under impact loads.



(a) Test setup and measurement of load (b) Load adaptor and measurement of deflection

Figure 20 Schematic of drop-weight impact test setup



(a) 1.0% SFRC beams under 0.5 m drop height (b) 1.0% SFRC beams under 1.0 m drop height

Figure 21 Comparison of load-deflection curves

From the comparison of load-deflection curves given in Figure 21a, it can be observed that although the hook-end SFRC beam was able to sustain higher impact loads for the 1st and 2nd drops from 0.5 m height, implying its relatively higher stiffness, it was more vulnerable to fibre debonding, and fractured after the 2nd impact with total displacement of about 15 mm. In comparison, the deformability of the beam with spiral fibre reinforcement was significantly higher with a total displacement of more than 35 mm. Moreover, while hook-end SFRC beam completely lost its load carrying capacity after the 2nd impact, spiral SFRC beam was still able to sustain a third impact. For impact tests with drop height of 1.0 m, although severe damage was found in both beams after the 2nd impact, the load-carrying capacity and the deformability of spiral SFRC beam were higher compared to those of the hook-end SFRC beam as shown in Figure 21b. The observations in Figure 21 clearly demonstrate the better bonding of spiral fibres to the concrete matrix compared to hook-end fibres, leading to a much higher energy absorption capability.

MESOSCALE MODELLING OF SPIRAL SFRC

The above experimental programs tested specimens prepared under well controlled laboratory environment with high-quality batching. As the mechanical properties, especially tensile properties, of the SFRC composite are highly dependent on the dosages and distributions of fibres and aggregates, conducting the statistical analysis accounting for these factors is believed to give less biased parameters for material modelling. Mesoscale modelling of spiral SFRC material under splitting tension as plane-stress problems has been conducted using LS-DYNA. Information about material models and parameters for mortar matrix, coarse aggregates, steel fibres and pressure bars, and mesh size convergence are given by Xu et al. (2012c). An example of the developed mesoscale model containing 1% spiral fibres is shown in Figure 22 while the model validation is given in Figure 23 below.

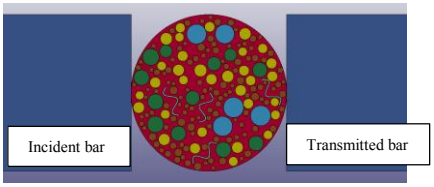


Figure 22 An example of SHPB simulation using mesoscale model

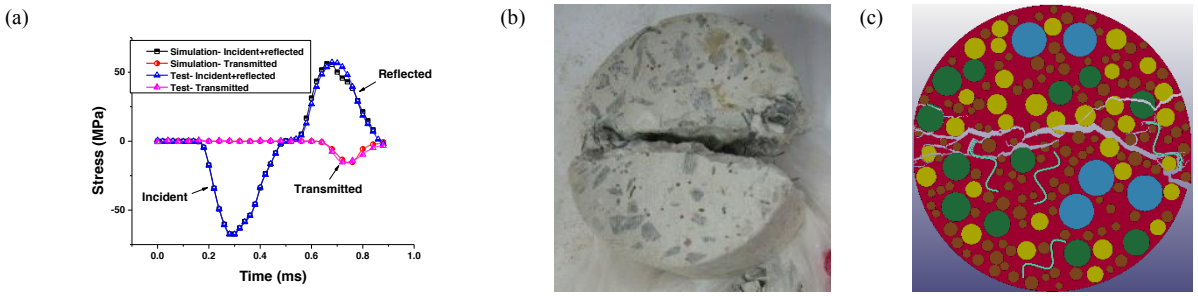

Figure 23 Comparison of numerical simulation and test results a) stress histories, b) damaged specimen from tests, and c) damaged specimen from numerical simulation

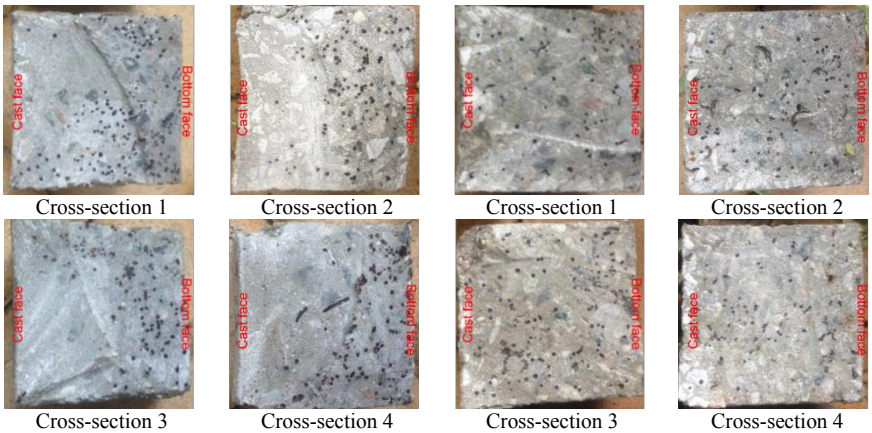
Intensive numerical simulations considering different volume fractions of spiral fibres and random distributions of coarse aggregates and fibres are underway for generating statistical distributions of SFRC material properties

accounting for the random distributions of aggregates and fibres, based on which further study will be conducted to develop the material model of spiral SFRC for predicting the dynamic responses of spiral SFRC structures subjected to blast and impact loads.

INVESTIGATION OF FIBRE DISTRIBUTIONS IN SFRC

Proper distribution of steel fibres in concrete mix is always a challenge and requires proper construction quality control to prevent fibre balling. Besides investigating the mechanical performances of spiral SFRC materials and structures, the distributions of discrete fibres in SFRC are also examined in this study. Laboratory tests were performed with SFRC beams cast with industrially utilised crimped fibres and spiral fibres, respectively. Steel fibres with volume fraction of 1% were dosed into concrete mix. The fresh SFRC was placed into formworks and internally vibrated using concrete vibrator. In total 16 beams were prepared. After being cured for 28 days, SFRC beams were segregated into five pieces using an angle grinder fitted with a diamond blade, which allowed internal examinations of fibre distributions along four cross-sections as shown in Figure 24 where the upper surface (cast face) is on the left hand side of each image.



(a) Crimped fibre reinforced concrete (b) Spiral fibre reinforced concrete

Figure 24 Comparison of fibre distributions along cross-sections

From Figure 24, it can be observed that the distribution of crimped fibres was dramatically affected between pouring and setting. The vibration caused them move away from the centre of the specimen and occupy the other regions, especially sink to the bottom of the formwork. On the other hand, the spiral fibre samples displayed a far more random or sporadic, less congregated, distribution. These results give reason to believe that the spiral fibres do, in fact, remain within the same vicinity of their original positions in the concrete matrix between pouring and setting. Once untangled, these fibres then become embedded within the concrete matrix, and do not significantly change positions between this time and the time at which setting of the sample is complete. Crimped fibre samples did not benefit from this internal vibration at all, with the increasing time of vibration forcing fibres further away from the centre of sample and towards the outer walls of the specimen, making it harder to sporadically distribute the crimped fibres throughout the concrete than it is to distribute spiral fibres, due to their ability to move after pouring has occurred.

SUMMARY

The present paper reports a series of laboratory tests for comprehensive studies of the performances of spiral-shaped steel fibre reinforced concrete materials and structures under different loading conditions. Studies summarised in the paper include pull-out tests on straight, hook-end and spiral fibres from concrete matrix, sensitivity analysis of mechanical properties of spiral SFRC to fibres geometries, SHPB tests on the dynamic compressive and splitting tensile properties of spiral SFRC, repeated drop-weight impact tests on SFRC beams, numerical SHPB tests of spiral SFRC considering different fibre volume fractions and random distributions of coarse aggregates and fibres, and evaluation of fibre distributions in beam specimens from the construction perspective. Results from these investigations demonstrate the promising effects of spiral fibres which can be considered as a potentially superior discrete reinforcement in concrete technology.

One possible drawback of spiral fibre is its slightly lower resistance in the beginning stage of bond-slip curves as shown in Figure 8. Replacing a portion of spiral fibres by short 2D fibres, namely using hybrid fibres to reinforce concrete matrix, is believed to be an effective measure to overcome spiral fibres' shortcoming.

Experimental studies on SFRC materials and structures with 1% volume fraction of steel fibre reinforcement considering different blend ratios of short hook-end and spiral fibres are underway.

ABSTRACT

The performance of buildings in seismic zone is usually more complicated than that in non-seismic zone. The buildings are not only required damage-limited for fully operational after frequent earthquakes, but collapse-prevented under rare earthquakes for life safety. Therefore, the buildings in seismic zone require the structure to bear proper stiffness and load-bearing capacity to resist frequent earthquakes, and possess proper ductility and energy-dissipating capacity to prevent collapse due to rare earthquakes as well. Structural metal damper is herein defined as a combination of structural member and energy-dissipating damper. It not only provides stiffness and strength to guarantee the operation of buildings under frequent earthquakes, but also dissipates energy to reduce seismic response to a considerable extent for the purpose of collapse-prevention. Three different structural metal dampers, including buckling-restrained brace (BRB), buckling-restrained steel plate shear wall (BRSW) and steel link elements, are introduced in this paper. BRB is not only a structural brace, but innovatively kept from buckling by using restrainers and its hysteretic curve is improved to be spindle-shape, ideal for dissipating energy to against seismic effects. BRSW is also ideal spindle-shape in hysteretic curve feature and can be used as an excellent structural metal damper. And in order to improve the performance of traditional shear walls and coupled shear walls under earthquakes, steel link elements are introduced. Finally, examples of using various structural metal dampers for buildings in seismic zone are presented.

KEYWORDS

Structural metal damper, buckling-restrained brace, buckling-restrained steel plate shear wall, steel link beam, buckling-restrained steel link wall.

INTRODUCTION

Installing energy-absorbing dampers in buildings in seismic zone is found to be a remarkable way to mitigate the structural response and residual deformation under earthquakes, owing to the fact that most damages are concentrated in the energy-dissipating members, however the other structural members still remain elastic or nearly elastic. While this sacrificing member is properly designed to not only consume inputted energy but also be capable of contributing stiffness and strength to structures at the same time, it is no longer a pure energy-consuming member, but also a structural member, which is the very definition of structural metal damper that proposed in this paper.

Therefore, the topic of this article is the introduction and elaboration of advantageous merits and successful application of structural metal dampers that are utilized for buildings in seismic zone in order to enhance its seismic performance to against natural hazards such as earthquake, on account of that behaviour of structures in seismic zone is much more complicated than that in non-seismic zone. And as known to all, the buildings in seismic zone are not only required damage-limited for fully operational after frequent earthquakes, but also collapse-prevented under rare earthquake events for life safety.

Generally speaking, structures in seismic zone are designed to withstand two different types of load, static load and dynamic one. The static load such as gravity remains constant all the time, while the latter such as earthquake excitation is however fluctuant and reaches the peak at a certain moment of a limited period of time. Therefore, buildings in seismic zone require the structure to bear proper stiffness and load-bearing capacity to resist static load, wind and frequent earthquakes. However, elastic design method for structures when subjected to rare earthquakes, indicated in Figure 1, seems uneconomical. Thus, plastic design method (Bruneau *et al*. 2011) is adopted, also shown in Figure 1, which requires the structures to possess proper ductility and energy-dissipating capacity to resist rare earthquakes. In other words, inadequate ductility and energy-absorbing capacity inevitably leads to damages even collapse of structures when subjected to rare earthquakes. That is to say, the more superior the hysteretic performance of structure, the smaller structural response and less damage.

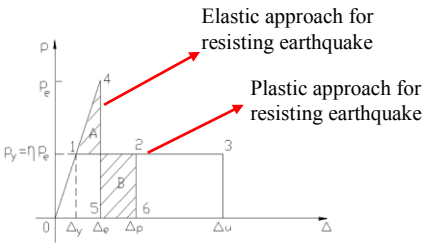

Figure 1 Relationship between force and displacement of structures

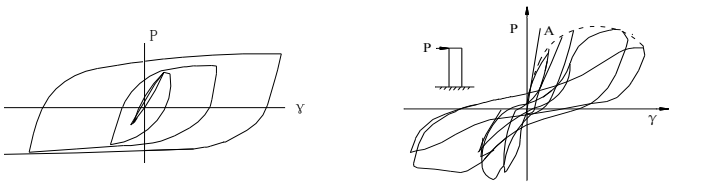

(a) Steel structures (b) Reinforced concrete structures

Figure 2 Typical hysteretic curves

Taking steel structures and reinforced concrete structures for example (Tremblay *et al*. 1995; Dogangun 2004). Both typical hysteretic curves are illustrated in Figure 2. Apparently, hysteretic performance of steel structures is better than that of reinforced concrete structures. Thus, given equal earthquake energy input to steel and concrete structures, their consequent structural responses and damages are at different levels. Structural response and damage of steel structure is proved to be much minor in comparison with that of reinforced concrete structures, as shown in Table 1 (Krawinkler *et al*. 1983).

Table 1. Damage of buildings in 1985 Mexico City Earthquake

Year of building	Steel structure		Reinforced concrete structure	
	Collapsed	Severely damaged	Collapsed	Severely damaged
Before 1957	7	1	27	16
1957-1976	3	1	51	23
After 1976	0	0	4	6

Considering the steel elements bear the merit of energy-dissipating and mitigating structural damage, structural metal dampers are brought forward and innovatively defined in this paper. Essentially, it is a combination of structural member and energy-dissipating damper. Three types of structural metal dampers are introduced. They are buckling-restrained steel brace, denoted as BRB (Yoshino *et al*. 1971; Wakabayashi *et al*. 1973; Fujimoto *et al*. 1988; Nagao *et al*. 1990, 1991), buckling-restrained steel plate shear wall, denoted as BRSW (Gao 2007; Tsai *et al*. 2006; Jin 2014), and steel link elements for concrete coupled shear walls, which can be used in enhancing the performance of buildings subjected to earthquakes.

BUCKLING-RESTRAINED BRACE (BRB)

Steel brace members that are used as diagonal members in framed structures are widely adopted for buildings in seismic zone. But their strength and deformation capacities turn out to deteriorate all of a sudden because of its premature buckling when subjected to seismic load, as shown in Figure 3. Therefore, an innovative concept of buckling-restrained steel brace has been proposed and investigated both theoretically and experimentally by researchers from all over the world (Saeki *et al*. 1995; Matsumoto *et al*. 1999; Iwata *et al*. 2001; Li *et al*. 2013; Guo *et al*. 2013).

BRB is a steel brace whose core panel is encased with a restraining part to avoid buckling under compressive axial forces. An unbonded material or a clearance is set up between the core panel and its restraining part so that the axial force borne by the core panel is not transmitted to the restraining part, as shown in Figure 4.

Figure 3 Buckling of ordinary steel braces under earthquakes

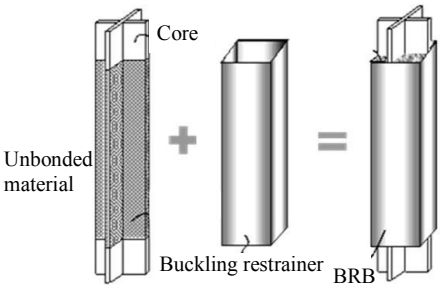

Figure 4 Components of buckling-restrained brace

Merits

The principle of BRB is that the buckling-against capacity should be larger than the yielding strength. So BRB will only yield even under compression and produce equal yielding strength under tensile and compressive axial forces, and exhibits a spindle-shape and stable hysteretic curve, as shown in Figure 5. This enables BRB bear proper stiffness and load-carrying capacity with excellent energy-dissipating capacity. By contrast, ordinary steel braces exhibit pinching hysteretic curve and poor energy-dissipating capacity on account of its premature buckling under compressive axial load, as illustrated in Figure 6.

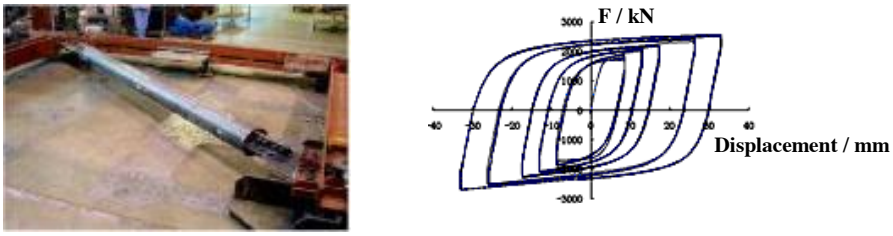

Figure 5 BRB and its typical hysteretic curve

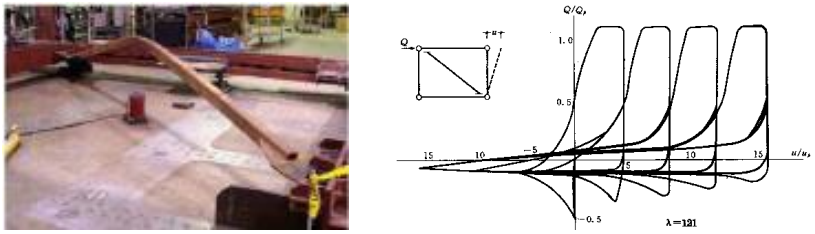

Figure 6 Buckled ordinary steel brace and its typical hysteretic curve

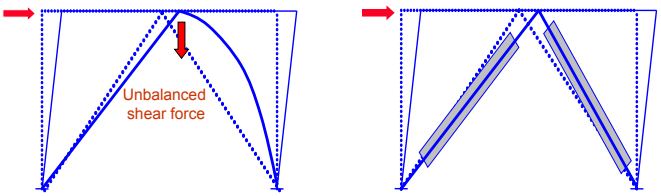
On the other hand, the problem of unbalanced shear force imposed on beam with chevron ordinary steel braces, which costs extra expenditures on augmented intersection of beams, can be prevented by utilizing BRBs instead, as shown in Figure 7.



(a) Ordinary steel brace (b) BRB

Figure 7 Unbalanced shear force imposed on beam

Exemplification

In order to illustrate the effectiveness and efficiency of using BRBs for structures in seismic zone in terms of reducing the structural seismic response for the purpose of mitigating damage and collapse prevention, one typical buckling-restrained braced frame (BRBF) and one ordinary concentrically braced frame (OCBF), as shown in Figure 8, located in the seismic zone of China with seismic intensity of 8, are exemplified analytically.

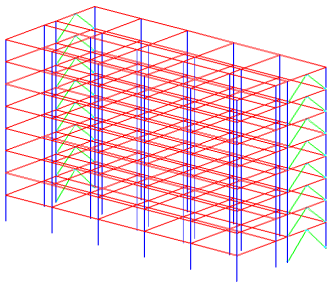


Figure 8 Analytical model

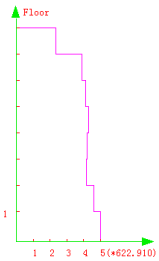
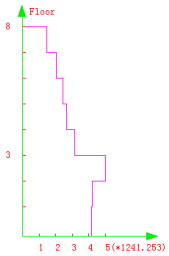
The result of analysis shows that base shear of BRBF is only around 60% of OCBF. And the maximum inter-story shear force of the former is much more uniform than the latter, as illustrated in Figure 9. And also, the maximum inter-story drift ratio is mitigated to a considerable extent of 66%, as can be concluded in Figure 10.

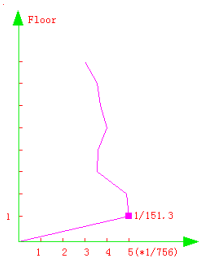


(a) BRBF

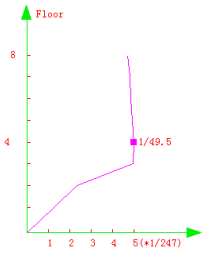


(b) OCBF

Figure 9 Maximum inter-story shear force



(a) BRBF



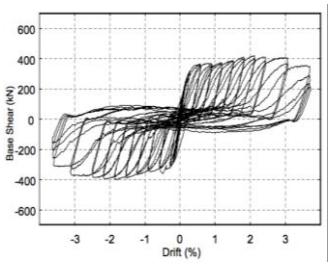
(b) OCBF

Figure 10 Maximum inter-story drift ratio

BUCKLING-RESTRAINED STEEL PLATE SHEAR WALL (BRSW)

Steel plate shear walls, denoted as SPSWs, have been used worldwide as lateral resisting members in tall buildings during the past few decades, as shown in Figure 11(a). However, traditional SPSW may easily buckle, which leads to a poor hysteretic behavior and energy dissipating capacity, as illustrated in Figure 11(b). For improving the hysteretic performance, the buckling-restraining concept is employed as BRB for SPSWs.

(a) SPSWs on site



(b) Typical hysteretic curve

Figure 11 SPSW

Merits

BRSW was first introduced in 1995 (Li *et al*. 1995). Buckling-restrainers are proposed at two sides of core plate like a "sandwich", as shown in Figure 12. The restrainers are designed to prevent core plate from buckling, but contribute nothing to lateral resisting, which can be concrete plates or steel case panels, as shown in Figure 13.

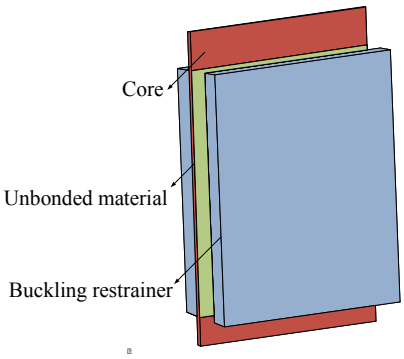


Figure 12. Components of BRSW

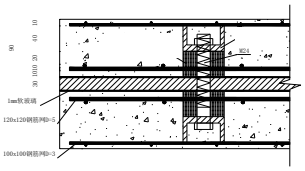
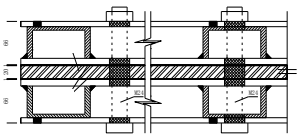
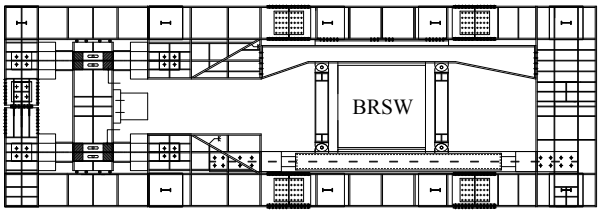


(a) Concrete plate

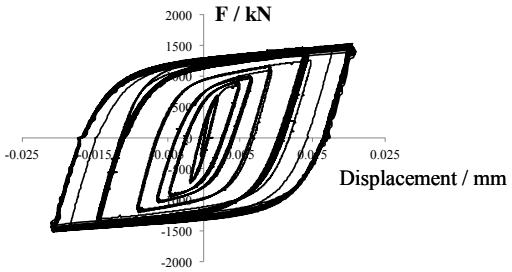


(b) Steel case panel

Figure 13 Two types of buckling restrainer



(a) Test setup of BRSW



(b) Typical hysteretic curve

Figure 14 BRSW

Similar to BRB, there is also a layer of unbonded material between inner steel plate and buckling restrainer. For buckling-restrained steel plate shear wall with properly-design restrainers, BRSW will only yield under shear and exhibit wonderful hysteretic behavior, as shown in Figure 14.

Exemplification

A case in point is the National Exhibition and Convention Center (NECC), which is projected to edge itself as the world's largest and most competitive MICE venue of our age, in which dozens of BRSWs were installed as shown in Figure 15. What is worth mentioning, the largest one used reaches 7m in height and 3m in width, and the yielding strength of which also makes a record of 12740kN, the mightiest BRSW in history ever.

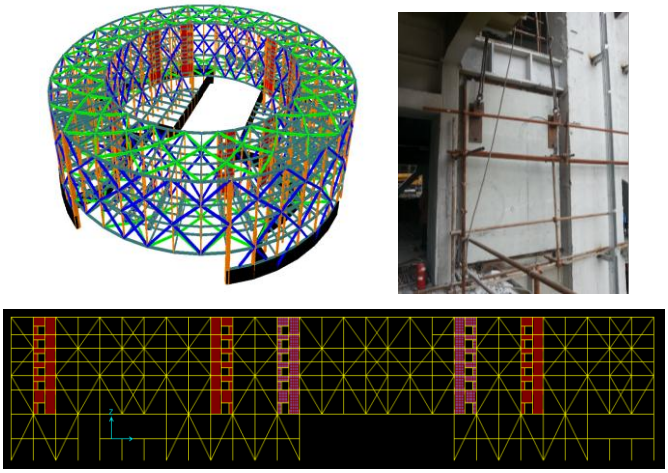


Figure 15 NECC and BRSW installed

By utilizing BRSWs in NECC, several problems have been meliorated and tackled. One leaping improvement is that the configuration of structural members is not restricted by architectural demands any longer, such as door openings and voids, thanks to flexible arrangement of BRSW. The second advantage is that BRSWs in NECC are somehow capable of taking part in resisting vertical load and also independent of loads from different dominant directions. The last but not the least, BRSWs play a vital role in both a provider of stiffness as well as strength and energy-dissipater. According to the analysis, BRSWs stay in elastic and bear proper stiffness and strength to limit the damage from frequent earthquakes, as shown in Figure 16(a), and also possess proper ductility and energy-absorbing capacity to prevent collapse under rare earthquakes, as shown in Figure 16(b).

STEEL LINK ELEMENTS FOR COUPLED CONCRETE SHEAR WALLS

Concrete shear walls are mostly used in structures to provide lateral stiffness, such as tall buildings. Due to their high stiffness, they are often designed to resist significant seismic shears. However, due of poor ductility in both material and structure, concrete shear walls are likely damaged in earthquakes, as shown in Figure 17. Stiffness and strength will not ensure concrete wall structures to survive from the earthquakes with satisfactory performance. Structural ductility and efficient energy-dissipation mechanism are also important to the structural seismic performance. Disappointingly, concrete wall structures are inherently lack of sufficient energy-dissipation capacities. They even tend to fail in shear and overturning moments, exhibiting a brittle failure mode.

Figure 17 Failure of concrete wall under earthquakes

In order to obtain a desirable seismic performance, two design rules are extensively emphasized in seismic design of concrete wall structures. One is that concrete shear walls are encouraged to possess the "plastic hinge" at the bottom of walls, which is able to dissipate the energy. The formation of plastic hinge is beneficial for shear walls to dissipate the earthquake-induced energy. However, severe damages are often observed in the plastic zone during earthquake events, which leads to a limited residual capacity in the aftershocks and are almost unable to be fully repaired. The other design principle is that wall structures should have effective coupling or link elements for energy-dissipation, which are, in most cases, developed by the architectural demands, such as door openings and voids, which accommodates conduit passing through.

The coupling beams provide an effective method to dissipate energy, as shown in Figure 18. Their seismic performance is always crucial to structural behavior in seismic events, because they are utilized to absorb most of the energy. At present, concrete link beams are the most common connecting medium for the concrete coupled shear walls. However, the seismic behavior of concrete link beams is poor in most cases, as illustrated in Figure 19. Therefore, many researchers devoted to improving the seismic performance of concrete coupling beams (Paulay 1986; Lam *et al*. 2003) or bringing forward other alternatives (Paulay *el al*. 1974; Harries *et al*. 1992; Gong *et al*. 2001). In this paper, steel link elements, which either can be steel link beams or buckling restrained steel link walls, are introduced to function as both structural member and energy-dissipating damper.

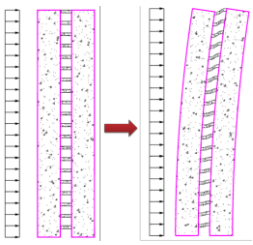

Figure 18 Coupled shear walls

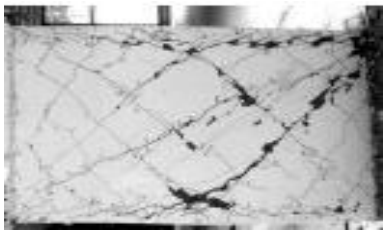
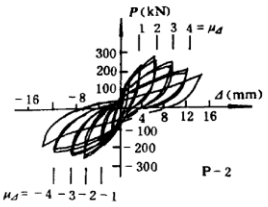


(a) Typical failure

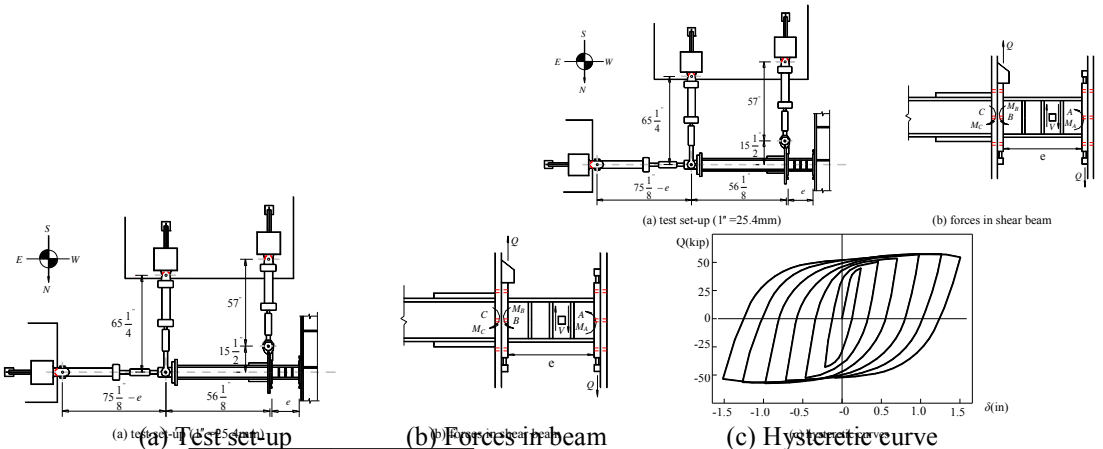


(b) Typical hysteretic curve

Figure 19 Concrete link beams

Steel link beam

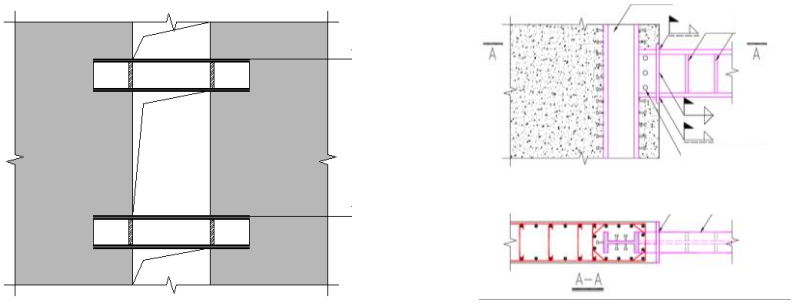
Steel link beam for coupled shear walls can be a normal steel beam. The key demands on the steel link beam are to limit the local buckling of the plates that consist of the beam and to develop large plasticity as large as possible to consume earthquake energy. So the steel link beam in the coupled shear walls can act as both a structural element when it doesn't yield and a damper to absorb energy when it yields, as shown in Figure 20.



(a) Test set-up (b) Forces in beam (c) Hysteretic curve

Figure 20 Steel link beams

In order to make the proposed steel link beams coordinate in concrete coupled shear wall structures, connection between coupling beams and walls should be well designed and detailed. Most researches to date focus on the method of embedding a certain length of link beams into the concrete walls (Park *et al*. 2005, 2006; Fortney *et al*. 2007), as indicated in Figure 21(a). Also, there is another kind of connection detail in which structural steel columns could be embedded in the wall boundary elements and connected with the steel link beams with moment connections, as shown in Figure 21(b). The latter one may be a more desirable method because it may ensure large connection stiffness as well as speed up the constructions.



(a) Traditional connection (b) Proposed connection

Figure 21 Connections between steel link beams and concrete walls

Steel link wall

Out of the drawbacks of solid cantilever shear wall structures, coupled shear wall structure with buckling-restrained steel link wall is introduced and it is comprised of a pair of individual cantilever concrete shear walls, between which an array of buckling-restrained steel plates for coupling or link elements is equally spaced along the structural height, as indicated in Figure 22.

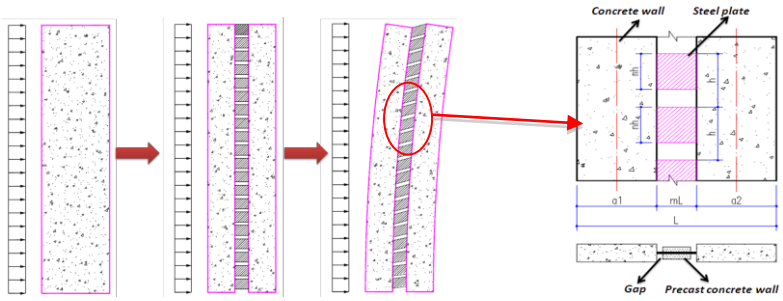


Figure 22 Coupled shear walls with steel link walls

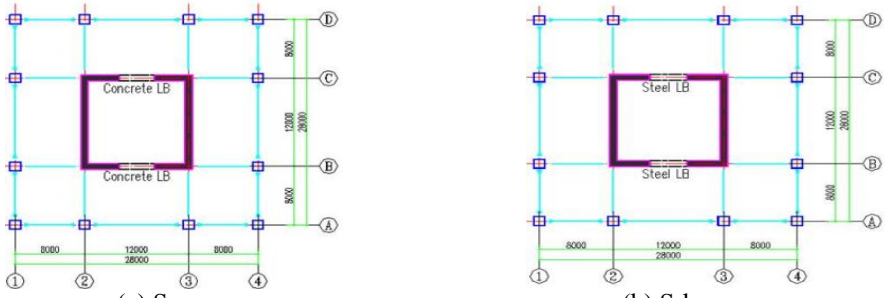
Analogous to the coupling beams in traditional coupled shear walls, the link elements (buckling-restrained steel link wall) function as both the energy-dissipation elements and structural elements with considerable stiffness to form coupled shear walls for drift control. Since steel plates may be thin, their height should be large enough to provide considerable shear stiffness to connect the adjacent shear wall piers. Actually, in practical structures, there are substantial amount of solid cantilever shear walls where architectural openings are not necessary. Therefore, they are innovatively inserted with buckling-restrained steel link walls in order to increase the seismic performance of these cantilever wall structures. And it turns out to have equal stiffness and strength, compared to that of solid cantilever shear wall structure.

Except for equal stiffness and strength, the energy-dissipating element, buckling-restrained steel link wall, possesses excellent and stable energy-absorption capacities, which is able to build a desirable energy dissipating mechanism as well as to protect the wall piers. The earthquake-induced energy could be mainly dissipated by the uniformly distributed steel link walls rather than concentrating in plastic hinge located at the bottom.

Exemplification

Two analytical examples are employed to elaborate high performance of proposed shear wall structures. One is coupled shear wall structure with steel link beams, while the other is coupled shear wall structure with buckling-restrained steel link walls.

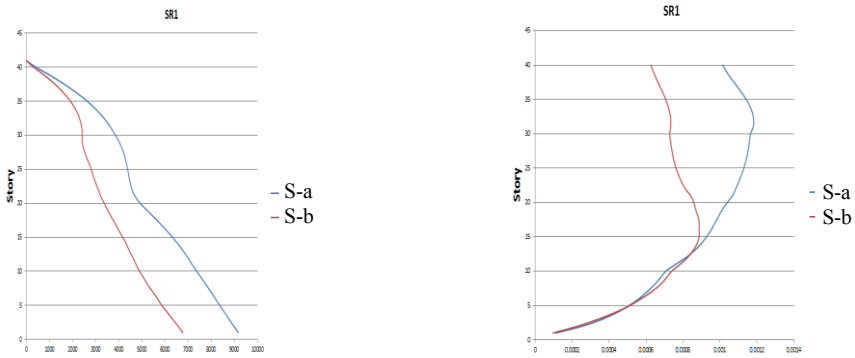
A wall-frame structure for a tall building with 40 stories is analyzed. A pair of channel wall piers constitutes the concrete core located at the center of plan, as shown in Figure 23. Concrete coupling beams are used in the x direction to connect the individual wall piers at each floor level, generating 'S-a' structure as shown in Figure 23(a). As a comparison, in the 'S-b' structure, as shown in Figure 23(b), steel link beams replace the concrete link beams in the x direction with the aim of encouraging more energy dissipated. By comparing seismic behavior of above two structures, efficiency of the steel link beams is demonstrated self-evidently.



(a) S-a (b) S-b

Figure 23 Plans of the structure for a tall building

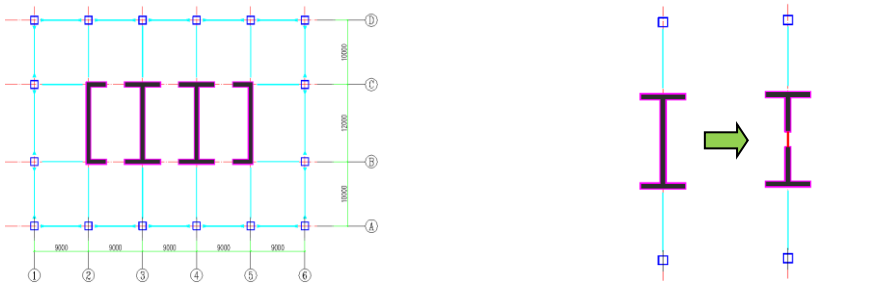
In order to verify the efficiency of proposed structures, elasto-plastic time-history analysis is conducted to investigate their structural behaviour under rare earthquakes. Comparisons on maximum base shear and inter-story drift ratio of 'S-a' and 'S-b' structures are shown in Figure 24.



(a) Base shear (b) Inter-story drift ratio

Figure 24 Comparison between S-a and S-b

Another typical shear wall structure is investigated to identify efficiency of steel link wall. The structure is assumed to have a total height of 200m and 50 stories with equal height for simplicity. The typical floor plan is shown in Figure 25(a). A noticeable characteristic of the plan is that, in the y-direction, cantilever shear walls are used to resist the lateral seismic loads, which is lack of sufficient energy-dissipation capacities. In order to enhance the seismic performance in this direction, buckling-restrained steel link wall are inserted to transform the previous cantilever shear wall structure to coupled shear wall structure, as shown in Figure 25(b).



(a) Layout of typical floor (b) Utilization of steel link wall

Figure 25 Coupled shear wall using steel link wall

The original shear wall structure is denoted as SW, and the transformed structure with steel link walls is denoted as CSW. Two sizes of steel link wall are employed for CSW-1 and CSW-2. A strong ground motion is chosen for the nonlinear dynamic time-history analysis, which is scaled to 400gal at the peak value, according to China code. Figure 26(a) well demonstrates that the proposed shear wall structure with buckling-restrained steel link wall could significantly reduce the base shear under the ground motions compared to the original cantilever shear walls. Elasto-plastic inter-story drift is compared in Figure 26(b), indicating a significant decrease in inter-story drift ratio. It is the reason for which steel link wall function as a competent structural metal damper that offers adequate stiffness and strength, and dissipates most energy that seismic response is largely relieved. As can seen from the results of time history analysis, compared to the original cantilever walls, damage of concrete shear wall is much more mitigated.

Figure 26 Comparison of SW and CSW

SUMMARY AND CONCLUSION

Three different structural metal dampers, including buckling-restrained brace (BRB), buckling-restrained steel plate shear wall (BRSW) and steel link elements, are introduced in this paper. Frames braced with BRBs and BRSWs, and shear walls coupled with steel link beams or buckling-restrained steel link walls, are brought forward to enhance the structural behaviour of buildings in seismic zone. And as indicated by typical hysteretic curves, above structural metal dampers are proved to be ideal for not only providing structural stiffness as well as strength for the buildings to against static load, wind and frequent earthquakes, but also contributes additional damping to dissipate earthquake energy and reduce structural seismic response to a considerable extent for the purpose of damage-mitigation and collapse-prevention.

BRBs and BRSWs can play a vital role in both a provider of stiffness as well as strength and energy-dissipater. They can stay in elastic to bear proper stiffness and load-bearing capacity to guarantee the proper operation of building under gravity, wind and frequent earthquakes, while possess proper ductility and energy-dissipating capacity by to prevent collapse due to rare earthquakes as well.

Seismic behaviour of coupled shear wall structure with steel link beams and buckling-restrained steel link walls is extremely desirable under severe earthquakes. Because of energy-dissipation by steel link elements, base shear and inter-story drift ratio are reduced remarkably compared to pure concrete wall structure, either cantilever or coupled.

ABSTRACT

The design of engineering structures for deconstructability can reduce the energy and cost required for their demolition and the disposal of their construction waste, and it also enhances the sustainability of a building by allowing for easy dismantling and the reuse or recycling of structural components and construction materials at the end of the service life of the building. In addition, using high performance materials such as High Strength Steel (HSS) can improve the sustainability of a structure by providing for higher design stresses and accordingly reducing the self-weight of the structure. This paper describes the results of four full-scale beam-to-column deconstructable composite joints with HSS S690 flush end plates. The structural behaviour of the new system in conjunction with application of post-installed friction-grip bolted shear connectors for developing deconstructable composite floors is investigated. The test results show that the proposed composite beam-to-column joints can provide the required strength and ductility according to EC3 and EC4 specifications, and that the system can be easily deconstructed at the end of the service life of the structure as a proof of concept.

INTRODUCTION

Among different construction materials, steel has a great potential to significantly improve the sustainability of the construction industry; steel structures have high strength to weight ratios, they can be erected rapidly and their construction and demolition waste can be minimised by employing prefabricated and deconstructable systems. Moreover, using prefabrication and deconstruction in conjunction with steel frames can drastically facilitate the full recycling and reuse of the construction materials and structural components. Accordingly, over the past decade several attempts have been made to enhance the sustainability of steel structures by either using high-strength durable steels or developing prefabricated demountable steel framing systems (Gogue 2012); however, the application of HSS in conjunction with deconstructable frames remains unexplored and this is the main focus of the present study.

The use of HSS has recently gained popularity in the construction industry owing to its higher yield strength, greater corrosion resistance and higher toughness compared with mild steel. In HSS construction, design stresses can be increased and thickness of plates may be reduced that, in turn, can save on the costs of labour, welding, transportation, erection and fabrication. The cost of the foundation may be reduced owing to lower self-weight of HSS structures compared to mild steel structures and significant cost benefits and reduced construction time can be achieved by increasing design stresses and reducing the thickness of plates (Mursi and Uy 2004). However, the efficient use of HSS in structural members has been hampered by problems associated with its lower ductility, weldability, toughness and fatigue resistance. In particular, the lower ductility of the HSS can potentially affect the structural performance of beam-to-column connections where the steel plates can experience large strains well-beyond the yield strain (Giaro Coelho and Bijlaard 2007; Girao Coelho et al. 2010). Girao Coelho and Bijlaard (2007) carried out an experimental investigation of moment connections with end plates made from HSS of grades S460, S690 and S960 to provide insight into the nonlinear behaviour of these joints and it was concluded that the extrapolation of the design philosophy in the current EC3 provisions, based on the semi-continuous or partially-restrained concepts, can provide accurate strength predictions. In addition, it was shown that the HSS end plate connections can provide the rotation demands required for beam-to-column connections of rigid or semi-rigid moment resisting frames.

Apart from its attributes of high-strength and high-performance, design for deconstruction in conjunction with the use of recycled steel can significantly enhance the sustainability of steel structures. In a fully deconstructable steel frame, the beam-to-column connections as well as the floor slab to steel beam connections should have the potential to be easily dismantled. Bolted beam-to-column connections with flush- or extended end plates can partly provide the ease required for dismantling steel frames, but existing composite steel-concrete floor systems typically take advantage of monolithic construction to ensure adequate performance (*i.e*. near full composite action) and hence they cannot be easily disassembled and reused at the end of the service life of the structure. Furthermore, the demolition of monolithic concrete-steel composite floors in which the shear studs have been permanently buried in cast *in situ* concrete (or pockets filled with grout), requires much energy and leads to large amounts of construction waste. Because of this, there is a need to develop deconstructable steel-concrete composite floors that can be easily dismantled at the end of a structure's service life.

Post-installed Friction-grip Bolted Shear Connectors (PFBSCs) installed through bolt holes placed in precast slabs and pre-drilled in the top flange of the steel beams is a novel method for developing composite action between precast concrete slabs and steel girders. The composite floors employing PFBSCs can be easily dismantled at the end of their service life, and this in turn can minimise the construction waste associated with the demolition of composite floors and can maximise the possibility for future reuse of the structural components (Marshall et al. 1971; Dallam 1968; Dallam and Harpster 1968; Kwon et al. 2010, 2011; Bradford and Pi 2012a, 2012b; Rowe and Bradford 2013; Lee and Bradford 2013; Ataei and Bradford 2013; Ataei et al. 2014, 2015). Furthermore, demountable composite floors with precast slabs and prefabricated steel girders can increase the speed, accuracy and quality of construction and reduce the time and environmental impact (*viz*. noise, disruption to traffic and pollution) of the construction.

The first tests on bolted shear connectors date back to the late 60s (Dallam 1968; Dallam and Harpster 1968), but surprisingly limited studies have been conducted on the behaviour and application of bolted shear connectors since then, and most of these studies are related to bolted shear connectors permanently buried in concrete or grout-filled pockets (Dallam 1968; Dallam and Harpster 1968; Kwon et al. 2010, 2011) with less attention being paid to the potential application of PFBSCs for developing deconstructable steel-concrete composite floors (Bradford and Pi 2012a, 2012b; Rowe and Bradford 2013; Lee and Bradford 2013; Ataei and Bradford 2013; Ataei et al. 2014, 2015). In general, the available test results show that bolted shear connectors exhibit higher load capacities and significantly higher fatigue strength than those of stud shear connectors (Dallam 1968; Dallam and Harpster 1968; Kwon et al. 2010, 2011). Moreover, limited experimental studies on bridge decks have demonstrated the adequacy of PFBSCs for strengthening non-composite bridge girders by increasing their stiffness, load carrying capacity and fatigue strength (Kwon et al. 2010, 2011).

This paper presents the results of static tests conducted on four full-scale Flush End Plate Semi Rigid (FEPSR) beam-to-column joints made up of grade S690 HSS in a steel-concrete composite frame that takes advantage of deconstructable PFBSCs and precast "Green Concrete" (GC) slabs associated with reduced cement content (Boral Australia 2013). The main objective is to determine the failure mode and characterise the moment and rotation capacity, moment-rotation relationship and ductility of this new sustainable composite system with high strength steel FEPSR beam-to-column joints. Moreover, the provisions of EC3 (2005) and EC4 (2006) are employed to assess the structural performance of the HSS FEPSR joints with deconstructable composite beams and the influence of the type of bolted shear connectors, degree of shear connection and type of columns (open sections and concrete filled steel tubes) on the structural behaviour of the proposed composite joints are investigated.

TEST SPECIMENS

Specimen Design

Four full-scale cruciform beam-to-column joints with flush end plates were designed and constructed according to the provisions of EC3 (2005) and EC4 (2006) to evaluate the stiffness, ductility and bending moment and rotation capacities of the proposed deconstructable composite joints with HSS flush end plates. The beam-to-column assemblages were symmetric to simulate the behaviour of an internal joint in a semi-rigid frame. The specimens were tested under a displacement-controlled vertical load applied at the tip of the beam. The geometry, dimensions and details of all specimens are illustrated in Figures 1 to 3 and the details of composite beams and post-tensioned PFBSCs are given in Table 1.

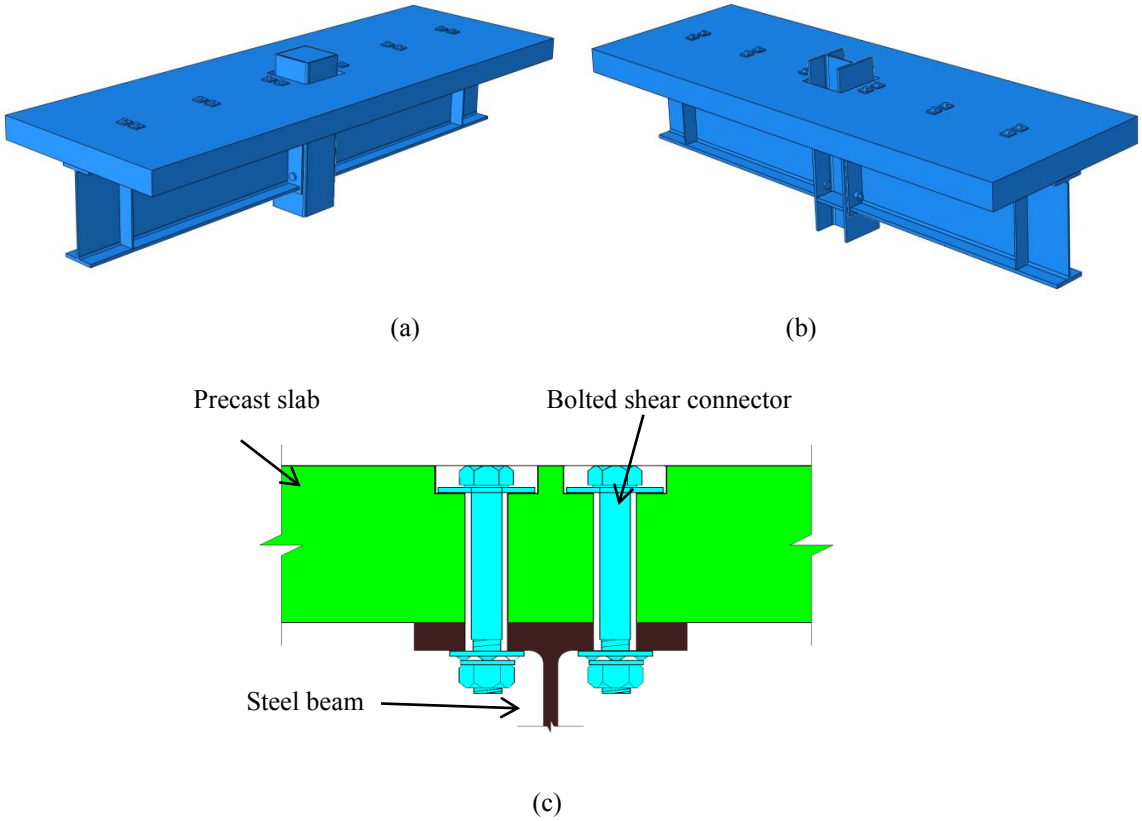

Figure 1 Schematic outline of deconstructable composite beam-to-column joint with flush end plate connection: (a) pictorial view of CJ1 and CJ2; (b) pictorial view of CJ3 and CJ4; (c) friction-grip bolted shear connection

Table 1 Test specimens

Specimen	Column type	Steel beam	Shear connector	Degree of shear connection (%)	Hole diameter in slab (mm)	Hole diameter in steel beam (mm)	Applied bolt pretension (kN)
CJ1	250×250×12.5	460UB82.1	6M20	195	24	22	145
CJ2	250×250×12.5	460UB82.1	6M16	124	20	18	95
CJ3	250UC89.5	460UB82.1	4M16	82	20	18	95
CJ4	250UC89.5	460UB82.1	4M20	130	24	22	145

All four cruciform joints (viz. CJ1 to CJ4) consisted of 460UB82.1 steel beam sections. For specimens CJ1 and CJ2, the columns were a concrete-filled tubular steel 250×250×12.5 mm columns and for specimens CJ3 and CJ4, a 250UC89.5 I-section was used. Composite action between the precast concrete slabs and steel beams was provided by the bolted shear connectors installed in pairs as shown in Figure 1(c). Grade 8.8 M20 or M16 high strength bolts were used to attach the precast concrete slab to the top flange of the steel beam. In order to confirm the minimum post-tensioning forces of 95 kN and 145 kN respectively induced in the M16 and M20 bolts, an electric control torque wrench with Squirter Direct Tension Indicating washers were used. The outline and general configuration of the cruciform joints before installation of the precast concrete slabs is shown in Figure 4(a), and the precast concrete slabs after de-molding are shown in Figure 4(b).

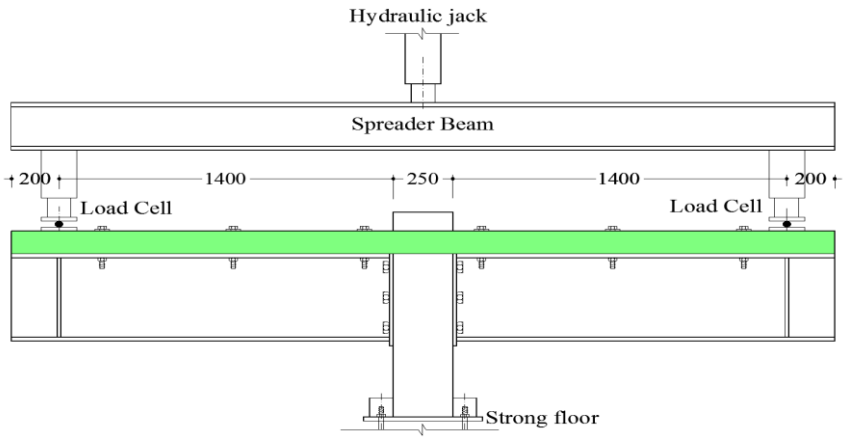

Figure 5 Test set up for the joint tests

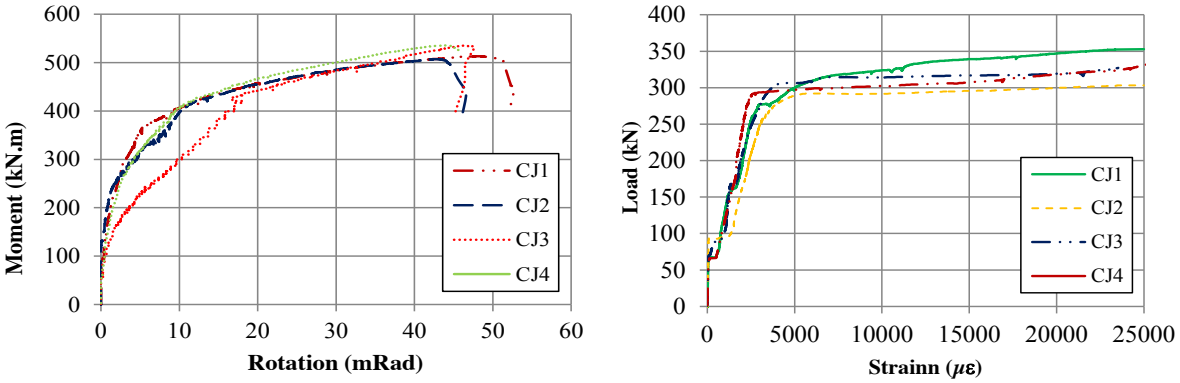
According to the provisions of EC3 and EC4, in order to prevent non-ductile failure of connections made up of mild steel grades, the thickness of the end plate should be limited to 60% of the bolt diameter (*e.g*. 12 mm thick plate for M20 bolts and 15 mm thick plate for M24 bolts). However, in a study conducted by Ataei *et al*. (2015), it was shown that the end plate thickness recommended in EC3/EC4 cannot sufficiently prevent the non-ductile mode of failure associated with rupture of bolts in FEPSR beam-to-column composite joints with deconstructable PFBSCs, mainly because of the stiffening effect of reinforced concrete slabs that has not been considered in the EC3/EC4 recommended end plate thickness. Accordingly, in this study, an 8 mm thick flush end plate (40% of the M20 bolt diameter for concrete-filled column and about 35% of the M24 bolt diameter for I-section column) made of S690 grade steel was welded to the end of steel girders to ensure ductile mode of failure. Six M20 grade 8.8 Hollow-bolt (blind bolts) (Lindapter International 2004; Standards Australia 1996; Loh et al. 2006) and four M24 grade 12.9 bolts were used for connecting the steel girders to CFST columns and I-section columns, respectively.

In all tested joints, the precast GC concrete slabs attached to the top flange of the steel girders were continuous over the column as shown in Figure 4(c). A longitudinal reinforcing ratio of 0.73% was provided for the slabs with the reinforcing bar configurations shown in Figures 2 and 3. It is noteworthy that the N10 bottom bars in the slabs were terminated near the column face to prevent their contributing to the bending moment resistance of the joints. Moreover, two layers of N10 bars were used in the transverse direction (see Figures 2 and 3) to prevent the longitudinal splitting of the precast slabs. The configuration of specimens CJ1 and CJ2 after assembling the continuous precast concrete slab are shown in Figure 4(c).

Experimental Setup and Loading Procedure

The test setup and loading procedure for the composite beam-to-column joints are shown in Figure 5.Vertical displacement-controlled loading was applied to the both ends of the composite beams by a 5000 kN capacity actuator and a spreader beam. In order to verify the test set-up and performance of the components and instrumentation, before conducting each test, a small load about 10% of the predicted ultimate load carrying

capacity of the specimens was applied to the specimens, and the specimens were then unloaded. The specimens were reloaded until no further load could be sustained by the specimen. Three displacement rates of 0.3 mm/min for the linear elastic range and 0.6 mm/min and 1.2 mm/min for the nonlinear plastic parts were used sequentially.



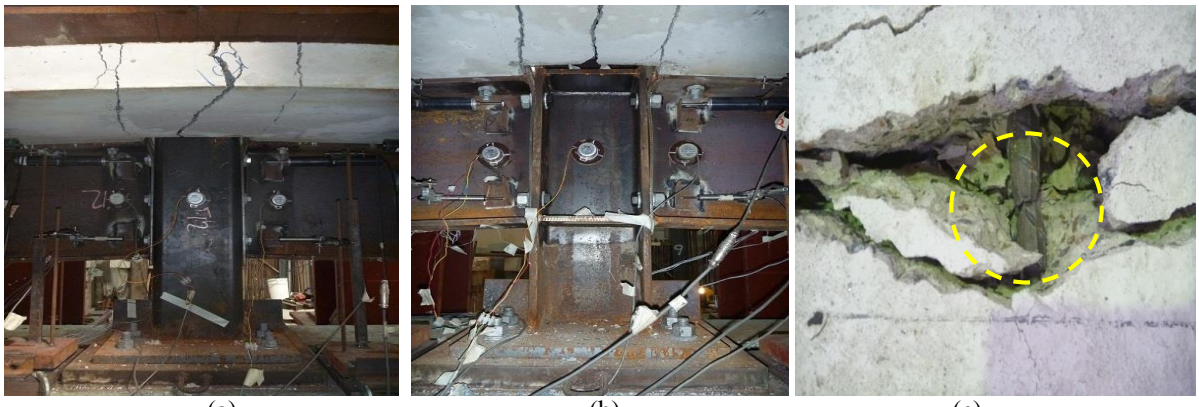
(a) (b)

Figure 6 (a) Moment-rotation response of the specimens and (b) tensile strain in longitudinal reinforcing steel bars at the mid-span

EXPERIMENTAL RESULTS

Moment-rotation Response

To establish the moment-rotation response of the joints, the moment acting on the connection was obtained by multiplying the load applied at the end of the composite beam by the lever arm (*i.e*. distance between the centre of the loading on composite beam and the column face). Regarding the rotation of the joints, two different methods were adopted; in the first method, the difference between the rotation of the column and the steel beam measured by inclinometers was considered as the rotation of the connection, whereas in the second method, the rotation of the joint was obtained by subtracting the displacements measured by bottom LSCT from that measured by top LSCT and dividing the result by the distance between these two LSCTs. The moment-rotation responses of all four specimens are shown in Figure 6(a). Moment capacities of 513.0, 506.8, 534.8 and 535.4 kNm with rotation capacities of 48.6, 43.3, 46.8 and 44.1 mrad were recorded for specimens CJ1, CJ2, CJ3 and CJ4 respectively, and all specimens exhibited significant non-linearity with very satisfactory moment-rotation behaviour. Figures 7 (a) and (b) illustrate the state of specimens CJ2 and CJ4 after the test. The typical failure mode of the specimens is also shown in Figure 7(c).



(a) (b) (c)

Figure 7 (a) Specimen CJ2 after the test; (b) specimen CJ4 after the test; (c) typical failure mode of the specimens

According to the EC3 and EC4 provisions, among three possible modes of failure, including yielding of the end plate or column flange, bolt failure combined with column flange or end plate yielding and bolt failure, only the first failure mode associated with complete yielding of the end plate or column flange can be considered as ductile and the third mode of failure in which only bolt rupture occurs should be considered as brittle (non-ductile). In the present experimental study, yielding and plastic deformation of the HSS grade S690 flush end

plate in the beam-to-column joints with deconstructable PFBSCs took place with no fracture of the bolts located in the tension zone of the connection, which is characteristic of the ductile failure mode specified in EC3/EC4. Moreover, in accordance with EC3 and EC4, in order to allow for plastic analysis and design, the rotation capacity of the joint must be greater than 30 mrad and as can be seen in Table 2, all specimens had a rotation capacity higher than that specified in the EC3/EC4 design codes. Accordingly, it can be concluded that despite using HSS flush end plates, the proposed deconstructable connections have sufficient rotation capacity and can be considered as ductile.

Table 2 Test result of composite and non-composite FEPSR beam-to-CFST column joints

Specimen	Moment capacity (kNm)	Rotation capacity (mrad)	Mode of failure
CJ1	512.3	48.6	Bar fracture
CJ2	506.8	43.3	Bar fracture
CJ3	534.8	46.8	Bar fracture
CJ4	535.4	44.1	Bar fracture

Strain in Longitudinal Reinforcing Bars

The load versus tensile strain in the longitudinal reinforcing bars at mid span of all specimens is shown in Figure 6(b). The sudden increase in tensile strain of steel bars at a load of about 80 kN can be attributed to the development of a transverse crack in the precast concrete slab and at sections adjacent to column. Moreover, it is observed that the average longitudinal strain in the reinforcing bar at the mid span for all composite specimens including the ones with weak partial shear interaction (*i.e*. specimen CJ3) exceeded the yield strain at the ultimate load.

Deconstructability of the System

One of the main objectives of this study was to propose a novel system which can be easily deconstructed at the end of service life of the structure and to facilitate possible recycling and reuse of the steel and concrete components. To verify that the proposed system can be easily deconstructed, specimen CJ4 was loaded up to 60% of the predicted ultimate load capacity (about the service load level), and then, the specimen was unloaded. The specimen was removed from the testing rig and the composite beams were dismantled and then reassembled as shown in Figure 8(a). The specimens were reloaded until failure occurred. It was demonstrated that the FEPSR beam-to-column joints with PFBSCs can be demounted easily and all components of these system can be pulled apart and reused in other buildings. Moreover, one of the blind bolts employed in the concrete-filled column was untightened and removed from the connection and then retightened (see Figure 8(b)) and accordingly it is concluded that the blind bolted FEPSR connections have the potential to be deconstructed at the end of their service life.

CONCLUSIONS

In this paper, the behaviour of four full-scale sustainable high strength steel Grade S690 FEPSR beam-to-column composite joints with deconstructable PPBSCs was investigated. A novel steel-concrete composite floor with precast GC concrete slabs and deconstructable PFBSCs was adapted to improve the sustainability of the

composite floor and enhance possibility for recycling and reuse of construction materials and subsequently reduce the carbon footprint of the construction industry. Type of bolted shear connectors, degree of shear connection and column type were the main variables in the experimental program. Based on the experimental results, the structural behaviour of this novel composite system that take advantage of precast slabs and PFBSCs in conjunction with high-strength steel flush end plates were investigated. From the experimental results the following conclusions can be drawn.

- The test results show that a HSS FEPSR composite joint with PFBSCs can provide a higher rotation capacity (43 mrad and above) than that specified in the EC3/EC4 codes.
- A ductile mode of failure (as specified in the EC3/EC4 provisions) for beam-to-column joints with deconstructable PFBSCs and HSS flush end plates can be achieved, provided the end plate thickness is limited to 35-40% of the bolt size.
- The friction-grip mechanism mobilised by the pre-tensioning force in the bolted shear connectors can effectively transmit the shear between the precast concrete slabs and top flange of the steel beam at the initial stage of loading.
- Decreasing the degree of shear connection leads to a decrease in the initial strength of a composite joint that, in turn, can increase the deflection of composite beams under service-load conditions.
- First slip with stronger bolted shear connectors occurs at higher levels of load as expected and partial shear connection leads to more ductile behaviour for the composite joint.
- Yielding and plastic deformation of the flush end plate made up of HSS S690 occurs without fracture of the bolts located in the tension zone of the connection, provided the thickness of end plate is limited to 35-40% of the bolt size.
- The FEPSR beam-to-column joints with PFBSCs can be demounted easily at the end of the service life of the structure and all components of the proposed system can be pulled apart and reused. Beam-to-column connections using blind bolting can also be deconstructed at the end of the structure's service life.

ACKNOWLEDGEMENTS

The work reported in this paper was undertaken with the financial support of the Australian Research Council through an Australian Laureate Fellowship (FL100100063) awarded to the first author. The assistance of the technical staff at the UNSW Heavy Structures Research Laboratory is also acknowledged with thanks.

FIELD EXPERIENCE AND THE LONG-TERM DURABILITY OF REINFORCED CONCRETE STRUCTURES

Robert E. Melchers
Centre for Infrastructure Performance and Reliability, Faculty of Engineering and the Built Environment, University of Newcastle, Newcastle, Australia, 2308. *Email: rob.melchers@newcastle.edu.au

ABSTRACT

For reinforced concrete structures the conventional wisdom is that after some years of exposure to marine conditions reinforcement corrosion is inevitable. Much attention is paid in the literature to the rate of ingress of chlorides through the concrete cover to the reinforcing bars and to ensuring highly impermeable cover and/or deeper cover, to try top prevent chloride-induced or carbonation-induced corrosion initiation. Actual field experience shows that there are many reinforced concrete structures that have survived remarkably well for many decades despite having very high chloride concentrations next to the reinforcing bars. Even with very modest concrete cover by modern standards, exhumation often finds bars free from corrosion. Detailed investigations of a number of such cases showed no corrosion if the concrete pH levels are above about 9. On the other hand, very severe reinforcement corrosion was observed in the few cases where the concrete had cracked right through the cover to the bars. Often there was no external evidence or signs of interior corrosion, including longitudinal cracking. The implications of these findings for practice are discussed.

Reinforced concrete, reinforcement, corrosion, alkalinity, field experience, evidence.

INTRODUCTION

The corrosion resistance of reinforcement in reinforced concrete structures exposed to marine environments is a matter of continuing concern for structural engineers and asset managers. According to most texts (Richardson 2002; Hunkeler 2005; Gjorv 2009) the build-up of aggressive ions such as chlorides adjacent to the reinforcement will cause it to corrode once a sufficient concentration has been reached. Attention is therefore focused sharply on reducing the diffusion of chlorides from the external environment, and for this thick concrete cover, high density concrete, permeability-reducing additives, and cathodic protection are often specified in an attempt to ensure a long life of the asset. High quality workmanship also has been seen as beneficial. As will be shown, these aspects, while desirable, are peripheral to attaining long-term durability.

The other main mechanism implicated in causing reinforcement corrosion is ‘carbonation’, the process by which carbon dioxide from the atmosphere diffuses into the concrete and, on reaching the reinforcement, is claimed to lower the local pH such that corrosion commences. Interestingly, it is well-known in the industry that good quality concretes permit only some few millimetres of carbonation from the outside surface even over extended periods of exposure (Parrott 1987). Nevertheless, carbonation receives considerable discussion in reinforcement corrosion texts.

One of the difficulties associated with durability studies is that they cannot be replicated in laboratory trials. Accelerated testing can be done for example using salt sprays, higher temperatures, impressed current on the reinforcement, but the relationship of the results obtained to actual in-service behaviour remains tenuous (Hansson 2000). This is not a problem unique to reinforcement corrosion (Lee et al. 2010). An alternative approach is to try to learn something from actual operational experience with real structures. The draw-back for such an approach usually is that there are few structures available for investigation, they tend to be one-off so that investigation of causative parameters is difficult, and typically they are not well-documented (or the documentation no longer exists or cannot be found). Despite these difficulties, the approach does have merits, and can be considered an archaeological one, such that with care useful observations can be made. Several investigations along these lines have been described for reinforced concrete structures (Melchers et al. 2009) as well as for materials of potential use in nuclear waste storage facilities (Chitty et al. 2005).

In the following the corrosion performance of a number of reinforced concrete structures exposed to marine environments is described, admittedly briefly. The observations are then interpreted in terms of research findings, mainly in the materials research literature, and not always well-known to structural engineers dealing with durability issues.

PRACTICAL EXAMPLES

Hornibrook Bridge, Brisbane

In 2010 the 2.7km long, timber superstructure, reinforced concrete substructure, bridge at Bramble Bay, Brisbane was demolished, with considerable difficulty, after some 80 years service immediately adjacent to the Pacific Ocean. Although the vehicular capacity of the bridge was no longer adequate, its substructure was largely in excellent condition. It consisted of 879 reinforced concrete driven piles, each 400 x 400mm in cross-section with (in most cases) only 4 reinforcing bars of 32 mm (1-1/4") diam. with 40 mm cover. The crossheads over the piles were in less good condition. The piles were removed from the seabed with considerable difficulty, in some cases having to be cut just above the seabed because they could not be withdrawn from the soil. With few exceptions, there was no visible evidence of reinforcement corrosion for any of the piles. Figure 1 shows a number of piles in the demolition yard. Several samples of the piles were taken to the Civil Engineering Laboratory, The University of Newcastle for detailed investigation. An early report on this is available (Pape and Melchers 2013) and a detailed paper is in preparation.

Figure 1 Sample piles after demolition showing no exterior evidence of internal corrosion.

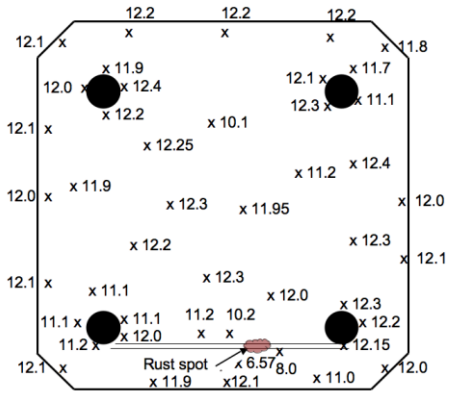

Figure 2 pH map of typical pile cross-section. The pH at the rust spot is about 7.

Schmidt hammer readings were high and compressive tests on cores showed concrete strength of 65-75MPa. This was confirmed empirically by the difficulty laboratory staff experienced in breaking open the samples for examination of the reinforcement. None of the samples showed signs of corrosion although some showed some surface discoloration. Some samples were cut across with a concrete saw and the pH sampled over the cross-sections. Figure 3 gives one example. It shows, as did all others so far examined, that even after some 80 years almost all the concrete still has a pH of at least 9 and mostly around 12. Mostly the cross-sections show no sign of reinforcement corrosion. Petrographic examination of the concrete indicated very minor evidence of alkali-silicate reactions and none of alkali-aggregate reactions. The chloride levels were very high, some 0.6% to 3% by weight of cement – much higher than any permitted by conventional design requirements.

Some of the people associated with the bridge during its construction and subsequently, and with knowledge of the construction industry in the decades after its construction, related that Sir John Hornibrook, the bridge designer and constructor, demanded high quality workmanship and always erred on the side of adding more rather than less cement. The likely sources of cement, sand and aggregate also were identified, although it has not yet been possible to drawn conclusions about their possible influence.

During demolition the contractor noted that one pile, on being pulled out of the soil, was obviously cracked about half-way up. Investigation of the cracked area showed the cross-section in Figure 3. It has half the concrete cross-section cracked and showing signs of watery-looking rust stains – the other half was broken during recovery and the reinforcing bars flame-cut. There are no reinforcement bars visible in the area of the rust-stained crack. Evidently, these bars have corroded away almost completely some distance into the concrete (Figure 4). There were no rust stains visible on the exterior concrete surfaces. This means that a routine visual inspection is unlikely to have signalled there were problems with the reinforcement inside.

Handrails at Arbroath, Scotland

Immediately next to the North Sea at Arbroath on the East coast of Scotland there is a 1.6 km long reinforced concrete balustrade constructed during 1943. It consists of some 1000 precast concrete handrail elements each about 2m long and 130 x 150mm in cross-section, with four 6 mm diam. steel reinforcing bars. Some 90% of the 1943 elements remain. The other 10% were replaced in 1968 and in 1993. Remarkably, all replacements have been badly damaged by longitudinal cracking from reinforcement corrosion (Melchers et al. 2009). Samples of the 1943 elements were selected at random by the local Council for detailed examination. This showed the presence of seashells in the concrete, indicating use of beach material and seawater for making the concrete. They also showed very high levels of chlorides in the concrete, much higher than the accepted thresholds for corrosion initiation. There also is wide variations in concrete cover and in aggregate size. There is almost no evidence of external rust staining, perhaps because of the high rainfall in the area washing away any ferrous chlorides (Melchers & Li 2009a). Almost all the cross-sections of the 1943 concrete elements examined showed pH of 9-10 or more, with slight evidence of corrosion initiation only for local pH at reinforcement less than 9.

A number of lengths of 1943 concrete handrails were broken open to reveal almost 'as-new' reinforcement. However, one section revealed extremely severe corrosion with almost complete loss of the reinforcing bars, even though there was no longitudinal cracking along the bars. The scenario was generally similar to that in Figs. 3 and 4. Close examination revealed a transverse crack across where the reinforcement had been, with light watery rust staining evident on the adjacent concrete surfaces – again similar to Figs. 3 and 4.

Second Progreso Pier, Yucatan, Mexico

The town of Progresso on the north Yucatan coast of Mexico is perhaps best known as the site of the (first) Progreso pier, completed in 1941 and very lightly reinforced with some stainless steel (grade 304) bars, mostly well inside the otherwise mass concrete structure. It has been used repeatedly to claim (Rostam 2003) the superiority of stainless steel as reinforcement, even though there is clear evidence (Ramboll 1999) of reinforcement corrosion near the ends where the bars protrude from the concrete and despite the bars being well inside the concrete elsewhere and thus well protected by concrete (there are only transverse bars though the bulk concrete). A second Progreso pier was built in about 1969 some 200m west, but was partly demolished some 17 years later because of severe corrosion of its conventional reinforcement in the flat slab deck and in the tops of the reinforced concrete piles. However, the lower parts of the piles, including the parts of the piles in the tidal zone, remain. They protrude above seawater at low tide and, from visual examination, appear not severely affected by reinforcement corrosion and spalling. This can be observed in the field and also in the report by consultants Ramboll (1999). In 2008 the present author was provided with a (random) sample of the concrete from one of the immersed piles. A fresh saw cut through that sample, when examined by optical microscope, showed a dense, highly calcareous structure. The pH of the concrete was 9.5-10.

In interpreting these observations it is noted that the quality of construction along the Yucatan coast is characterized by many examples of severe corrosion damage of reinforced concrete structures (Solis-Carcano et al. 2008). This has been attributed in part to the aggregates and fines used for all concrete construction being the natural limestones that are the only source of rock for much of the Yucatan peninsula (Castro et al. 2000). The resulting concretes typically are relatively porous and sometimes also of poor quality, blamed for domestic construction at least on poor 'construction practices' (Solis-Carcano et al. 2008) including the use of high water-cement ratios (Moreno et al. 2004, Sosa et al. 2007). Although field observations show spalling and delamination of concrete, the reinforcement corrosion rates are not considered to be high. It is unlikely that the second Progreso pier shared the poor quality workmanship but it is likely that with the use of the local limestones it consisted of relatively porous concrete. Despite the deck and the upper parts of the supporting piers not lasting very long, its piers continue to survive, both in the seawater immersion zone and through the tidal zone. This is despite the latter usually being considered the most aggressive of marine exposure zones, with a combination of high salinity, high moisture and high oxygen availability.

Other Cases

A number of older papers describe cases of good quality concrete being made with seawater and in some cases with alkaline materials such as coral (Wig and Ferguson 1917; Narver 1954; Wakeman et al. 1958; Dewar 1963, Mather 1964; Boqi et al. 1983; Burnside and Pomerening 1984) In addition several more recent cases with features similar to those above have been described. They include:

1. Maria Island cement works silos (1922) (Melchers et al. 2014),
2. Newcastle harbour fortifications (1941) (Melchers 2010a)
3. Thames estuary forts (British Navy, Airforce) (1943) (Melchers 2011),
4. U-boat bunkers along the east Atlantic coast (1940s) (Melchers 2011; Melchers and Pape 2012),
5. Mulberry harbour Phoenix caissons (1944) (Melchers 2010a)
6. Concrete lighters (Severn estuary, Sydney Harbour) (Melchers 2010b; Melchers & Papé 2011)
7. German highway bridges (Lukas 1985)
8. Cylindrical bridge piers in the Gulf of Mexico (Lau et al. 2007).

There also is a review of some 30 reports, extracted from the literature, covering around 300 individual reinforced concrete structures (Melchers and Li 2009b). For these the times to corrosion initiation and to active corrosion were correlated with chloride content and with type of aggregates (both fine and coarse). Within the bounds of the available data, both times were greater for structures likely to have been made with alkaline aggregates (limestones, non-reactive dolomites and blast furnace slags) compared with concretes made with igneous aggregates. Neither times could be correlated with chloride concentration at the reinforcement, concrete cover, concrete quality or cement-making practices (Melchers 2011). The results did not change substantially when cases suspected of alkali-aggregate reactions (AAR) or alkali-silicate reactions (ASR) were removed.

An important observation is that these examples largely are for older reinforced concrete structures made without any of the modern additives claimed to reduce the probability of reinforcement corrosion such as through decreasing concrete permeability. They also were made largely with very modest concrete cover, often much less than increasingly being mandated in modern design codes. It has been proposed that the concretes for the older structures were made with cements that were clinkered at lower temperatures and not as finely ground but close examination shows that there is only a minor difference in active ingredients between the 'older' and 'new' cements (Nixon and Spooner 1993). Further, there certainly were problems with reinforcement corrosion even for the older structures (Wakeman et al. 1958).

ANALYSIS

Several questions arise immediately from the above observations:

1. why very high chloride concentrations do not cause reinforcement corrosion in some concrete structures,
2. how to reconcile the corrosion threshold of pH 11 stated in older texts with field observations showing a much lower threshold (of around pH 9),
3. the reason for pH >9 in some concrete structures even after many years in-service in aggressive environments,
4. why carbonaceous aggregates appear to inhibit corrosion initiation when 'carbonation' is considered to cause corrosion, and
5. how to reconcile severe reinforcement corrosion inside some concrete structures with the lack of exterior signs such as rust staining.

Answers to these questions largely are available in the existing corrosion literature but appear not well-known. It is useful to begin with the fundamentals of corrosion of ferrous materials such as steel. The key recognition is that the structures that behave very well are those for which reinforcement corrosion has not yet become active. Earlier this was idealized as a bi-linear function attributed to Tuuti (1982) but more properly it should consider the possibility that some minor corrosion may occur when small reservoirs of oxygen and water are available immediately around the bars, left over from the casting process and perhaps inadequate compaction (Melchers and Li 2006). Typically the early corrosion will be minor, unless the concrete is of poor quality. For the following, let this possibility be ignored and attention focussed on good quality concretes. Figure 5 shows the modified behaviour. The important time is thus t_{ac} at which active corrosion commences.

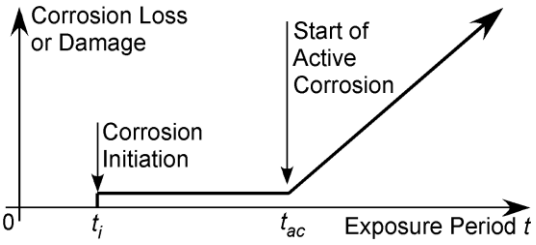

Figure 5 Model for corrosion initiation at time t_i and active corrosion at t_{ac}.

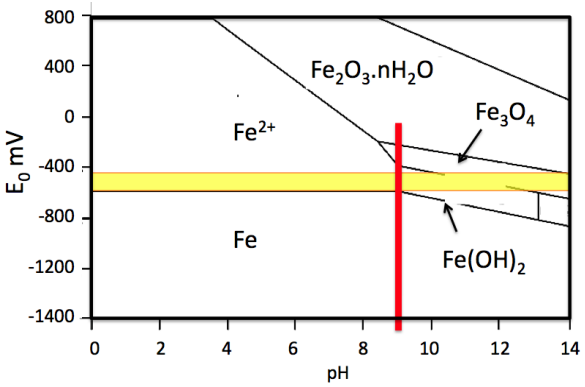

Figure 6 Schematic Pourbaix diagram showing main rust products and pH for initiation.

Corrosion initiation of reinforcing steel (essentially iron, Fe) must follow corrosion science principles. It can occur only when the reaction(s) involved becomes feasible, and this is when the net free (Gibbs) energy ΔG becomes negative (Brown and LeMay 1981). In the corrosion literature this is usually summarized in a Pourbaix diagram for Fe (Figure 6). It shows the various relationships for different reaction outcomes in terms of electrochemical potential E and pH. For Fe in water the relevant potential E_0 at which corrosion products are formed is around -440 mV (SHE) and the pH for corrosion initiation occurs is about 9-9.5 (the exact value depending on the energy level taken as 'zero' corrosion). These values are not changed very much by the presence of chlorides (Garrels and Christ 1965; Jones 1996; Huet et al. 2005). Note that this value corresponds with the observations for actual structures with very high chloride levels for which reinforcement corrosion has not yet occurred (e.g. Figure 2). The important point is that corrosion initiation cannot occur as long as the pH of the concrete (or pore space fluid) in the immediate vicinity of the reinforcement bar is maintained above 9-9.5. Obviously this condition can be violated by cracking of the concrete along, or across, the bar if this results in a mechanism that allows the local pH to reduce below 9-9.5 in value. This possibility is discussed further below.

Not all texts now make the claim that the criterion for reinforcement initiation is pH of around 11 but that was the situation for many years (e.g. Gjorv 2009). The reason is as follows. It arises from laboratory experiments in which $Ca(OH)_2$ (calcium hydroxide) added to water, or a similar alkali solution, was used to mimic (approximately) concrete alkalinity achieving a pH of about 12.5-13. A steel bar was then added to the solution and the pH of the solution lowered chemically until corrosion initiation of the bar was observed (visually or electrochemically). In such experiments the solution is agitated by stirring or air bubbling to reduce boundary effects (concentration control effects) and so speed-up the reaction. Unfortunately this does not mimic the real condition for a reinforcement bar inside concrete. There, no water velocity conditions are involved and the initiation reaction must occur, if it is to occur at all, under stagnant conditions. Already in 1908 it was demonstrated that salts (including NaCl and $CaCl_2$) have almost no effect on corrosion in stagnant conditions (Brauns and Schwenk 1908) and this was confirmed by Brasher (1967) who showed that chlorides only become important for corrosion initiation in non-stagnant solutions. It was confirmed independently also by Mercer & Lumbard (1995). Experiments with agitated solutions will cause corrosion to initiate at a higher pH when chlorides are involved.

The above remarks clearly indicate the important of pH in relation to corrosion initiation. New concretes have a pH around 13.5 and it is well-known that the alkalis primarily responsible are KOH, NaOH and $Ca(OH)_2$. Of these, KOH and NaOH are highly soluble and leach out of concrete relatively easily. In the process the pH reduces to about 12 because of the remaining $Ca(OH)_2$. It is not very soluble and takes a long time to leach out under the action of freshwater. Thus the concrete will tend to retain a pH around 12. Two mechanisms may lower it. One is well-known as 'carbonation', in which carbon dioxide from the atmosphere diffuses into the

concrete and then eventually reacts with the $Ca(OH)_2$ to form $CaCO_3$ (and possibly carbonic acid) which is claimed to reduce the pH sufficiently for corrosion to initiate. However, for good quality concretes this mechanism may be ignored since field experience shows that carbonation penetration seldom exceeds a few millimetres into the concrete (St John et al. 1998; Moreno et al. 2004). The other possibility is that chlorides play a role in lowering concrete pH.

It has been shown that the presence of NaCl increases the solubility of dilute $Ca(OH)_2$ solutions (Johnston and Grove 1931), thereby permitting a faster rate of leaching out of the concrete matrix. This mechanism has been proposed also for solutions with higher concentrations of $Ca(OH)_2$ (Hewlett 1988). It is also possible that the magnesium sulfates and chlorides ($MgSO_4$, $MgCl_2$) present in seawater react with $Ca(OH)_2$ and so reduce its presence and hence the alkalinity of the concrete (Hewlett 1988). These mechanisms are presently again under investigation (Melchers 2014a). However, irrespective of the precise mechanisms involved, the fact remains that seawater is somehow implicated in loss of alkalinity, that is, the loss of *buffering capacity* for maintaining pH, and this is the central factor in maintaining pH high enough for initiation not to occur. This point was made already many years ago in a slightly different context (Glass and Buenfeld 1997; Moreno et al. 2004). Of course, the rate at which $Ca(OH)_2$ (and KOH and NaOH) leaching can occur depends on the permeability of the concrete matrix and this is consistent with the notion that high quality, high density concretes are less prone to reinforcement corrosion. It follows that it is not the rate of inward diffusion of chlorides, but the rate of outward leaching of alkalis that is the determining factor for the time to corrosion initiation.

For concretes immersed in seawater it often is claimed that the low oxygen concentration in seawater is responsible for the very low rates of reinforcement corrosion under water, that is, after corrosion initiation has already occurred. Unfortunately, the idea that the dissolved oxygen level in waters are so low that corrosion is inhibited is not supported by the considerable corrosion of bare steels, which corrode severely in seawater as well as in fresh water. Examples are shown in Figure 7 for general corrosion and for corrosion pit depth in sea, brackish and fresh waters of similar pH (Forgeson et al. 1960). This shows also that salinity *per se* is not a major issue. The factor actually responsible for reducing the *rate* of corrosion of reinforcement in concrete immersed in seawater is the surface pH of the concrete and, for long-term durability, its alkalinity. It is well-known in the literature that the alkaline surfaces of good concrete attracts deposition of $CaCO_3$ in the form of aragonite as well as brucite ($MgCO_3$). This build-up reduces the rate at which oxygen can diffuse to the reinforcement (Buenfeld and Newman 1984). The build-up also tends to increase with time, further reducing the rate of corrosion.

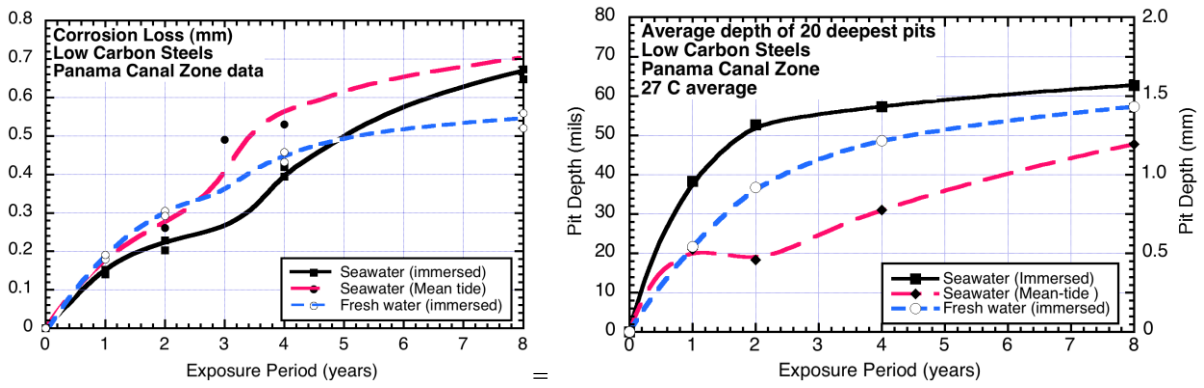

Figure 7 Corrosion trends for seawater and fresh water immersed conditions: (a) corrosion loss and (b) pit depths. (Data from Forgeson et al. 1960 for average of 3 steels with replicate samples).

As noted for the examples given above, the reinforced concrete structures containing calcium carbonates ($CaCO_3$) (such as limestone aggregates, blast furnace slag or seashells) generally showed longer times to corrosion initiation than other reinforced concrete structures. At first sight this conflicts with the well-known concept of carbonation, for which, as noted, carbon dioxide CO_2 reacts with $Ca(OH)_2$ to form $CaCO_3$ which is generally considered, theoretically at least, to be a harmful in terms of corrosion initiation. The contradiction with practical experience that has concretes made with limestones, for example, is sometimes sidestepped by noting that the initiation of corrosion is 'induced' by carbonation, without being specific about the mechanism actually involved. However, the most likely mechanism can be seen from the explanation of the processes involved. To diffuse into the concrete matrix CO_2 must combine with moisture (water). This may be thought of as forming 'carbonic acid' through the 'reaction' $CO_2 + H_2O \rightarrow H_2CO_3$ (Brown and Lemay 1981). This

proceeds into the concrete and in so doing reacts with $Ca(OH)_2$ to form $CaCO_3$ along the way. Evidently, as the $Ca(OH)_2$ is consumed more $CaCO_3$ is formed but eventually the $Ca(OH)_2$ reachable by the carbonic acid will be exhausted along the carbonation path. Excess H_2CO_3 can then attack the steel (Hamada 1969). Hence it is not the $CaCO_3$ that lowers the concrete pH under 'carbonation' but the (eventual) excess carbonic acid. Particularly under anoxic conditions carbonic acid is very corrosive to steels. Such a condition also is likely to exist inside well-made concretes. All this assumes, of course, that the 'carbonation' front reaches the steel. As noted, this is very unlikely for good quality concretes.

Consider now the severe corrosion such as seen in Figure 4. As noted above, for the cases in which this occurred, the concrete showed cracking, usually transverse to the reinforcement but little or no trace of corrosion products, despite the significant loss of steel reinforcement. The immediate question is where did the steel go, and how? The watery rust stains are a direct indicator that the chlorides present in waters reacted with Fe to form highly soluble, almost clear coloured, $FeCl_2$ that, in wet conditions, such as in the tidal zone (Hornibrook), or under frequent periodic rain (Arbroath, Yucatan), can easily diffuse away. In so doing it leaves little trace, and what is there is oxidized to conventional insoluble rusts. These are the visible watery-looking stains on the cross-section.

The only mechanism consistent with the dissolution of Fe by chlorides is that of highly aggressive pitting or crevice corrosion under anoxic conditions within pits (Wranglen 1974). The fine crack in the concrete adjacent to and interacting with the steel reinforcing bar permits such anoxic conditions. It can be seen as a pitting or crevice corrosion initiator, noting that MnS inclusions, always present in steels, are involved also (Wranglen 1974). No other mechanism is known to cause such aggressive localized corrosion, although it may be aggravated by microbiologically influenced corrosion particularly in nutrient-polluted marine conditions (Melchers 2014b).

DISCUSSION

It should be clear from the above that the most important factor for long term durability of reinforcement in concrete structures is the alkalinity of the concrete, that is, its capacity to buffer the pH of the concrete to a value above that which would allow corrosion initiation. The evidence is that such buffering is provided by high cement content, and addition of high alkalinity aggregates and sands. As shown above, there is strong field experience in support. There also is evidence from controlled corrosion science experiments (Davies and Burstein 1980).

Many of the observations in the analyses given above are already known within various niches in corrosion science and to a lesser extent in the reinforcement corrosion literature. Nevertheless, the notions persist that chlorides (and carbonation) are responsible primarily, sooner or later, for causing the initiation of reinforcement corrosion. This is despite much practical evidence that very high concentrations of chlorides can exist without reinforcement corrosion. In science, one valid piece of evidence that does not fit accepted theory tenders the theory invalid - and the scientists 'go back to the drawing board'. The same should apply in engineering science.

Unfortunately, there appears also to be a lack of 'memory' or, worse, failure to do homework. Prior to about the 1960s in most countries the possibility of using seawater as mixing water for making concretes was not prohibited. There is a rich history of using seawater in concretes (Narver 1954; Wakeman et al. 1958). Although not considered in detail here, all the evidence that is available indicates that sea sands and seawater from the North Sea were used in the construction of the U-boat bunkers along the French coast (Neitzel 1991; Showell 2002) and which even today are in remarkably good condition. Similarly, seawaters and beach sands appear to have been used for many of the Phoenix caissons constructed for the Normandy invasion (1944) and a considerable number of those not destroyed by storm conditions remain in still reasonable condition (Melchers 2010b, 2011).

In practice, to achieve long-term durability of concrete structures and in particular their reinforcement in exposed environments, much more attention needs to be given to producing concretes with high pH buffering capability (i.e. with high alkalinity). The obvious way of doing this is to add more cement, as indeed Hornibrook is reputed to have recommended for his bridge. However, cement is expensive and its production increasingly being seen as environmentally unfriendly, as a result of which there are strong moves to reduce usage of cement. If this causes earlier deterioration of reinforced concrete structures, cement reduction may be counter-productive overall, since structures may need to be repaired pre-maturely, or replaced with consequent direct and indirect costs and environmental implications and consequences.

The present review, and earlier examinations of the available data (Melchers & Li 2009), indicates that an alternative approach is to make greater use of limestones and similar alkaline materials as part of the concrete mix. The evidence shows that concretes made with such aggregates can delay reinforcement corrosion initiation considerably in time, provided the concretes also are of high quality including low permeability. In marine environments the concrete also must be of sufficient tensile strength to reduce as much as possible the occurrence of cracking since, as noted above, this may permit the occurrence of aggressive localized corrosion under chloride conditions. The possible effect of the use of other additives, for example fly-ash, if their reduces concrete tensile strength.

It follows from the above observations that potential causes of concrete cracking must be considered in design for durability. Cracking may result from applied loading during service, but also from early loading when the concrete is still developing strength. For example, it is likely that the cracking seen in Figure 3 was caused during pile handling or driving since after installation the pile would have been in compression. It follows that much more attention needs to be given to the stresses imposed by any of the loadings possible during the whole lifetime, focussing on the possibility of cracking deep enough to allow, eventually, the development of the severe corrosion seen in Figure 4. Also, the current codified design rules for concrete cracking need revisiting. They are based largely on early research that did not consider *long-term* marine exposure conditions (Beeby 1978).

Finally, the observations given above make clear that particularly in marine environments visual inspection may not be sufficient to detect evidence of reinforcement corrosion.

CONCLUSIONS

1. The conventional notion that a high concentration of chlorides is the prime reason for initiation of reinforcement corrosion is not supported by evidence from actual concrete structures. It also is not consistent with fundamental corrosion science. Corrosion initiation largely is the result of the loss of sufficient alkalinity immediately adjacent to the reinforcement bars. This loss can be accelerated by the presence of chlorides.

2. Long-term durability of steel reinforcement in concrete structures requires the concrete matrix to retain high alkalinity, that is, sufficient buffering capacity to maintain the pH of the concrete matrix around the reinforcement to greater than 9 for the desired time to corrosion initiation,

3. The highly alkaline concrete matrix must be in intimate contact with the reinforcement to ensure the pH at the bars is maintained. This requires well-compacted concretes of high density.

4. A high quality, low permeability concrete matrix is required to slow the outward diffusion of the alkalis in the concrete, particularly in chloride environments.

5. Lowering of the pH around reinforcement bars can result also from carbonic acid not neutralized in the carbonation process during inward diffusion of carbon dioxide. Practical experience shows that, except for poor quality concretes, such diffusion extends only a few millimetres into the concrete.

6. The tensile strength of the concrete, including in the initial period, should be high to reduce the probability of concrete cracking severe enough to reach the reinforcement. Field experience shows that particularly in chloride environments such cracking can initiate very severe localized reinforcement corrosion.

7. To assist in developing new criteria for long-term durability, improved understanding is required of the quantitative relationships between concrete permeability, concrete density and the outward diffusion of alkalis as well as the effect of concrete additives on concrete tensile strength and concrete permeability.

ACKNOWLEDGMENT

The author acknowledges the continued financial support of the Australian Research Council, currently through a DORA Fellowship. The author is indebted also to (the late) Dr. Eric Moreno of the Autonomous University of Yucatan, Mexico for stimulating discussions and for the provision (in 2008) of a 200mm sized sample of one of the piles from the second pier at Progreso, Mexico, as well as the support of Prof. C.Q. Li (now at RMIT University, Melbourne Australia), Dr. Torill Pape (now with ARRB, Brisbane), Dr. Robert Heywood (Consultant, Brisbane) and Dr Igor Chaves (The University of Newcastle) for their support during various parts of the investigations reported herein.

ABSTRACT

Increasing plastic production and lack of adequate recycling in developing nations is a critical global issue which must be addressed. This paper forms part of a larger feasibility study investigating a small scale plastic recycling plant housed in a shipping container for use in developing nations. The overall project is motivated by the desire to provide a cleaner environment, self-sustained communities and reduce the impact of plastics on our society. It is envisaged that the recycled mixed plastic product will be of use to the community by way of rudimentary building materials such as bricks and tiles. The concept has the potential to benefit communities in developing nations by providing secure and reliable accommodation whilst also utilising an untapped and abundant resource. This paper details the experimental component of the larger study and presents the manufacturing techniques utilised, the samples produced and resulting properties. The effects of filler materials on thermoplastic polymers are investigated in addition to the comparison of recycled and virgin polymers. It was determined that the status of the polymer used in the manufacture of samples (i.e. whether the polymer was virgin or recycled) had no significant effect on selected properties of material produced and that overall recycled PET produced the most consistently high performing sample materials. The PET samples produced had low water absorption, the highest average tensile strengths and medium impact resistance (compared to the other materials). They also exhibited the smallest decrease in tensile properties as a result of UV exposure and had no observed surface degradation. In addition, PET bottles are some of the most frequently occurring plastic wastes. A number of additional conclusions were made and are contained within this paper.

KEYWORDS

Sustainable design, recycling, thermoplastics, filler materials, developing nations, building materials, environment.

INTRODUCTION

Billions of people in developing nations are affected by the unresolved issue of plastics recycling. With no adequate system in place to sort these recyclables and no clear purpose for their reuse, non-biodegradable plastics continue to pile in the streets presenting economic, environmental and public health issues. This has a negative impact on the livelihood, sanitation and environment of communities in developing nations. One possible use for these plastics is the production of composites with reinforcement materials to be used as affordable alternative housing materials such as bricks.

Filler Materials

Biron (2013) defines filler materials asnon-plastic components which can beadded to polymers to provide increased directional strength to composite products and reduce costs. These materials include organic fillers such as natural fibres (e.g. wood flour, flax) and inorganic fillers such as glass fibres. This study investigates the use of two organic fillers: wood flour and newspaper. Due to the cellulose fibres, wood flour is hydrophilic

(attracts water) and hence increased cellulose will result in increased water absorption of the wood flour composites. Studies by Kord (2011), Maiti et al (1985) and Raj et al (1992) determined that increasing wood flour content increased the water absorption and decreased the impact resistance of thermoplastic/wood flour composites. Additionally, in their study, Peng et al (2014) concluded that prolonged exposure to UV promotes the generation of surface cracking in wood flour/polymer composites and resulted in increased water absorption. Paper items often become mixed in with plastic wastes, and therefore it is of interest to determine if newspaper could be beneficial to the end product saving onwaste-sorting time. In their study, Serrano et al (2014) assessed the potential of replacing glass fibres with shredded newspapers as reinforcement in PP composite materials. The results indicated that newspaper fibres could be a suitable alternative to glass fibres due to increased tensile strength and Young's modulus (for up to 30% newspaper content). However, further increases to the newspaper content showed a gradual decline in tensile strength, indicating that the content of newspaper must be carefully controlled.

Mixing of Common Plastics

In order to increase productivity, it is desirable to minimise the amount of plastic sorting required in the recycling process. For example, in the case of HDPE bottles with PP caps, it is beneficial to recycle these components together rather than separating them. It is therefore important to understand the compatibility of plastics with each other. This compatibility can vary greatly due to the wide range of plastic applications and the seemingly endless number of chemical compositions manufacturers utilise. Stephan Tall's paper (2000)states that commingled polymers often become phase separated as a result of poor interfacial interactions during the recycling process. This can result in highly brittle products.An example of this issue is seen in the incompatibility of PE or PP with PET. Both PE and PP are non-polar hydrocarbons whereas PET is a polar hydrocarbon. As such, PET requires polar-polar interfacial interactions and therefore its compatibility with non-polar polymers such as PE and PP is low. Studies have shown that the compatibility of PE with PP is extremely varied. In some recycling cases, compatibilisers (e.g. elastomeric polymers) may be used to assist overall adhesion of polymer blends. This study will focus on the products obtained without the use of compatibilisers.

METHODLOGY

Manufacture

The polymers selected for testing were PET, HDPE, and PP as they are some of the most commonly occurring thermoplastic polymers, according to Plastics Europe (2013). Post-consumer plastics of this variety were collected, cleaned and dried. Labels were removed from all materials except for some PET bottles. In addition newspapers were also collected. The plastic items and newspapers were then cut into strips and shredded into rectangular flakes approximately 10x5mm in sizeusing a LabTech Engineering pelletiser. Batches weremixed together using scales to obtain the correct ratio of polymer and filler and placed in individual, labelled bags.

Each batch was extruded individually using a Thermo Scientific Eurolab 16 extruder, with a L/D ratio of 40:1. A circular die with a diameter of 3mm was used. Batches 1 to 6 were extruded at 175-185°C and batches 7 and 8 were extruded at 250°C. The screw speed was 50RPM. After extrusion, the pelletiser was used to cut the cables into pellets. The pellets were injection moulded with a Babyplast 610P Standard Injection Moulder to produce the final test specimens shown in Figure 1. It must be noted that due to material limitations, some batches could be manufactured into rectangular section samples only.

Testing

Water Absorption

The water absorption tests were conducted in accordance with ASTM D570-98 (2010), Procedure 7.4 Long-Term Immersion. Two samples from each batch were labelled and placed in a vacuum hopper dryer for 12 hours at 50℃. Each sample was then weighed (W_1). Two beakers were filled with 1000mL of tap water at room temperature. One sample of each batch was placed in each beaker and left for 24 hrs. Samples were removed one at a time and their surface was dried with paper towel before being weighed (W_2). The samples were then re-immersed back into their respective beakers and left for another 24 hrs. The weighing process was repeated for the samples every 24 hrs for a period of 2 weeks.

Impact Test

The impact tests were conducted in accordance with ASTM D6110-10 (2010). First, the dimensions of each rectangular section composite sample were measured with electronic callipers. Each sample was labelled and placed centrally on top of the Pendulum Impact Machine (Zwick D7900 Type 5102.100/00) with anvils which were set at 40mm apart. The dial on the pendulum impact machine gauge was zeroed and the pendulum was released. The pendulum impact machine gauge energy reading was recorded for each sample tested in each composite batch.

Tensile Test

The tensile tests were conducted in accordance with ASTM D638-14 (2014). The Instron 4505 machine was set up with hydraulic grips and a 10 kN load cell. An optical strain gauge with 25 mm gauge length and a cross head speed of 1200 N/min was used for the tests.

Ultraviolet-exposed Tensile Test

The ultraviolet (UV) exposure and tensile tests were conducted in accordance with ASTM D4329-13 (2013) and ASTM D638-14 (2014). The QUV Accelerated Weathering Tester was set on Cycle A for the duration of the test - UV for 8 hrs at 60 °C, irradiance at peak emission 340 nm was 0.89 W/(m^2.nm), condensation for 4 hrs at 50°C. Four samples from each batch were labelled and placed in the QUV machine for 620 hrs. At 310 hrs of exposure, the samples were removed, turned over and placed back in the QUV machine. At 620 hrs, the samples were removed from the QUV machine and left overnight to cool. The dimensions of each rectangular section and tensile test sample to be tested were measured with electronic callipers and inputted into the Bluehill 3 Instron computer program.

Table 1. Composite batch compositions

Batch Number	Batch Composition
1	50/50 HPDE/PP mix. Virgin materials
2	50/50 HDPE/PP mix. Recycled materials
3	2/5 HDPE, 2/5 PP, 1/5 newspaper. Virgin materials
4	2/5 HDPE, 2/5 PP, 1/5 newspaper. Recycled materials
5	1/3 HDPE, 1/3 PP, 1/3 wood flour. Virgin materials
6	1/3 HDPE, 1/3 PP, 1/3 wood flour. Recycled materials
7	PET (without labels). Recycled materials
8	PET (with labels). Recycled materials

Figure 1. Rectangular section and tensile test samples for composite batch 2

RESULTS AND DISCUSSION

In general, during the manufacturing process, it was observed that the batches produced using the recycled polymers exhibited less die swelling and lower screw torque than those manufactured with virgin polymers. Samples which contained fillers had significantly lower screw torque than samples without.

Water Absorption Test

Water absorption (%) of each sample was calculated using Eq. 1.Average water absorption (%) of each batch was determined by taking an average of the two sets of results (beaker A and B). Figure 2 shows the average water absorption (%) in 24 hours for each composite batch. Data from batches 1-8 are shown from left to right.

$$Water\ absorption\ (\%) = \frac{W_2 - W_1}{W_1} \times 100 \quad [1]$$

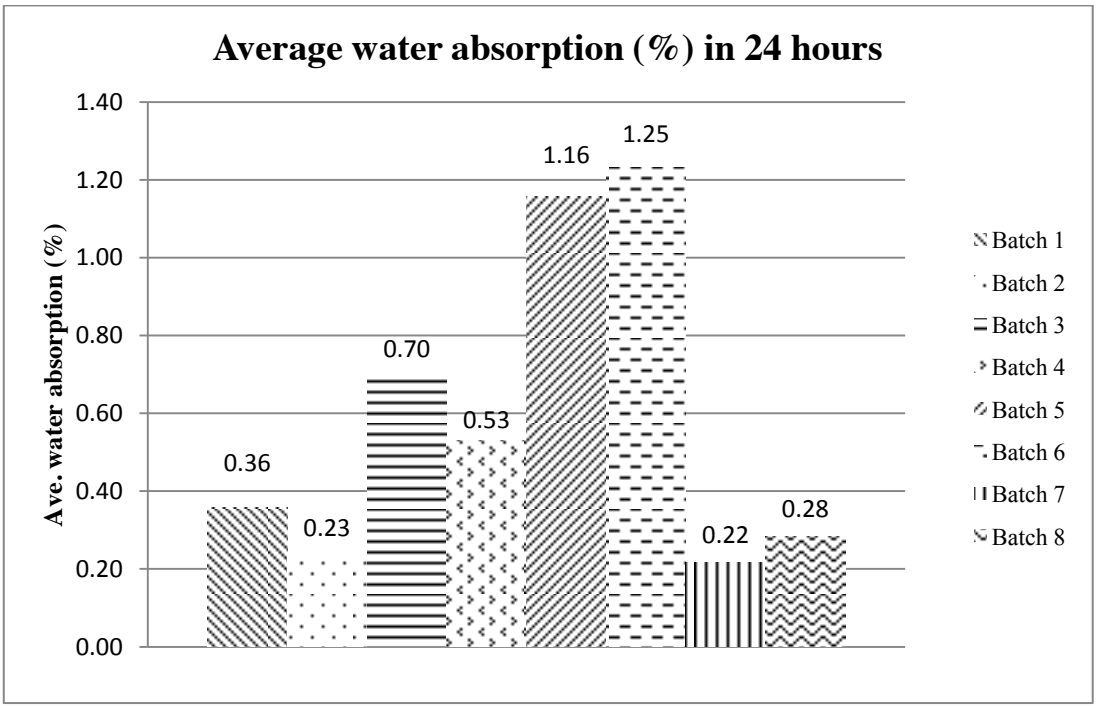

Figure 2. Average Water Absorption (%) in 24 Hours Per Batch

The samples containing wood flour (batches 5 and 6) performed the worst in terms of water absorption, as these samples showed the highest initial water absorption after 24 hours and continued to absorb the most water over the full duration of the test. Wood flour contains high amounts of hydrophilic cellulose meaning that samples from batches 5 and 6 attract water more rapidly when compared to the other samples. The next highest water absorption levels are seen in batches 3 and 4 which contain newspaper. This is also expected due to the levels of cellulose contained in the paper-based filler. The best performing materials were PET without labels which hadthe lowest average water absorption in 24 hours. The average water absorption for common construction bricks is between 0.5-10% therefore these results are acceptable.

Tensile Test

Moderate to significant discolouration and fading was evident in all UV-exposed samples. During testing, a powdery residue was present on the UV-exposed samples from batches 1 through to 6 however; the PET samples (batches 7 and 8) did not present any flaking or powdery residue as a result of UV exposure. All samples (UV-exposed and non UV-exposed) broke in a brittle manner, this was most likely due to the phase separation of mixed polymers or the added filler material. As expected, the average tensile strengths are lower

for the recycled plastic samples compared to the virgin polymer samples with the lowest average tensile strength recorded at 6.8MPa (for batch 2). The samples produced comparable tensile strength results with common building materials such as brick and concrete, which range from 7-14 MPa and 2-6 MPa respectively.

Both PET composites batches produced higher average tensile strengths than the maximum brick tensile strength which is a positive result. The best performing materials regarding the effect of UV exposure on tensile properties were batches 5 and 6. UV exposure actually increased the average tensile strength of these materals by 1.85% and 2.38%, for batch 5 and 6 respectively. This is in contradition to the information contained in Peng et al. (2014) indicating that prolonged UV exposure (such as that experienced in the QUV machine) increases degradation of wood flour/polymer composites and hence the observed properties should be decreased. The result is definitely interesting and should be investigated further. The Young's modulus of the produced samples is much lower than the Young's modulus of common building materials indicating that the samples.

Table 2. Average Tensile Results, Non UV-Exposed Samples

Batch No.	Batch	Ave. Maximum Load (N)	Ave. Tensile Strength at Maximum Load (MPa)	Ave. Young's Modulus (GPa)
1	Virgin HDPE/PP mix	252.5	9	0.7443
2	Recycled HDPE/PP mix	177.3	6.8	0.7161
3	Virgin HDPE/PP/newspaper	323.0	10.0	0.914
4	Recycled HDPE/PP/newspaper	250.5	8.5	0.8839
5	Virgin HDPE/PP/wood flour	268.5	10.8	1.2819
6	Recycled HDPE/PP/wood flour	211.2	8.4	1.1802
7	Recycled PET without labels	400.5	16.3	1.3463
8	Recycled PET with labels	424.5	17.0	1.5242

Table 3. Average Tensile Results, UV-Exposed Samples

Batch No.	Batch	Ave. Maximum Load (N)	Ave. Tensile Strength at Maximum Load (MPa)	Ave. Young's Modulus (GPa)
1	Virgin HDPE/PP mix	136.4	5.2	0.8104
2	Recycled HDPE/PP mix	148.4	5.8	0.7661
3	Virgin HDPE/PP/newspaper	274.7	9.0	0.10283
4	Recycled HDPE/PP/newspaper	217.6	7.2	0.9379
5	Virgin HDPE/PP/wood flour	272.2	11	1.3879
6	Recycled HDPE/PP/wood flour	218.2	8.6	1.2986
7	Recycled PET without labels	368.6	15.0	1.7635
8	Recycled PET with labels	313.4	12.8	1.5637

Impact Test

The material which produced the highest average impact energy was the virgin HDPE/PP/newspaper mix. However it must be noted that due to material limitations, only three samples of this batch could be tested and the testing of further samples may have produced a different average impact result. The poorest performing materials regarding average impact energy were the wood flour batches (5 and 6).

This finding is supported by the work of Peng et al (2014) who determined that increasing wood flour content resulted in a decreased in impact resistance. The samples which fractured in the most brittle manner were those from batches 7 and 8, the PET composites, with some breaking into multiple pieces. According to Goodfellow (2015), the average impact energy for virgin PET is between 13 and 35 J/m. The PET samples produced here have comparable impact results with the virgin materials of 20.1 and 21.2 J/m for the unlabelled and labelled batches respectively. It is important to note that, similar to the non UV-exposed tensile specimens the labelled variety of PET produced the higher result. The average impact energy is from 20 to 210 J/m for virgin HDPE and from 20 to 100 J/m for virgin PP. All batches containing HDPE and PP exhibit average impact energies within this range, apart from the wood flour samples which produced lower results as discussed.

Table 4. Impact Test Results

	Batch Number							
	1	2	3	4	5	6	7	8
Average (Joules)	0.250	0.266	0.315	0.231	0.192	0.180	0.196	0.207
Average Impact Energy Per Unit Width (J/m)	25.694	27.364	32.374	23.778	19.761	18.536	20.144	21.262

CONCLUSIONS

From the results obtained, the following experimental product conclusions can be made:

- The status of the polymer used in the manufacture of samples (i.e. whether the polymer was virgin or recycled) had no significant effect on selected properties of material produced
- Water absorption properties of all samples were comparable with that of brick and concrete
- The addition of selected fillers promotes the absorption of water
- Tensile properties of all samples were comparable to that of bricks and concrete, with the PET samples exhibiting the highest average tensile strengths
- UV exposure had a moderate to significant effect on all samples by way of discolouration, flaking and a general reduction in average tensile strength
- Addition of wood flour in recycled polymer samples produced improvements in tensile strength for UV-exposed samples when compared to non UV-exposed samples. This is an unexpected result and further investigation is recommended
- The virgin HDPE/PP batch fared the worst, compared to the other batches, with a 42.2% reduction in average tensile strength as a result of UV exposure
- The PET samples (without labels) showed the smallest decrease in average tensile strength of 7.9% compared to the other batches
- Wood flour reduced screw torque during the extrusion and increasing tensile strength but also increases water absorption and decreases impact strength (compared to the HDPE/PP mix).It can be concluded that it would be beneficial to include this filler specifically in the HDPE/PP polymer blend, if it is available and at low-cost
- Newspaper reduced screw torque during the extrusion, increasing tensile strength and increasing impact strength but also increases water absorption (compared to the HDPE/PP mix). It can be concluded that it would be beneficial to include this filler and prior separation of HDPE/PP and newspaper waste is not necessary
- It can be concluded that filler materials improve or do not significantly reduce the properties of HDPE/PP recycled polymer blends

- PET samples with labels produced higher tensile and impact results than the unlabelled PET samples. However, the addition of labels in the PET mix resulted in increased water absorption and the second highest reduction of tensile strength as a result of UV exposure (24.7%)
- Overall, the recycled PET samples were the most consistently high performing materials. These batches had low water absorption (compared to the filled materials), the highest average tensile strengths and medium impact resistance (compared to the other materials). They also exhibited the smallest decrease in tensile properties as a result of UV exposure and had no observed surface degradation. In addition, PET bottles are some of the most frequently occurring plastic wastes

Recommendations for Further Study

- Optimisation of product – further detailed investigation is required into the quality of the recycled product which could be produced including: testing of other properties, using alternative types of plastics, use of compatibilisers and other fillers, use of single polymer types (separation of plastics), use of other plastics in combination with PET;
- Further investigation into the effects of UV-exposure on the tensile properties of wood flour/polymer.

ACKNOWLEDGEMENTS

We would like to express our gratitude to Mr. Doug Malcolm for his assistance with the mechanical testing presented in this study.

HEMP HURD FLOUR AS AN ALTERNATIVE LOW COST FILLER IN WOOD PLASTIC COMPOSITES

Michael T. Heitzmann [1], Afifah Md Ali[1], Angelica Legras[1,*], Luigi J. Vandi[1],andJohn Milne[1]

ABSTRACT

Hemp hurd, also commonly referred to as hemp shives, is a low cost byproduct from the decortication process of hemp, retailing for less than 0.2 $/kg. In the context of establishing a hemp agri-fibre operation, value adding to this underutilized waste stream is crucial to improve the overall economics of the operation. In this research the use of hemp hurd as an alternative to wood flour for the production of wood plastic composites is investigated. Hemp hurd filled Polypropylene composites were produced via compounding in a co-rotating twin screw extruder. Taguchi design of experiment methodology in combination with Analysis of Means (ANOM) was used to gain an understanding of the influence of the different processing parameters. Parameters investigated were screw-configuration, temperature profile and fibre loading. Best results were obtained with a relatively gentle mixing zone at a temperature of 200 °C and 40%wt. and 20%wt. of fibre loading for highest stiffness and highest strength respectively.

KEYWORDS

Wood plastic composites, Compounding, Natural fibres.

INTRODUCTION

Hemp hurd is an underutilised by-product from the decortication process of hemp. Whilst hemp fibres are highly thought after, both for textile as well as for composite applications, hemp hurd is rarely used in technical applications and typically finds its way into animal bedding. Value adding to the hemp hurd is crucial for any hemp agri-fibre operation as only 20-30% of the hemp stem is made up the bast fibres.

The use of hemp hurd as a filler in polymer matrix composites is not entirely new and previous research has shown that properties comparable to the ones obtained using wood flour as a filler (Cigasova et al., n.d.; Khan et al., 2015; Kidalova et al., 2015; Stevulova et al., 2015) can be achieved. As shown in Table 1, the chemical composition of hemp hurd is comparable to wood four. Hemp hurd has a slightly higher ash and cellulose content and a lower hemicellulose content. It is worth noting that whilst the chemical composition of hemp hurd and wood is similar, the microstructure of hemp hurd is very different to the one of wood flour. Therefore a detailed investigation of both chemical surface composition as well as microstructure would be required to relate any composite properties back to the chemical composition and microstructure.

Table 1:Comparison of chemical composition of hemp hurd and wood flour

Components	Hemp hurd (Gandolfi et al., 2013)	Wood four (Xanthos, 2010; Baldock & Smernik, 2002; Poletto et al., 2012)
Ash	2-4	0.4-0.5
Lignin	16-23	21-34
Cellulose	39-49	37-47
Hemicellulose	16-23	19-30

Whilst previous research has already investigated physical and mechanical properties of hemp hurd composites, this research aims to investigate the effect on processing parameters on the final composite properties. The

results from this research can be used to optimise the compounding process and will provide future direction to compounding/extrusion research.

MATERIALS

Hemp hurd was sourced from Ecofibre Industries and originates from industrial hemp gown in northern New South Wales (Australia). The hemp hurd was processed into a powder using an air-jet mill (Aximill). A fine powder was produced with a wide particle/fibre size distribution ranging from 10 µm to 500 µm. There was deliberately no use of sifts or cyclone separation to increase the yield. As shown in
Figure 1 the aspect ratio is relatively low and varies from 2-20 for the majority of fibres and particles.

For the study presented here Polypropylene from Lyondellbasell, Moplen HP442M, with a melt flow rate of 8.5g/10 min was used. Maleic-Anyhidride-Polypropylene, Grade Licocene PP MA 6452, from Clariant was used as the compatibiliser. PP MA 6452 was added at 3% per weight relative to the proportion of matrix material used. Details of all materials used in this study are summarised in Table 2.

EQUIPMENT

Compounding was carried out on a parallel twin-screw extruder, PRISM Eurolab XL, with a barrel diameter=16m and a L/D ratio of 40:1. The compound was extruded through a slit die with a width of 100 mm and a height 1.98 mm. The slid die was feed with a melt pump mounted to the end of the barrel. A main objective of the research was to investigate the effect of screw configuration on resulting composite properties. Three screw configurations where tested, ranging from soft to aggressive mixing intensity. The severity of the mixing was controlled via the arrangement of the kneading blocks in the second mixing zone (see Figure 2). Table 3 shows the configuration of the second mixing zone which was used to achieve the three levels of mixing intensity. Fibre and polymer were feed separately. All materials were feed at the start of the barrel but with two separate volumetric feeders. The volumetric feeders were calibrated beforehand to allow precise metering of the fibre/matrix fraction. In order to investigate the effect of processing temperature the barrel temperature was held constant across the entire length of the barrel. The die and melt pump temperature was 190 °C for all combinations tested.

METHODLOLOGY

Design of experiment (DOE) was used following the fractional factorial design approach by Taguchi. The test matrix consisted of three factors (screw design, temperature and fibre loading) at three levels (see Table 4). Via the fractional design approach by Taguchi the full factorial combination 27 was reduced to 9. Table 5 shows the test matrix with the reduced number of combinations tested as part of this research.

Table 4:Factors and levels used in the design of experiments

	Level		
Factors	1	2	3
Screw design	Soft	Mild	Aggressive
Temperature	190	200	210
Fibre loading (%wt.)	20	30	40

Table 5:Factorial design combinations investigated as part of this research

Trial number	Screw configuration	Temperature (°C)	Fibre loading (%)
1	Soft	190	20
2	Soft	200	30

7	Aggressive	210	20
8	Aggressive	190	30
9	Aggressive	200	40

RESULTS & DISCUSSION

Tensile test coupons according to ASTM 638-2 type IV were cut from the extruded strips with a water jet cutter. Samples were tested with an INSTRON 5582 universal testing machine equipped with a 1kN load cell and pneumatic grips. An INSTRON optical video extensometer was used to measure the strain. The gauge length was 25mm and a cross head speed of 5 mm/min. Six samples were tested for each combination.

The test results are shown in Table 6 and the ANOM analysis results are shown in Figure 3 and
Figure 4. As expected, the addition of the hemp hurd filler lead to a significant increase in stiffness. For Run 6 the recorded average tensile modulus was 2.02 MPa which is a 83% increase in modulus compared to the virgin PP. The increase in modulus comes at the cost of a reduction in elongation to break. The elongation to break for the filled specimens ranges from a low 1.34 % to a more acceptable 4.03 %. It is somewhat surprising that a modest increase in tensile strength was also recorded for all but two combinations tested. The maximum average tensile strength recorded was for Run 1 where an average tensile strength of 28.98 MPa was measured. This corresponds to a 16% increase compared to the virgin PP material.

The ANOM analysis provides some interesting insights into the effects of the three processing parameters, screw configuration, fiber loading and temperature. The barrel temperature appears to have a relatively small effect on both modulus and tensile strength of the extruded specimens. As shown in Figure 3 and
Figure 4, the best tensile strength and modulus are obtained at 200 °C. It is expected that temperatures above 200 °C degrade the filler and hence result in a reduction of the final properties. A likely explanation for the lower results at 190 °C could be the higher viscosity of the polymer resulting in less mixing and/or more shear during mixing. The findings in relation to the mixing zone configuration are interesting as they suggest that a relatively mild mixing is sufficient during the compounding process. Both tensile strength and modulus show higher values for a gentle mixing zone configuration. A possible explanation for this trend is that excessive mixing might leads to fibre attrition and hence reduce the reinforcement effect of the fibres. The increase in modulus with increasing fibre loading was to be expected. As shown in Figure 3 there is a noticeable increase in tensile modulus as the fibre loading is increased. As already mentioned the increase in modulus comes at the cost of elongation to break with the results following the same trend as the tensile strength. A sharp drop in tensile strength is observed when the fibre loading is increased (see
Figure 4). This reduction in tensile strength is most pronounced when the fibre loading is increased from 20%wt. to 30%wt. A further increase in fibre loading does not significantly drop the tensile strength.

Table 6: Tensile test results

Run	Screw design	Fibre loading (% wt.)	Temperature (°C)	Tensile strength (MPa)	Tensile modulus (GPa)	Elongation at break (%)
1	Soft	20	190	28.982	1.601	4.03
2	Soft	30	200	24.970	1.870	2.21
3	Soft	40	210	20.646	1,871	1.48

CONCLUSION

The results presented in this paper show that finely ground hemp hurd flour can be used as a filler in poloyolefine matrix composites. By using an efficient processing method, such as the air-jet milling trialed in this research, the cost of the filler can be kept low compared to other filler alternatives. With a cost of 0.2-0.3 $/kg the filler is 3-5 times cheaper than most other filler alternatives such as natural or glass fibres. However, the properties obtained are not as good as what is typically reported for short natural or glass fibre composites using the same matrix material. The research has shown that a significant increase in stiffness of up to 83% can be obtained. The gains in strength are however modest (max. 16%) and the elongation to break is drastically reduced compared to the virgin material. The ANOM analysis has shown that all three parameters investigated have a distinct effect on the final composite properties. The results suggest that a processing temperature of 200 °C and a soft mixing zone configuration is the most promising parameter configuration irrespective of one aiming to optimise strength or stiffness. The trend for stiffness and strength in relation to fibre loading are opposed and whilst an increase in fibre loading increases the stiffness at the same time strength is significantly reduced. From an economical aspect a high fibre loading is desirable as the overall compound cost is reduced by the addition of the filler. It is expected that under the right processing conditions a compound with a tensile strength of 28 MPa and a modulus of 2 GPa can be obtained. Due to the low cost of the hemp hurd it is also expected that the cost of the final compound can be reduced by 30-40%. These properties make the produced material a low cost alternative for wood replacement in non-structures building and construction applications. To further investigate the suitability of these materials for applications in building and constitution industry the long-term behavior of these materials needs to be carefully investigated, paying particular attention to creep and environmental degradation behaviour.

ABSTRACT

The tensile properties of natural plant fibres are commonly determined by single fibre testing. The cross-sectional area used to determine the modulus and strength is usually obtained by measuring the fibre width and using this as the fibre diameter, on the assumption that the fibres are circular in section. While the assumption of circularity is reasonably true for synthetic fibres, it is not correct for natural fibres and this can lead to substantial error whendetermining the tensile properties of the fibres. The present study determined the tensile properties of 113 flax technical fibres, using an experimentally determined fibre areacorrection factor to account for the non-circularity of the fibres. The data was then compared to that obtained from back-calculation of the results obtained from longitudinal tensile testing of flax/vinyl ester unidirectional composites,which were manufactured from the same material as that used for the single fibre tests. Account was taken of the effect of fibre length on strength. The experimentally determined fibre area correction factor was found to be 2.70. Taking this into account for the single fibre tests, the back- calculated modulus of the flax fibres was within 6% of that obtained from the single fibre tests while the strength was within 7%.

KEYWORDS

Natural fibre composites, flax fibres, flax/vinyl ester, single fibre tensile testing, fibre area correction factor.

INTRODUCTION

The tensile properties of natural fibres are commonly determined from tensile testing of single technical fibres. The technical fibres themselves are composed of elementary fibres, several of which span the fibre cross-section. Conventionally, the modulus and strength of the fibres are determined assuming the fibres to be circular in nature. Accordingly, the fibre width is measured and taken as the fibre diameter in the calculations. However, as noted by Virk *et al*. (2009), and subsequently by Thomason *et al*. (2011), the fibres do not have a circular cross section and this leads to substantial error in the calculated mechanical properties.

To account for this discrepancy, Virk *et al*.(2012) introduced a fibre area correction factor *K* given by

$$K = A_D/A_T \quad (1)$$

where A_D and A_T are the measured and true fibre cross-sectional areas, respectively. The true values of the modulus and strength can then be determined by multiplying the measured values by the area correction factor. Virk *et al*. (2012) used this procedure to predict the modulus and strength of jute unidirectional composites and obtained good agreement with the measured values obtained from the composites. The present study was undertaken to compare the predicted and measured values of the modulus and strength offlax composites.

METHODOLOGY

Materials

Biotex untreated flax unidirectional fabric provided by Composites Evolution Ltd, UK, was used for the study. The fabric had an areal weight of 275 g/m^2 and was made from yarns of untwisted fibres held together by two spiral rayon wrapping threads. The spiral angle for the first thread was ~15° while that for the second was ~30°. As result of the presence of the wrapping threads, the fibres themselves became undulated with a spiral angle of

~15° (Soatthiyanon, 2013). The wrapping threads comprised 19.4% of the fabric. The yarns were held in place in the fabric by transverse threads applied every 10 mm.

Unidirectional composites with a fibre volume fraction of 25% (31% including wrapping threads) were fabricated from the flax fabric using rigid cavity vacuum resin transfer moulding. ArmorStar® IVSXH210 vinyl ester infusion resin with Arkema Luperox® DHD-9 hardener, supplied by CCP Composites, USA, was used as the matrix resin. A panel of the neat matrix resin was also fabricated in an identical manner.

Single Fibre Testing

Single fibre tensile testing was carried out on 113 technical fibres, extracted from the unidirectional flax fabric. Each fibre was glued to a 0.6-mm thick paper tab, as shown in Figure 1, using cyanoacrylate adhesive. The specimens were then conditioned in a humidity chamber at 23°C and 50% relative humidity for a minimum of 24 h.

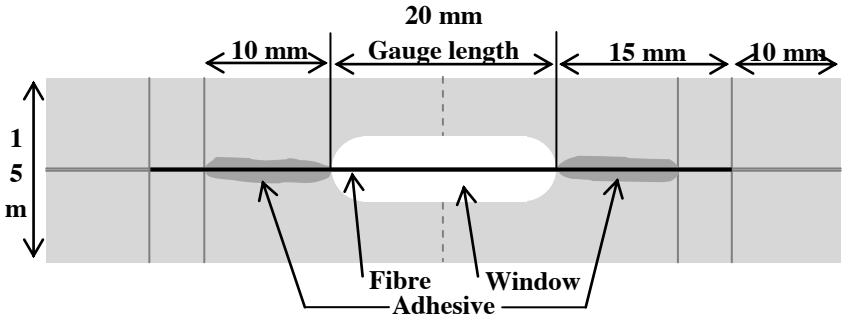

Figure 1Schematic diagram of mounting tab for single fibre testing.

The diameter of each of the technical fibres was measured in two orthogonal planes after conditioning, using a Nikon Eclipse ME600 optical microscope. The measurements were made at 18 locations, which were approximately equally spaced along the 20 mm length of the slot of the mounted specimen. The average diameter D was then calculated for each specimen and the measured fibre cross-sectional area A_D (assuming the fibre to be circular in section) was then determined as $\pi D^2/4$.

Prior to testing, the fibres were conditioned once again in a humidity chamber at 23°C and 50% relative humidity for at least 24 h. Tensile testing was then conducted under ambient conditions of temperature and humidity, using a method adapted from ASTM Standard C 1557-03. The tests were carried out using an Instron 5543 universal testing machine, with a 50 N load cell, at a crosshead speed of 0.2 mm/min, using pneumatic grips. The specimens were mounted with the grips extending right up to the end of the slot in the paper tab. The paper tab was then cut on either side of the slot and the test commenced. The measured tensile strength was determined as the maximum stress from the stress-strain curve, while the strain to failure was determined as the strain at break. The measured tensile modulus was determined over the strain range of 0.5-0.7% for fibres with a strain to failure of <1.2%, and 0.5-1.0% for fibres with a strain to failure of >1.2%.

To determine the true modulus and strength from the measured values it was necessary to determine a fibre correction factor. This was determined from 113 technical fibres extracted from the unidirectional fabric yarns and mounted in transverse cross-section in epoxy resin. The specimens were then metallographically ground and polished. The polished fibre surfaces were subsequently sputter coated with gold, then examined using a Hitachi S3400-X scanning electron microscope operated in high vacuum mode at an accelerating voltage of 15 kV. Imaging was done using backscattered electrons to enhance the contrast. The true fibre cross-sectional area $A_T$was determined from the images using Image J. The fibre area correction factor was determined fromEquation 1 using geometric means for $A_D$and A_T,as perthe procedure given by Virk et al. (2010). The true modulus and strength were then determined by multiplying the measured values by the fibre area correction factor.

Testing of Composites

Tensile testing ofthe unidirectional composites was carried out by Industrial Technology Centre (ITC), Canada, under ambient laboratory conditions (22°C and ~40% relative humidity), using a MTS Landmark load-frame with a Tovey load cell and MTS controller/acquisition software. A mechanical extensometer with a 25.4 mm

gauge length was used to measure the strain. The extensometer was removed from the specimens after a strain of ~0.6% to avoid damage to the instrument and this precluded accurate measurement of the strain to failure.

Testing was carried out in accordance with ASTM D638 using dog-bone shaped specimens having Type I dimensions. The longitudinal axis of the specimens was parallel to the fibre direction and five replicate specimens were tested. The tensile modulus was determined as the chord modulus at a strain range of 0.1% - 0.3% and the ultimate tensile strength determined as the maximum stress from the stress-strain curve.

The tensile properties of the neat matrix resin were also determined in an identical manner.For subsequent analysis of the results it was necessary to determine the length of the technical fibres in the composite. This was done by measuring the length of 100 fibres randomly selected from a yarn taken from the dry unidirectional fabric.

RESULTS AND DISCUSSION

Single Fibre Testing

The results from the single fibre tensile tests are given in Table 1. The measured modulus was 19.4 GPa with a standard deviation of 7.4 GPa, the measured strength was 347 MPa with astandard deviation of 136 MPa, andthe strain to failure was 1.8% with a standard deviation of 0.5%.

The fibre area correction factor was determined to be 2.70, which compares well with the value of 2.55 obtained previously for flax fibres by Thomason *et al*. (2011). Using the fibre correction factor gave the true modulus as 52.4 GPa and the true strength as 936 MPa, Table 1.

Table 1 Measured and true tensile properties of flax technical fibres

Property	Average Value	Standard Deviation
Measured modulus (GPa)	19.4	7.4
True modulus (GPa)	52.4	20.0
Measured strength (MPa)	347	136
True strength (MPa)	936	368
Failure Strain (%)	1.8	0.5

Testing of Composites

The tensile properties for the unidirectional composite and also for the neat matrix resin are given in Table 2. The composite had a modulus of 13.2 GPa with a standard deviation of 0.4 GPa, while the strength was 122 MPa with a standard deviation of 5 MPa. The modulus of the neat resin was 3.62 GPa (standard deviation 0.02 GPa) while itsstrength was 59.8 MPa (standard deviation 4.1 MPa).

Table 2 Tensile modulus and strength for composites and neat resin

Property	Average Value	Standard Deviation
Composite		
Modulus (GPa)	13.2	0.4
Strength (MPa)	122	5
Neat Resin		
Modulus (GPa)	3.62	0.02
Strength (MPa)	59.8	4.1

The measured length of the technical fibres used to make the composite was 93 mm, with a standard deviation of 25 mm.

Calculation of Fibre Modulus and Strength from Composite Tensile Test Data

The data obtained from tensile testing of the composites was used to calculate the modulus and strength of the fibres, using the rule of mixtures, for comparison with the results obtained from the single fibre tests. As the

fibres had been deformed into a spiral shape by the spiral wrapping threads, the misalignment was taken into account using the Krenchel reinforcing efficiency factor η as used by Virk *et al*. (2012) for prediction of modulus and by Shah *et al*. (2012) for prediction of strength. The Krenchel reinforcing efficiency factor is given by:

$$\eta = \cos^4 \theta \quad (2)$$

where θ is the angle between the fibre direction and the loading direction. The transverse supporting thread was not considered since it was perpendicular to the loading direction.A value for the modulus of rayon was required for the calculations. Hearle (2001) gives a range of 4.8-8.8 N/tex which equates to 7.2-13.1 GPa. The mean value of 10.2 GPa was used in the calculations.

Based on the above, and also assuming linear behaviour and isostrain conditions, the rule of mixtures equations give the modulus E and strength σ of the fibres as:

$$E_f = [E_c - (E_m V_m - E_{w1} V_{w1} \cos^4 \theta_{w1} - E_{w2} V_{w2} \cos^4 \theta_{w2})]/V_f \cos^4 \theta_f \quad (3)$$

$$\sigma_f = \left[\sigma_c - \left(E_m \varepsilon_f V_m - E_{w1} \varepsilon_f V_{w1} \cos^4 \theta_{w1} - E_{w2} \varepsilon_f V_{w2} \cos^4 \theta_{w2}\right)\right]/V_f \cos^4 \theta_f \quad (4)$$

where V is the volume fraction and the subscripts *c, f, m, w1 and w2* refer to the composite, the fibres, the matrix and the wrapping threads, respectively.

Calculation of the modulus and strength of the fibres using these equations gave values of 47.0 GPa and of 337 MPa, respectively. The value of $E_m \varepsilon_f$ given in Equation 4 was slightly higher than the measured strength of the matrix so the latter was used when calculating fibre strength. This anomaly is considered to be due to the assumption of linear behaviour.

The predicted fibre modulus of 47.0 GPa is within 9% of the experimental true value of 52.4 GPa. The calculation was made using the 0.001-0.003 chord modulus from the composite tensile tests. However, the stress-strain curves for the composites showed a distinct knee at a strain of ~0.2%,which is in the middle of the strain range used to calculate the chord modulus, after which the slope decreased by ~40%. It is considered that the knee is the result of damage occurring in the composites, as proposed by Hughes*et al*. (2007), rather than being an intrinsic property of the fibres. On this basis, the modulus value of the composite before the knee was considered to be more appropriate for determining the fibre modulus for comparison with the single fibre data. Using the strain range of 0.0001-0.0015 for both the composite and the vinyl ester resin gave a value of 55.6 GPa, which is within 6% of the value obtained from the single fibre tests.

In contrast to the predicted modulus, the predicted fibre strength of 337 MPa is very much lower than the experimental true value of 936 MPa. However, the experimental value of fibre strength was determined using a 20 mm gauge length, whereas the average fibre length in the flax yarns used to make the composites was 93 mm. As fibre strength decreases considerably with increasing fibre length (Romhányet al.2003; Virk et al. 2011), this needs to be taken into account. Romhány*et al*. (2003) used data from testing of flax technical fibres with gauge lengths of 20, 40 and 80 mm, together with additional data for flax technical fibres reported by Stambouli*et al*. (2000) and Bos*et al*. (2002).They found the following relationship between gauge length g (mm) and fibre strength σ (MPa):

$$\sigma = 12.2\, exp[883.7/(g + 206.4)] \quad (14)$$

This equation was used to determine the ratio of strength at a 20 mm gauge length to that at 93 mm. This ratio was then used to convert the true fibre strength of 936 MPa obtained in the present study for a 20 mm gauge length to its equivalent strength at 93 mm, giving a value of 361 MPa. The value of 337 MPa calculated from the composite tests is within 7% of this value and the agreement is again considered to be reasonably good.

CONCLUSIONS

- The fibre area correction factor for the technical flax fibres was found to be 2.70. This is in good agreement with the value obtained for flax fibres by other workers.
- The modulus and strength of the fibres for a 20 mm gauge length, determined after incorporation of the fibre area correction factor, were 52.4 GPa and 936 MPa, respectively.
- The modulus and strength values determined after incorporation of the fibre area correction factor were within 6% and 7% respectively of the values determined by back-calculation of the results obtained from longitudinal tensile testing of unidirectional composites. The good agreement is consistent with results obtained by other workers for jute fibres.

ACKNOWLEDGMENTS

The work was undertaken as part of a CRC-ACS research programme, established and supported under the Australian Government Cooperative Research Program. The authors gratefully acknowledge the assistance provided by Composites Innovation Centre (CIC), Canada, in fabricating the compositesamples and of Industrial Technology Centre (ITC), Canada, in carrying out the composite tensile tests.

ABSTRACT

One of the greatest challenge in working with natural fibre composites is the large variation in mechanical properties that result from the geometric inconsistency amongst fibres. Traditional design tools and models are unable to accurately incorporate this non-homogeneity to predict the resulting local behaviour of biocomposite materials. The following paper presents a methodology to generate a representative volume element (RVE) to simulate the material microstructure of short fibre composites, with the intent of modelling the popular class of short fibre biocomposites materials. The capabilities of a range of particle packing algorithms used in literature are compared in terms of the maximum volume fraction they have been able to achieve and for what fibre length to diameter aspect ratio. The methodology is able to account for the characteristics of fibre geometry samples, according to their probability density functions (PDFs). The RVE generation strategy imposes periodic boundary conditions and fibres are declared invalid if an intersection between fibres is detected. The effect of different PDFs on the resulting RVE are discussed. An RVE populated with data following a Weibull distribution is compared to that from normally distributed data with an equal mean but varied standard deviations. Using a Weibull distribution to simulate the characteristics of an RVE requires a significantly higher number of fibres than any comparable normal distribution, due to the skewness of the data towards large values at low probabilities. The highest volume fraction achieved was 40% for an RVE containing fibres with lengths distributed according to a Weibull distribution and aspect ratios of 15. The future intent of this work is to perform finite element analysis on RVE samples with a range of varied microstructure characteristics to determine the effect on overall composite properties, which will provide new insights on how best to formulate short fibre compounds.

Biocomposites, representative volume element, probabilistic design, particle packing, volume fraction.

INTRODUCTION

This study is focused on the analysis of short, or discontinuous, fibre biocomposites. Attributed that influence the microstructure of such a material include the fibre geometry, orientation, packing arrangement and volume fraction (Fowler, Hughes et al. 2006). The geometric properties of the short fibres' geometry are stochastic and are best described by a probability density function (PDF) rather than a discrete value. The most important feature to note from the PDF curves for natural fibre properties is the typically asymmetric shape. An example of the PDF curves for fibre length and diameter of short flax fibres is shown in Figure 1. The source for the PDFs of asymmetric nature stems from the fibre mastication during processing (Biagiotti, Fiori et al. 2004).

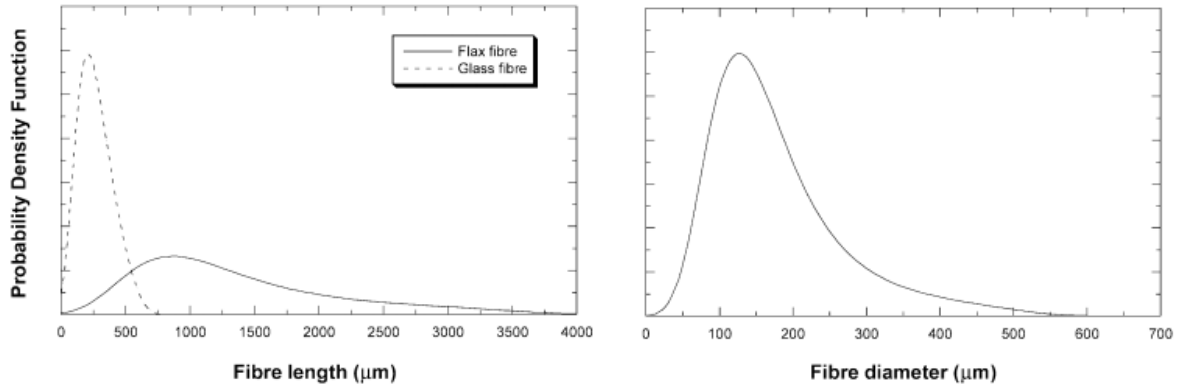

Figure 1: Probability density function (PDF) curves of geometric characteristics of flax fibres: Length (left) and Diameter (right). (Biagiotti, Fiori et al. 2004)

In order to account for the variability in natural fibres, a probabilistic design approach needs to be applied. Traditional structural design analysis does not directly account for the random nature of most input parameters, and thus cannot quantify the inherent risk of design and performance sensitivity to input variables (Long and Narciso 1999). Probabilistic design tools are a well-established concept in civil and structural engineering, despite being somewhat unheard of in the areas of mechanical and composites engineering. The probabilistic modelling approach will focus on the micro-scale. The results from this research can be used to better understand the behaviour of short fibre composites with large property variations. Ultimately this will support the formulation of better performing compounds and industry uptake.

Under the micromechanical classification of material analysis, a heterogeneous composite material is modelled on the level of the individual constituents. Such a model will require the generation of a representative volume element (RVE) containing individual short fibres characterised by their PDFs. The methodology designed and used in this study to generate a computational RVE to simulate biocomposites, will be discussed in terms of their results and implication on future modelling capabilities.

METHODOLOGY

For short fibre composites, fibres may be modelled as cylinders (Pan, Iorga et al. 2008). With this in mind, methods for packing cylindrical particles has been the focus of the research. An extensive literature search was conducted to evaluate different strategies for packing cylindrical particles in a volume element, with the key findings presented in Table 1. The highest volume fraction Vf achieved for a given aspect ratio AR has been tabulated to provide a grounds for comparison between models.

Table 1 Investigation of Cylindrical Particle Packing Algorithms

Source and Packing Algorithm	Description
(Böhm, Eckschlager et al. 2002)  Basic RSA Max Vf: 15% Max AR: 5	Basic Random Sequential Adsorption (RSA) method. Sequentially add fibre elements to a volume by randomly generating candidate inclusion positions, which are accepted if a reinforcement does not overlap any previously accepted inclusion and are rejected otherwise. Periodic boundary conditions. Maximum volume fraction is limited by fibre aspect ratio observed.
(Kari, Berger et al. 2007)  Modified RSA Max Vf: 40% Max AR: Varies	Introduce definition of "jamming limit" i.e. it is not possible to generate higher volume fraction RVE models because of the jamming limit. To overcome the jamming problem and to achieve higher volume fraction, different sizes of fibres used by depositing them inside the RVE in a descending manner using RSA algorithm. They first deposited the largest aspect ratio fibres, and after reaching the jamming limit, deposited the next largest possible aspect ratio fibres in the RVE.
(Pan, Iorga et al. 2008)  Modified RSA Max Vf: 55% Max AR: 10	RSA algorithm applied for fixed aspect ratio fibres and if no match is found, a new fibre position and orientation is generated until the desired volume fraction is achieved.
(Pan et al, 2008)  Modified RSA Max Vf: 35-40% Max AR: 20	The representative volume element is divided into sublayers. Fibers are randomly oriented in the *xy* plane, and in the case of overlap, the newly added fibre changes the sublayer to avoid the existing fibre. The buckled polyhedra do not appear to be very realistic, and the orientation distribution is restricted to the *xy* plane.
(Duschlbauer, BÖhm et al. 2006)  Monte Carlo Max Vf: 21% Max AR: 10	Monte Carlo method. Procedures starts with a configuration of random fibre locations and orientations in a large box. Fibres are rearranged until a predetermined orientation state is reached. Final step decreases the size of the box towards the desired volume fraction without altering the orientation of the fibres. Intersection of fibres is not allowed at either step during the process. Requires significantly more processing power then RSA with little gain in volume fraction.
(Zhang 2006)  Collective Rearrangement Max Vf: 35% Max AR: 10	Collective Rearrangement. Periodic boundary conditions not applied in this research, aim wasn't to generate an RVE but to investigate the limits of the algorithm. A number of cylinders are placed in a domain and a Monte Carlo perturbation process is applied until overlaps between cylinders are removed.
	Sequential Deposition algorithm simulates a fall of random particles until they reach a local minimum of their potential energy.

Requires significantly more processing power then other models with significant volume fraction improvements.</td></tr>
</table>

Summary of Findings

The following findings have been considered prior to developing the methodology to generate the RVE using Python 2.7 coding language:

- Large fibre aspect ratios inhibit the maximum achievable fibre volume fraction resulting in a “jamming limit”
- The Random Sequential Adsorption (RSA) algorithm should not be used for composites with uniformly sized fibres but may increase in capability if fibre geometry is varied
- Monte Carlo and Random Walk algorithms are very effective in packing fibres, especially for higher aspect ratios at high volume fractions. Trade off performance with significant increase in time and processing power required to generate a valid RVE
- RVE models containing fibres with lengths sampled from a Weibull distribution have not been found in literature
- In all cases for RVE generation, periodic boundary conditions have been applied
- Intersections between cylindrical elements have been tested and rejected in all models by either numerical algorithms or through modelling software capabilities
- Natural fibres may be characterised by a Weibull distribution and these may be contrasted to relatively uniform normally distributed data that is more typical to man-made fibres

Modelling approach

The short fibres will be represented as cylinders of varying length and diameter. The fibre’s centre points will be described by their offset in the X, Y and Z directions from the global origin, constrained within the RVE boundary. Two Euler rotations will be imposed about the X and then the Y axes. The RVE boundary will take the form of a cube with edges of length L3, where the term L3 denotes the maximum fibre length of the sample. The cube is centred symmetrically on the origin of the global coordinate system.

The particle packing strategy follows a modified Random Sequential Adsorption (RSA) algorithm. The RSA algorithm arranges the fibres to be placed in descending order by size then randomly generating a three dimensional coordinate for the centre point of each fibre within the RVE boundary and a rotation about both X and Y axes. If the fibre position and orientation results in an intersection between fibres, then the fibre is rejected and the random values are regenerated until a successful placement is made. The modified RSA algorithm has been chosen as it has proven capable of generating RVEs of significant volume fraction for fixed aspect ratio fibres (maximum of 55% V_f for aspect ratio of 10 by Pan, Iorga et al. 2008). The results offer room for improvement if variable fibre dimensions are introduced, as is the intention of this project.

The RVE is a finite micro-representation of a sample of material. A macro-scale component can be obtained by homogenisation or identically replicating the RVE and extending it periodically in all X, Y, and Z directions (Pan, Iorga et al. 2008). In order to keep the periodicity conditions of the RVE, parts of any fibre that protrude from any surface of the cubic RVE are cut and shifted to the opposite face. In the method developed as part of this study, the fibre returns a true clash if the magnitude of the distance between the fibre's centre point and RVE boundary surface is less than half the fibre's length. The concept of periodic boundary conditions in two- and three-dimensions is visualised in Figure 2.

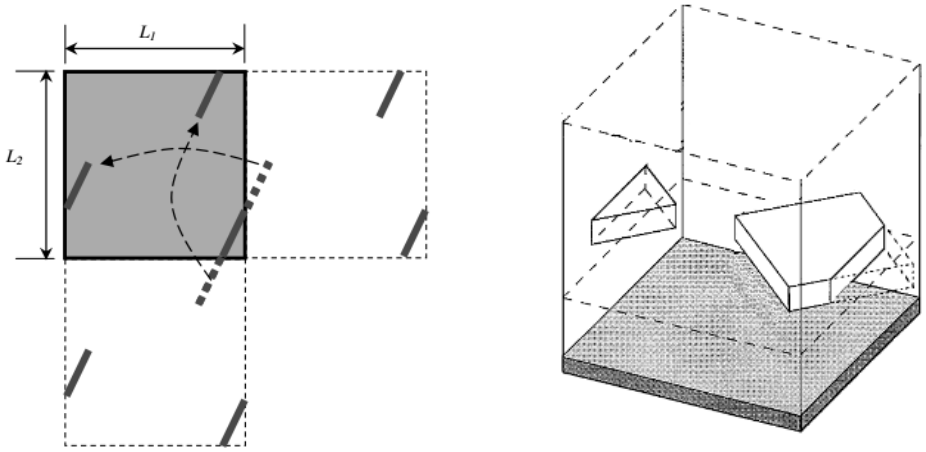

Figure 2 Example of periodic boundary conditions over a volume element in two-dimensions (left) (Pan, Iorga et al. 2008) and three-dimensions (right) (D. Coelho, J.F. Thovert, and P.M. Adler. 1997)

In order to generate a valid RVE that is a true representation of the desired volume fraction, once the periodic state of the fibre is established, the fibre and all its periodic realisations must be checked for any intersection with existing fibres before it may be accepted.

When deciding on the best course of action to take when numerically checking for the intersection between the cylindrical elements, the most obvious choice is to check for the intersection between two cylinders. Literature shows that detecting the intersection of two cylinders is computationally expensive (Eberly 2000). Instead the intersection between capsules has been used to conservatively approximate the volume of a cylinder. This approach is simpler and less computational resource-intensive procedure. A capsule is defined as the surface on which all points on the surface are the same distance from a line segment. Two capsules intersect if the shortest distance between the line segments is less than the sum of their radii (Eberly 2000). The same conditions hold for even arbitrarily rotated capsules, which is why this approach is appealing for the purpose it is intended in this work (Lene 2015). The intersection detection algorithm has been developed from Dan Sunday's Geometry Algorithms originally written in C+ (Sunday 2012). The intersection detection procedure requires the numerical transformation of the local coordinates at the end of the line segment contained within each cylinder to the global reference frame. Rotation matrices have been used to perform this transformation based on the orientations imposed about the local X and Y axes of a fibre.

The overall strategy to generate a short fibre biocomposite RVE based on probabilistic micro-mechanical analysis is outlined in detail in the flow chart shown in Figure 3 over the page.

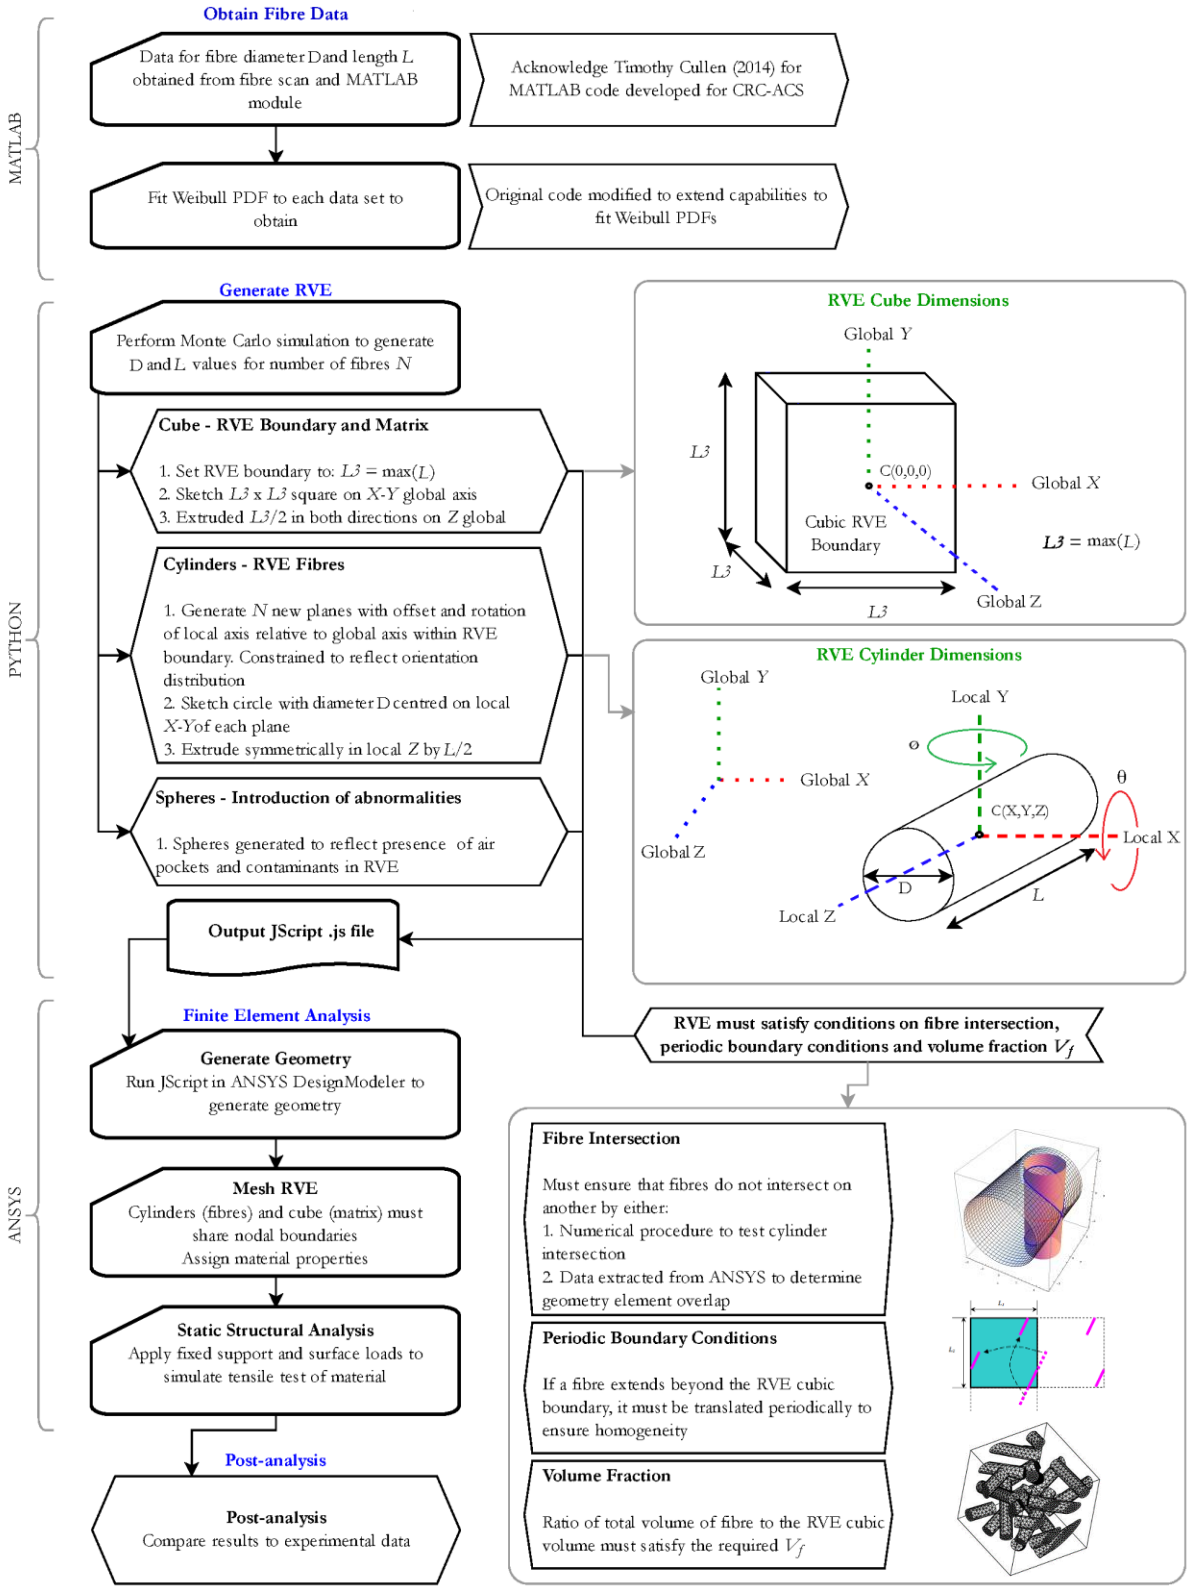

Figure 3 Methodology Flow Diagram

RESULTS AND DISCUSSION

To assess the developed code's capability in generating an RVE for short natural fibre composites in contrast to more geometrically uniform samples, Monte Carlo simulation of normally distributed fibres with varied standard deviations have been generated. The normally distributed fibre data has been generated to have approximately the same mean value as the data generated from a Weibull distribution to allow for a meaningful comparison between the data sets. The probability density function curves of Monte Carlo simulated fibre lengths are seen in Figure 4 below. Natural fibre data has been sourced through The University of Queensland chapter of the CRC-ACS (Cullen 2014).

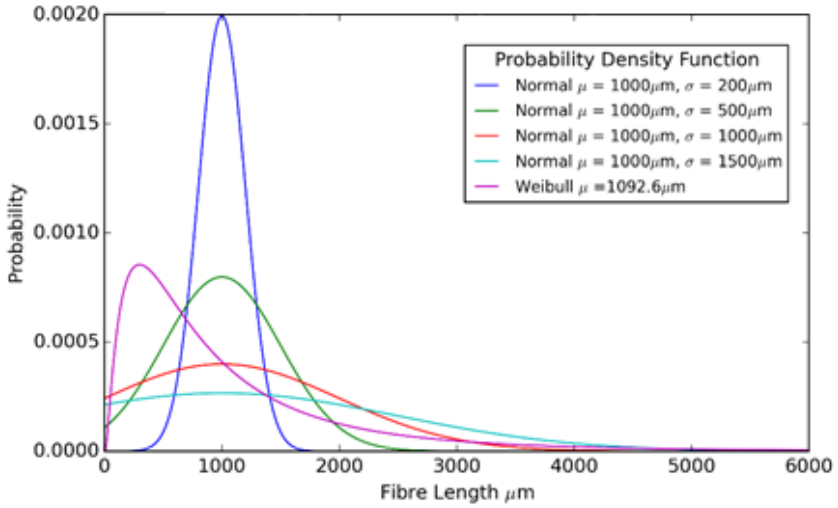

Figure 4 Monte Carlo Simulated Fibre Length Probability Density Functions

It must also be noted that each sample has been truncated at a lower bound value of length equal to 100μm. The lower bound has been imposed to simulate the sieving out of small, powder like fibres which would occur in the manufacturing of fibre composites.

The number of fibres that the Python code would need to generate and place successfully in the RVE volume in order to meet a user specified volume fraction has been calculated based on the fibre lengths from each PDF using a fixed aspect ratio to calculate their diameter. A summary of each fibre data set estimation for a volume fraction of 30% and aspect ratio of 15 is shown in Table 2.

Table 2 Results of Fibre Sample Prediction for 30% Volume Fraction and Aspect Ratio of 15

Distribution Sample	Number of Fibres N	Smallest Fibre Length [μm]	Largest Fibre Length [μm]	Second Largest Fibre Length [μm]	Percentage Difference Between Largest and Second Largest
Weibull μ = 1092.6μm	7795	100.09	6756.39	6349.65	6.21%
Normal μ = 1000μm, σ = 200μm	402	426.03	1544.70	1540.62	0.26%
Normal μ = 1000μm, σ = 500μm	1008	120.90	2447.92	2410.57	1.54%
Normal μ = 1000μm, σ = 1000μm	1582	100.72	4027.31	4017.20	0.25%
Normal μ = 1000μm, σ = 1500μm	3364	100.24	6825.00	6689.08	2.01%

The length of the largest and second largest fibres have been recorded and the percentage difference calculated. The higher percentage difference observed in the Weibull distribution data compared to the normally distributed

data demonstrations the sparseness of long fibres contained in the Weibull distribution sample. The normally distributed data sets contain more large fibres as opposed to the comparatively few found in the Weibull distribution samples. These large fibres which occur with higher probability in normal distributions determine the cubic dimension of the RVE L3, recalling that L3 is equal to the maximum fibre length of the sample. For a Weibull distribution, a large fibre appears and designates a large RVE, but then there are few large fibres to contribute to filling the volume to the specified volume fraction, requiring a significantly higher number or small fibres which occur at higher frequency to occupy the space.

As the volume fraction of an RVE sample is increased a larger sample of fibres is captured. For the data containing fibres with lengths distributed according to the Weibull distributions, as more fibres are included in a sample, the percentage difference between the longest and the second longest fibre decreases. Figure 5 shows the decrease in percentage difference between the longest and second longest fibre found in an RVE sample with Weibull distributed fibre lengths as the volume fraction increases.

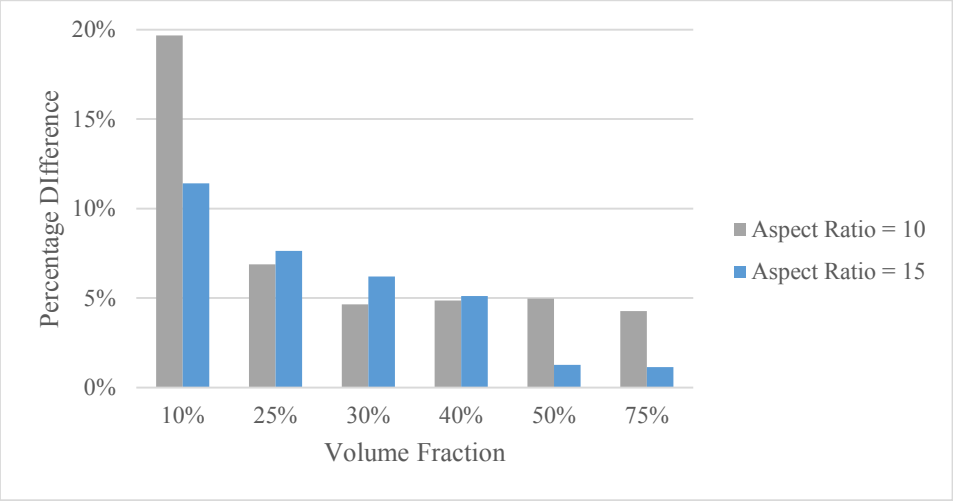

Figure 5 Percentage Difference Between Largest and Second Largest Fibre - Weibull Distribution.

An immediate observation from the fibre sample prediction is that the number of fibres required to generate an RVE for fibre lengths distributed according to a Weibull distribution is much higher than for those of normally distributed data with an equivalent mean. A comparison between the numbers of fibres of an aspect ratio of 15 require to fill an RVE to a range of volume fractions between 10% and 50% may be seen in Figure 6. The results of this figure highlight the obvious spike in the number of fibres required when a Weibull distribution is used to parametise the fibre length input.

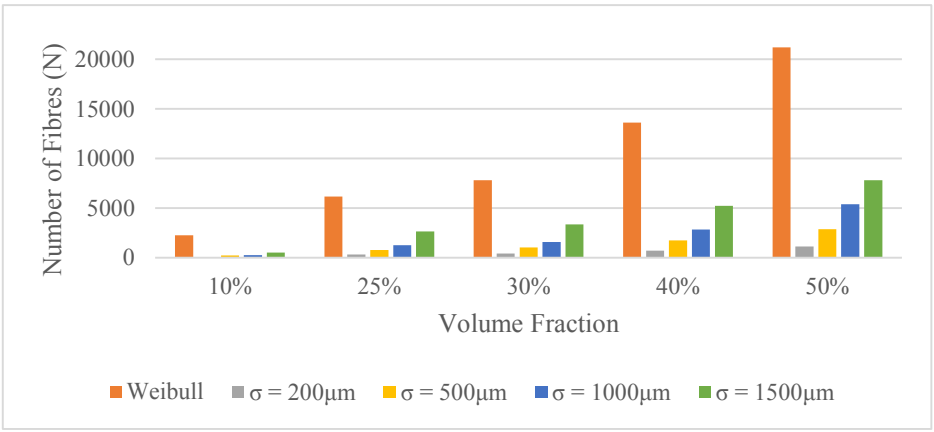

Figure 6 Number of Fibres Required to Fill an RVE to Various Volume Fractions. Fibre Length to Diameter Aspect Ratio of 15.

Comparing the Weibull distribution data to the normally distributed data with a standard deviation of 1500μm shows the increase in the number of fibres required to fill the RVE. While the difference in the maximum length

and thus L3 of the two samples is only approximately 1% in the sample with a volume fraction of 30% (resulting in a 3% difference in the cubic RVE volume), the number of fibres required to characterise the Weibull RVE is 2.3 times that of the normally distributed sample.

Results from RVE JScript Generation

To date the RVE generation python script has been successfully able to run the RVE generation code up to a volume fraction of 30% for all distributions, for aspect ratios of both 10 and 15. The results for a volume fraction of 20% and a fibre to length aspect ratio of 15 may be seen in Figure 7. These samples contain fibres that may be oriented about the X and Y axis anywhere between positive and negative 45°.

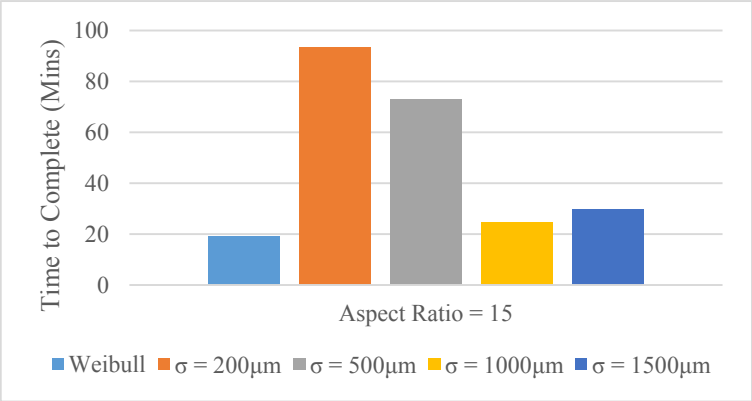

Figure 7 Time to Complete Simulation (mins) for an RVE of 20% Volume Fraction Versus Fibre Aspect Ratios

The Python code is able to reach a solution in approximately 20 minutes for the Weibull distribution containing 3166 fibres. The slowest to reach a solution is the normally distributed sample with a standard deviation of 200µm containing 227 fibres which takes approximately an hour and a half to complete. The discrepancy between the solution times in contrast to the number of fibres required for the two samples is a result of the difference in the fibre length variance function between the two samples. The Weibull distribution contains few large fibres and many small fibres, which increases the likelihood that a randomly placed fibre will not intersect at low volume fractions, but required more fibres to fill the RVE to the required volume fraction. The normally distributed sample contains fewer fibres than the Weibull distribution sample, but these fibres are of similar proportions, meaning that the chances a new fibre will intersect will increase rapidly with each successive fibre.

The increased chance of detecting a fibre intersection has been measured indirectly by recording the maximum number of attempts taken to place a fibre. For the Weibull distribution, the maximum number if attempts is 557, which is just over one third of the maximum number of attempts required to place a fibre in the normally distributed sample, of roughly 15000. This phenomenon has been observed in literature such as Kari, Berger et al. (2007) who have referred to it as reaching the samples "jamming limit". An important observation that may be made from the results of this project that extends on the state of current literature on the subject, is that placing fibres whose geometry is generated according to a Weibull distribution can increase the jamming limit threshold of a sample for a given volume fraction.

To reduce the time taken to reach a solution, the orientation of fibres were constrained within positive and negative 30° for samples with an aspect ratio of 10, and 20° for samples with an aspect ratio for 15. The intention is to reduce the likelihood that fibres will intersect and thus reduce the attempts required to place a fibre. Even with the reduced orientation parameter, the samples containing fibres with an aspect ratio of 15 took significantly longer to complete a simulation. A comparison of the times taken to complete a simulation between the fibre length distributions at an aspect ratio of 10 versus 15 may be seen in Figure 8.

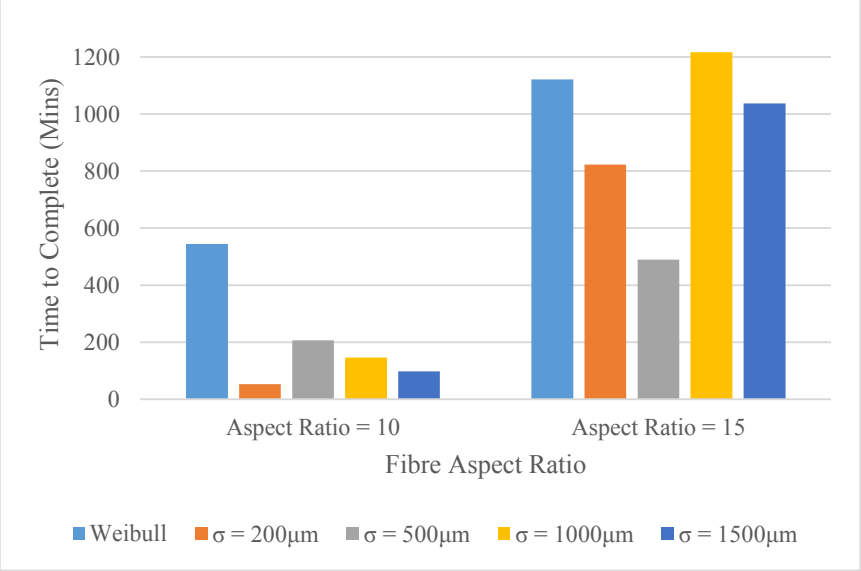

Figure 8 Time to Complete Simulation (mins) for an RVE of 30% Volume Fraction Versus Fibre Aspect Ratios

An attempt to generate an RVE with a volume fraction of 40% was successful when the orientation a fibre may take was reduced to 10°. This scenario was simulated for Weibull distributed data with an aspect ratio of 10 only, and took approximately 20 hours to produce a solution containing 5084 fibres. The maximum number of attempts to place a fibre was less than observed for samples with larger orientation factors at only 4993 attempts. The number of fibres required to generate an RVE of volume fraction of 40% containing fibres with length to diameter aspect ratios of 15 is 1.75 times the number of fibres required for a Weibull distribution of 30% volume fraction, increasing from 7795 to 13618. Attempts to generate an RVE with a volume fraction of 40% and rotations within positive and negative 10° have exceeded reasonable amounts of time that a simulation could be run for, and were cancelled after 72hours of execution.

The maximum number of attempts at placing a fibre may be set prior to initiating the code, however the time taken to reach a solution will unavoidably increase using the modified RSA algorithm. There is potential in future to generate random positions intelligently, as a function of the space already occupied, to cut down on time to generate an RVE wasted on generating coordinates already occupied.

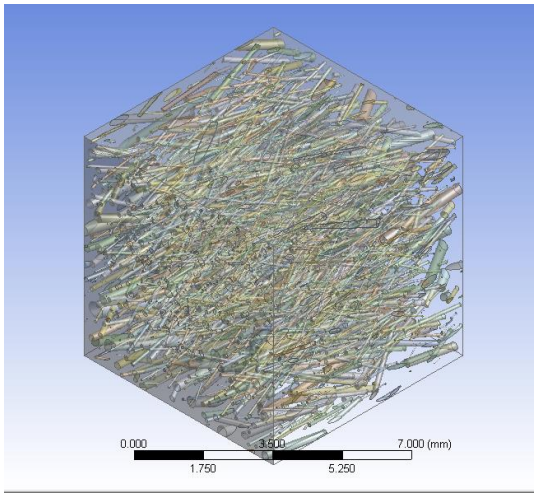

Figure 9 Three-Dimensional RVE with Weibull Distributed Fibres, 10% Volume Fraction and Aspect Ratio of 15. Isometric view.

CONCLUSIONS

Modelling the microstructure of biocomposite materials requires the simulation of a representative volume element (RVE) to capture the inconsistencies in characteristics between fibres. A methodology for the generation of an RVE that enforces periodic boundary conditions and ensures that no fibres occupy the same space has been presented. Short fibres are modelled as cylinders and intersection detection has been performed conservatively by modelling cylinders as capsules. The capabilities of different particle packing algorithms has been evaluated, and the modified random sequential adsorption algorithm has been adopted. RVEs generated from data with a Weibull distribution versus normally distributed data with an equal mean have been compared to evaluate the behaviour of the algorithm. The higher number of fibres required to fill an RVE for a specified volume fraction for a Weibull distribution versus a comparable normal distribution has been attributed to the skewness of the data towards large values at low probabilities. The highest volume fraction that has been achieved to date is 40% for an RVE containing fibres with lengths distributed according to a Weibull distribution and aspect ratios of 15. The future of this work may extend to modelling the RVE samples in finite element software to determine the effects of microstructure characteristics on the macro-scale material properties.

Even at its current stage the developed tool presents a new way of assessing the achievable maximum fibre volume fraction that can be achieved in a short fibre compound as a function of the fibre length and diameter distributions. In contrast to most research where a single discrete fibre length is used the presented tool allows the use of distributions. It was demonstrated in his paper that the fibre size and diameter distribution has a significant impact on the maximum packing density that can be achieved. These findings can be translated directly to practice, by using the metric presented in this paper to specify/assess suitable fibre distributions for compounding and assessing maximum packing density, viz. maximum obtainable fibre volume fraction. Measures such as the number of placement attempts can also be used as a measure to gauge the ease of packing which in the practical sense can be related to the ease of compoundability.

FUTURE OUTLOOK

The purpose of generating a 3D model of an RVE is to then perform finite element analysis to determine the homogenised material properties of the sample. From the results computed by finite element analysis, it is possible to calculate the overall modulus of the sample. Thus the resulting modulus can be compared between samples with different PDF and micro-scale characteristics. It is expected that the tool will also prove its usefulness in other areas where fibrous materials with lager dimensional variability are used. Examples include fibre boards, geo-textiles or filter materials. The developed tool also makes the first step towards the development of RVE to be used in finite element simulations to numerically determine mechanical properties of compounds.

ABSTRACT

Biocomposites produced from renewable biomass were investigated for suitability in food packaging applications. Poly(lactic acid) was compounded with 10 – 30 wt. % hemp hurd through extrusion and injection moulding to produce rigid plastic biocomposites. In addition to their cost-effectiveness and equivalent mechanical properties, the biocomposites were particularly effective as antimicrobial materials with the inclusion of silver nanoparticles. A 16% cost margin was achieved in the biocomposites with additional antimicrobial capabilities. Through further research, development, and supply chain management, economic and environmental sustainability can be achieved in production.

KEYWORDS

INTRODUCTION

Bio based economies are burgeoning throughout the world and with growing support from federal governments and international collaborations, a sustainable bio-based future can be envisioned. Programmes have been developed withinNorth America, Europe and the AsiaPacific on greater usage of biomass and development of sustainable materials for commercial applications(Salentijn et al., 2015). With only 3% of biomass utilised worldwide, there is a huge opportunity for using lignocellulosic biomass as precursor for organic macromolecules, bioenergy, and for biofuel development.

However, the use of biomass has taken a back step since the industrial revolution and with the emergence of fossil fuels, the supply chains for biomass have not received attention for solving contemporary world problems of fuel, energy, food, and sustainability. To develop sustainable, well-designed supply chains, innovative business models are required, with strong government support and involvement of end users.
A key end use of biomass is fordevelopment of polymers and macromolecules and fillers in existing plastics, with food packaging as the end market. In packaging, the rising demand for safe, minimally processed materials that can resist foodborne pathogens such as Escherichia coli, Salmonella spp. and listeria monocytogenesis a major driving factor for innovations in food quality, freshness, and safety (Khan et al., 2015, Khan et al., 2014, Appendini and Hotchkiss, 2002).

Antibacterial packaging for increasing the shelf life of minimally processed foodsisreplacing traditional materials and production methods. Many recent innovations, primarily antimicrobial agents for microbiological safety of food (Su Cha and Chinnan, 2004) are revolutionising the advancements in the packaging materials market. The use of antimicrobial agents in packaging materialsis a solution for preventing growth of microorganisms at the surface,and realising increasedshelflife.

The key objective for food packaging is containing food in a cost-effective way that satisfies industry/consumer requirements, maintains food safety, and minimises environmental impact (Marsh and Bugusu, 2007). The market for rigid thermoplasticsis currently rising at a rate of 6.4% per annum and projected to reach a value of US$472 B in 2016, with 30% of this market in food packaging, primarily as polyolefins, polyesters, ionomers, styrenics, nitriles, fluoropolymers, andcellulosics (Coles et al., 2003). Plastic packaging is often contaminated with foodstuff; hence recycling is not economical (Siracusa et al., 2008) because of the increased extraction

steps. Hence, plastic packaging is landfilled every year, raising environmental concerns, and biodegradability has emerged as a functional requirement for packaging today.

Many biodegradable polymers are derived from renewable materials, which are inherently compostable (Tharanathan, 2003). Biodegradable polymers in food-contact articles include disposable cutlery, drinking cups, salad cups, plates, overwrap and lamination film, straws, stirrers, lids and cups, plates and containers for commercial food establishments (Siracusa et al., 2008). The increase in the development of biodegradable polymers has not evidenced a concomitant decrease in retail price. Moreover, some biopolymers show a lack of thermo-mechanical stability. This shortcoming has led new research on combinations of natural fillers with biodegradable thermoplastics to provide lower cost and higher durability. The focus of this study is hemp hurd, which is derived from the hemp plant after the bast has been removed for textiles and technical fibres.

An antibacterial packaging material based on poly(lactic acid) (PLA) and hemp hurd (HH) can be hypothesised to be superior to existing antibacterial alternatives because of lower raw material cost, effective antibacterial activity, fewer regulatory concerns, biodegradability, and environmental friendliness. Findings of toxicological studies have shown that PLA is safe and generally recognized as safe for use in manufacturing food-contact packaging because the level of lactic acid migrating to food from packaging containers is lower than the amount of lactic acid used in common food ingredients themselves.

In HH filler, inherent antimicrobial activity is the result of the heavy metal absorption capability of industrial hemp plant. Heavy metals uptake by hemp plant is an effect of soil and plant factors (Angelova et al., 2004), including heavy metal content, absorptive capacity of soil, redox conditions, organic matter, and pH of the soil (Alloway, 1995). Plant genotype is considered the most critical plant factor affecting heavy metal uptake (Hocking and McLaughlin, 2000). Angelova et al (2004) suggested that flax and hemp production is suitable for industrially polluted regions, as they remove considerable amounts of heavy metals from the soil through their roots, and can be used as potential crops for cleansing heavy metals. In addition to increasing soil quality, heavy metals bear no influence on future crop development and productivity (Baraniecki et al., 2001). However, it can be an issue of health risk if food packaging contains a high level of heavy metals that migrate to the food in contact.

In food packaging plastics, the heavy metals act through termination of bacterial or microbial activity through gradual damage to the bacterial cell walls, preventing nutrient uptake and reducing survival. The unique porous microstructure of the HH is beneficial for light weighting and controlled release of additives such as antimicrobial additives and self-healing chemicals.

The current study is a continuing effort to create a value added HH application in the food packaging industry. The increased utilisation of PLA in food packaging with certain shortcomings in thermomechanical properties and high cost can be alleviated with the use of a multifunctional filler. HH is such a filler that provides benefits in property retention, but at the same time strengthens the case for economic and environmental sustainability. In this study, the focus is on the utilisation of novel value chains for industrial hemp products.

MATERIALS AND METHODS

A commercial grade of PLA was used as the polymer for the biocomposite. The HH, which is the biomass filler in the biocomposite was received from Ecofibre Industrial Operations Pty Ltd, Maleny, QLD, Australia as powder of 40 μm mean size. Glicidyl methacrylate (GMA) tert butyl perbenzoate (TBPB) were used for grafting the PLA for interfacial compatibilization. The 2015 estimated price and composition of the biocomposites are shown in Table 1.

Table 1. Cost and Constituents of Biocomposites

Raw materials	Price (USD/kg)	Weight Fraction (wt. %)
PLA (4032D)	3.00 - 3.80	68.5-88.5
HH*	0.20 - 0.40	10.0-30.0
GMA	6.20 - 7.60	1.0
TBPB	3.80 - 4.50	0.5
AgNP-loaded HH*	0.50 - 0.80	10.0-30.0

* Either HH or AgNP-loaded or as-received HH is used in different grades

The approximate cost of raw materials produced using processing techniques similar to that of PLA for the 10-30 wt. % AgNP-loadedHH/PLA biocomposite is on an average16% lower than that of the neat PLA. At increased loading of the biomass filler, further cost savings can be surmised.

A proprietary method of loading silver nanoparticles (AgNP) was used. Neat PLA, HH/PLA, HH/GMA/PLA and AgNP-HH/GMA/PLA were compounded on a laboratory-scale twin screw extruder with a speed of 40 rpm at a nozzle temperature of 175°C, followed by injection moulding as standard coupons on aninjection moulder. X-ray diffraction was conducted using Cu Kα radiation (λx = 0.154nm). A scanning electron microscope (SEM) was used to image the structure and morphology of the blends. The macro- and micro-structure of the hemp hurd featuring the porous structure is shown in Figure 1.

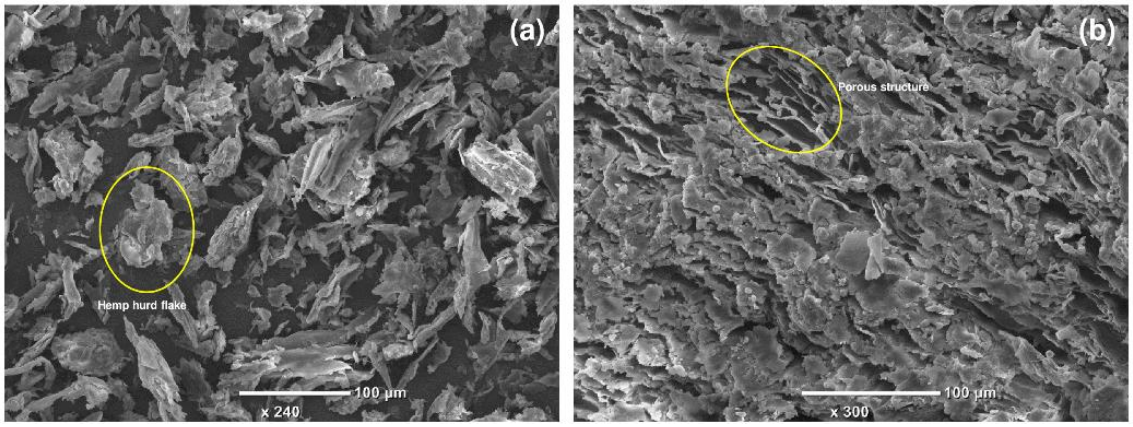

Figure 1. Hemp hurd as (a) ground, and (b) morphology.

Fourier transform infrared (FT-IR) was used as a spectroscopic method of chemical analysis. All tests were conducted with at least a duplicate and according to international testing standards.The antibacterial efficacy of the biocomposites was determined on E. coli (ATCC # 25922), through bacterial cultures maintained on nutrient agar slopes. The antibacterial performance of the HH powder was investigated according to ASTM E2149-10 standard. The migration testing for plastic materials was conducted according to guidelines of the European Council Directive 82/711/EEC with two food simulants, i.e., 3% (v/v) aqueous acetic acid and 95% (v/v) aqueous ethanol. This selection encompasses all alcoholic, aqueous, and acidic foods. The elemental migration from the biocomposites in the aforementioned food simulants was conducted at 40 °C and 70 °Cin an oven at specific time intervals, followed by analysis on an inductively coupled plasma optical emission spectrometer (ICP-OES).

RESULTS AND DISCUSSION

The AgNP loading on the HH was confirmed through XRD analysis on the AgNP-loaded HH and the PLA and unfilled HH counterparts. The deconvolution of Ag planes in the XRD patterns of AgNP-loaded HH supported the presence of Ag in the filler. The mechanical properties of the 10 – 30 wt. % AgNP-loaded HH are near equivalent tothat of neat PLA, as confirmed from previous studies by the authors. The AgNP loading in HH showed no specific influenceon mechanical behaviour, as the strength and modulus of the AgNP-loaded HH/PLA were nearly similar to those of the as-received HH/PLA biocomposites.

The addition of HH and GMA often affect the recrystallization of the base polymer, with the HH acting as a nucleating agent, accelerating recrystallization, a desirable effect for realising faster production cycles. The retention of the Tg (~3.5% change), lowering of crystallisation temperature (~8 °C), and moderate change in melting temperature (~4.5 °C) with respect to the neat PLA preclude the need for heavy re-engineering of the processing and production of these biocomposites for commercial use.

The antibacterial activity was assessed against the gram negative E Coli, showing a distinct benefit of adding AgNP to the HH. The enhanced antibacterial activity was confirmed through a viable cell counting method of determining the colony forming units, and the AgNP-loaded HH/PLA composites showed a greater resistance to the formation and survival of E Coli at five successive concentrations, each increasing by an order of magnitude.

Table 2 shows the migrated amount of heavy metals from HH in food simulants at 70 °C for 48 hours. The migration values of heavy metals is practically negligible, and bears no health risk to food in contact. Thus, using HH, which is loaded with heavy metals in HH/PLA biocomposite does not have any effect on food safety because of high retention within the HH structure and consequent low migration to food.

Table 2. Migration of Heavy Metals in Food Simulants at 70°C after 2 Days

	Absorption (mg/kg)			
	Ni	Cd	Pb	Cr
Acetic Acid (3% v/v)	0.013	0.002	0.004	0.199
Ethanol (95% v/v)	0.012	0.002	0.003	0.147

Many heavy metals are capable of imparting antimicrobial activity in food packaging plastics. However, Ag as a nanoscale additive has emerged as an effective solution for a diverse range of plastics for this purpose. However, the main concern with the usage of nanoscale additive in plastics without encapsulation is the ready migration into foodstuffs, which causes adverse toxic effects on human physiology. The encapsulation of AgNP in HH specifically is a way of precluding excessive nanoparticle migration.

CONCLUSIONS

Poly(lactic acid) was compounded with hemp hurd and injection moulded as a biocomposite. Silver nanoparticles were introduced into hemp hurd to achieve additional antimicrobial activity. The mechanical and thermomechanical properties of the biocomposite with and without the silver nanoparticle loading on hemp hurd were comparable. The heavy metal and silver migration from the biocomposites into food simulants tested at standard conditions was determined to be within the safe limits as prescribed by regulatory authorities. Overall, a cost-effective biocomposite was produced from a biomass-based renewable resource and combined with a biopolymer, will provide a commercially viable, biodegradable solution for food packaging.

ABSTRACT

The incorporation of sustainability is becoming increasingly important in manufacturing practices worldwide. This includes the development of natural fibre composites with mechanical and flammability characteristics suitable for structural interiors. Composites manufactured from kenaf fibres and polypropylene (PP) were investigated as to their suitability as materials for the interiors of buildings, aircraft and such-like. Natural fibres like kenaf act as fuel sources during combustion, and hence, flame retardants are added to the mix. In the present study, the ammonium polyphosphate (APP)-based flame retardant Budit® 3167 was used to address this issue. Limited studies exist on how the inclusion of APP influences the composites' mechanical properties. Hence the main objective of this research project was to evaluate the effect of adding Budit 3167 on both mechanical and flammability properties of kenaf-PP composites. Kenaf-PP composites were manufactured with various fibre weight percentages, with and without Budit 3167. The composites were subjected to different experiments to assess their mechanical and flammability behaviour. It was found that Budit 3167 not only improved the flammability properties of the composites, but also the tensile and flexural moduli due to the flame retardant behaving like a particle reinforcement. However, weak interfacial bonds arising from the addition of Budit 3167 led to a decrease in mechanical strength, providing a basis for further investigation. It was concluded that kenaf-PP composites with Budit 3167 show good potential as a sustainable alternative for structural interiors.

Kenaf-polypropylene composites, APP flame retardant, Budit® 3167, mechanical properties, fire performance.

INTRODUCTION

There is growing interest in the use of natural fibre reinforcements in polymer composites. The traditional composites that are synthetic fibre-based with a thermoset matrix are difficult to recycle after their designed service life (Rai and Jha 2004). Recent developments in natural fibre composites have influenced its use in structural and infrastructural applications. For instance, natural fibre composites have been used to develop load-bearing elements such as beams and multipurpose panels. The attraction of using natural fibre composites in beam development is driven by the lower density of natural fibres, lower cost and environmental benefits (Ticoalu et al. 2010). Natural fibre composites offer high specific strength, high specific stiffness, low weight, recyclability and renewability. However, there are concerns around their structural strength and stiffness, as well as flammability requirements for the material. Past studies such as Sobczak et al. (2012) on natural fibres have shown that they possess comparable specific mechanical properties to synthetic alternatives, indicating reinforcement potential. However, natural fibres represent an additional fuel source for combustion (Ohlemiller et al. 1993; Chai et al. 2012), and therefore, natural fibre composites have been known to perform poorly in flammability testing. In order to satisfy flammability requirements, a potential solution is the incorporation of flame retardants. Various studies have been carried out using a wide range of flame retardants applied to natural fibre composites, showing positive results (Jeencham et al. 2010; Suppakarn et al. 2009). However, there has been a lack of studies on how the inclusion of flame retardants within natural fibre composites affect the composites' mechanical and structural properties.

This paper describes a final year undergraduate research project in mechanical engineering which examined how the inclusion of flame retardants affects the mechanical and flammability properties of natural fibre composites. The project focused on evaluating composites constructed with kenaf as the fibre reinforcement and PP as the matrix. MAPP and APP-based Budit 3167 have been used as the compatibiliser and flame retardant, respectively.

The work began with research and experiments to determine optimal processing procedures and parameters for the manufacture of the composites. Once determined, composites were manufactured with and without the flame retardant, and experiments were conducted to evaluate the performance of the composites. An important aim of the project was to determine if there is a relationship between the input materials for the natural fibre composites, when evaluated for their mechanical and flammability properties.

Project Objectives and Outline

Table 1 presents an overview of the project. The main objective was to evaluate how the inclusion of an APP flame retardant affects the mechanical and flammability properties of kenaf-PP composites. This was broken down into the following aspects:

- To evaluate the effects of various kenaf fibre weight percentages as a reinforcement for a PP matrix, with MAPP as a compatibiliser to improve interfacial bonding.
- To assess the mechanical and flammability properties of the kenaf fibre-PP composite.
- To evaluate the effects that an APP flame retardant has on a kenaf-PP composite's mechanical and flammability properties.
- To test various compositions of kenaf and PP, while keeping MAPP and APP fixed. This was to assess whether these have any relationship to the mechanical and flammability properties of the composite.

Table 1 Project overview

	Description	Main Processes	Blends (wt%) (with nomenclature)
Stage 1: Determination of machinery	Establishing fibre length retention of the available extruders	Extrusion, soxhlet extraction, fibre length analysis	30% kenaf; 4% MAPP; 66% PP
Stage 2: Setting the control standard	Creation of specimens without flame retardants	Extrusion, injection moulding	0% kenaf; 0% MAPP; 100% PP (K0)
			25% kenaf; 4% MAPP; 71%PP (K25)
			30% kenaf; 4% MAPP; 66% PP (K30)
			35% kenaf; 4% MAPP; 61% PP (K35)
Stage 3: Adding the flame retardant	Addition of APP-based Budit 3167 flame retardant to the specimens	Extrusion, injection moulding	0% kenaf; 0% MAPP; 30% APP; 70% PP (K0F)
			25% kenaf; 4% MAPP; 30% APP; 41% PP (K25F)
			30% kenaf; 4% MAPP; 30% APP; 36% PP (K30F)
			35% kenaf; 4% MAPP; 30% APP; 31% PP (K35F)
Stage 4: Testing and analysis	Determination of mechanical and flammability properties of the specimens	Tensile, flexural, Charpy impact, drop tower impact, vertical burn and cone calorimeter testing	All injection moulded blends
Stage 5: Analysis of composite's mechanisms	Further evaluation of the composites to better understand their mechanisms	Scanning electron microscopy and differential scanning calorimetry	All composite blends and the constituent materials

MANUFACTURE OF TEST SPECIMENS

To study the effects of a flame retardant on the composites' mechanical and flammability properties, a control standard first needs to be set by manufacturing specimens without the flame retardant. Specimens manufactured with the addition of the flame retardant can then be compared to the standard. Four constituent materials were used for the production of the test specimens, as shown in Table 1. The parameters selected for the compositions were based off the best results, as identified in the literature review, to achieve desirable properties. Two independent parameters were isolated for the production of the test specimens. These were the flame retardant and MAPP content, set to 30 wt% (El-Shekeil et al. 2012) and 4 wt% respectively. Test specimens with kenaf fibre loadings of 25 wt% and 35 wt% were also manufactured.

Materials Procurement

The Moplen HP400L polypropylene was supplied by Lyondell Basell Australia. This PP is a moderate melt flow homopolymer, designed for injection moulding applications. Its characteristics are summarised in Table 2.

Table 2 Characteristics of Moplen HP400L PP

Density (g/cm^3)	Melt flow index (g/10min)	Tensile modulus (GPa)	Flexural modulus (GPa)	Impact strength[A] (kJ/m^2)	Softening temperature[B] (ºC)
0.9	5.5	1.3	1.4	3.0	155

[A]Notched Izod impact test; [B]Vicat softening temperature

Jute-Bangladesh Ltd. supplied the kenaf fibres. The characteristics of kenaf are shown in Table 3. The maleic anhydride grafted polypropylene, TP Licocene PP MA 6452, was purchased from Clariant International Ltd. This grade of MAPP is specially formulated for natural fibre composites reinforced in PP. The ammonium polyphosphate based flame retardant, Budit® 3167, was manufactured by Budenheim Ibérica Comercial. It is an intumescent mixture, optimised for use with PP and PE. Budit 3167 has a decomposition temperature above 250ºC and a bulk density of 0.47 g/cm^3, as per the technical data sheet.

Table 3 Characteristics of kenaf fibres (Akil et al. 2011)

Density (g/cm^3)	Tensile strength (MPa)	Tensile modulus (GPa)	Tensile elongation (%)	Cellulose content (%)
1.44	930	53	1.6	45 – 57

Material Preparation

Before the constituent materials could be compounded together using an extruder, a degree of preparation was required. In general, the finer the constituent materials, the better the opportunity for mixing. This leads to a more homogeneous material. The PP came in a large granular form and therefore, to achieve better dispersion, it was outsourced to be professionally granulated into fine particles. The kenaf came in a yarn form and thus, needed to be processed into a more suitable state. The kenaf yarns were firstly cut using a LabTech Scientific pelletiser into lengths between 20 – 30 mm. These fibres were then taken and fine cut using a Webner granulator with a fine mesh, achieving lengths between 3 – 4 mm. The flame retardant and MAPP both came in fine particle forms which were directly usable.

Natural fibres are prone to moisture absorption. Moisture content greatly affects the performance of natural fibre composites, lowering their mechanical properties. With the intention of producing a natural fibre composite with good mechanical properties, drying the kenaf fibres prior to compounding was a critical stage in the manufacturing process. The kenaf fibres were dried overnight at 80°C prior to extrusion. A moisture analysis showed that the moisture content decreased from 11.0% to 3.3%. In general, increasing the fibre content significantly increases the composite's stiffness and strength but also increases the moisture content uptake (Lee et al. 2013). The moisture content at a given relative humidity can have a great effect on the performance of natural fibre composites, lowering its mechanical properties (Helwig and Paukszta 2000). The moisture content and rate of accumulation is directly related to the ambient relative humidity and therefore, drying the natural fibres prior to processing is a significant step (Robertson et al. 2013).

Extrusion

The constituent materials were first premixed by hand and then intensively mixed with the use of a high speed mixer, set to 21 Hz and turned on for periods no longer than 2 minutes at a time. It was critical that the speed and duration did not exceed these parameters as MAPP is prone to melting. The constituent materials were compounded using a LabTech Scientific co-rotating extruder with kneading blocks. The temperature profile utilised started at 165°C near the hopper, and ended at 185°C near the die, increasing in steps of 5°C. It was essential to heat up the materials gradually due to the poor thermal conductivity of PP. This allowed heat to conduct into the material without first degrading the exterior. The temperature profile was also not to exceed the kenaf fibre degradation temperature, identified as around 200°C. Only the temperature of the die exceeded this limit. It was set to 210°C to lower the pressure build up in this area. With the entire extruder set to a speed of 185 rpm, residence time was generally short for all areas (especially in the die), reducing the risk of degradation. It was also ensured that the melt temperature did not exceed 185°C at any point within the extruder. The extrudates were cooled on a conveyor belt with fans and pelletised using a LabTech Scientific pelletiser. The pelletised

extrudates were dried overnight at 80°C prior to injection and compression moulding, adhering to best practices to achieve desirable properties for the specimens produced.

Injection Moulding

Specimens manufactured via an injection moulding process may not produce the best properties, as the extrusion processes are known to reduce the kenaf fibre length. However, this process is representative of how many structural interior components are currently produced and thus, will allow the results to be more applicable to the manufacturing industry. Various types of specimens were injection moulded at 180°C using a Procan CT injection moulder. Specimens compliant with a range of standards were created for tensile, flexural, impact, vertical burn and cone calorimeter testing. A strict procedure was followed in order to prevent contamination.

Compression Moulding

Another method of producing parts for structural interiors is through compression moulding. This process is less common due to factors such as lower production rates and larger inconsistencies. However, compression moulding requires smaller capital investment and therefore, is at times utilised for the production of low quantity, non-critical parts where it is not feasible to manufacture costly injection dies. Even though one of the benefits of compression moulding is fibre length retention, the pelletised extrudates were utilised for the purpose of comparison. Specimens were produced for the drop tower impact test using a 10 tonne hydraulic press and a customised die.

EXPERIMENTAL METHODOLOGY

A wide range of experiments, tensile, flexural, Charpy impact, drop tower impact, vertical burn and cone calorimetry, were conducted on the test specimens manufactured. This was done to evaluate the performance of and to gain a clearer understanding of how the inclusion of an APP flame retardant affects the composites' mechanical and flammability properties. All the test specimens were conditioned at 23°C and 50% humidity for a minimum of 72 hours prior to testing, in accordance with ASTM International standard D618-13: Standard Practice for Conditioning Plastics for Testing. Due to the random orientation of the kenaf fibres, the composites were assumed to be isotropic materials. To simplify analysis, the direction of injection moulding was ignored. In addition, differential scanning calorimetry (DSC) and scanning electron microscopy (SEM) analyses were also conducted to better understand the mechanisms behind the composites' behaviour. However, due to space limitations, only the flexural, Charpy impact, vertical burn and some of the cone calorimetry results are discussed in the present instance.

Flexural Test

Flexural tests were carried out in accordance with ASTM D790-10: Standard Test Methods for Flexural Properties of Unreinforced and Reinforced Plastics and Electrical Insulating Materials. Dog bone test specimens manufactured through the injection moulding process were tested on an Instron 1185 universal testing machine with a 1 kN load cell. Five specimens of each blend were tested, with the crosshead speed set to 13 mm/min.

Charpy Impact Test

Charpy impact tests were carried out in accordance with ASTM D6110-10: Standard Test Method for Determining the Charpy Impact Resistance of Notched Specimens of Plastics. Bar specimens manufactured through the injection moulding process were prepared using a notch cutter and tested on a Charpy impact machine. Five specimens of each blend were tested.

Vertical Burning Test

Vertical burning tests were carried out in accordance with Underwriters Laboratories flammability standard UL94: Standard for Tests for Flammability of Plastic Materials for Parts in Devices and Appliances. Bar specimens manufactured through the injection moulding process were held vertically and the bottom ends exposed to a laboratory Bunsen burner flame at 45°C. Each specimen was ignited for a period of 10 seconds. If the flame self-extinguished, the specimen was ignited an additional time for 10 seconds. The time taken for the flame to extinguish was recorded. If the flame did not self-extinguish, the test was terminated after 60 seconds. This is because such a specimen has essentially failed to meet any of the ratings. The events during the burning process were also documented, in particular, whether there was burning char, glow or falling material. The aim

was for the specimens to achieve the highest rating, UL94 V-0. To achieve this, the flame must self-extinguish in 10 seconds or less, no glow beyond 30 seconds and no material should fall.

Cone Calorimeter Test

To better understand the flammability characteristics of the composite blends manufactured, cone calorimetry tests were carried out in accordance with ASTM E1354-13: Standard Test Method for Heat and Visible Smoke Release Rates for Materials and Products Using an Oxygen Consumption Calorimeter. The 100 mm diameter injection moulded specimens were tested on the FTT cone calorimeter. Utilising a heat flux of 50 kW/m^2, the cone calorimeter was able to determine important burn properties such as the ignitability, heat release rate (HRR), mass lost rate and development of smoke and other by-products. This test method is based on the observation that the net heat of combustion is directly related to the amount of oxygen required for combustion. Three specimens of each blend were tested. To increase accuracy, the required measurements were inputted individually for each specimen. Furthermore, every specimen underwent a calibration process prior to testing.

RESULTS AND DISCUSSION

Flexural Tests

The flexural tests determined the flexural modulus and maximum flexural stress of the composite specimens. These are summarised in Figures 1 and 2, while Figure 3 shows the legends for these and later figures that present results for composites with and without the fire retardant.

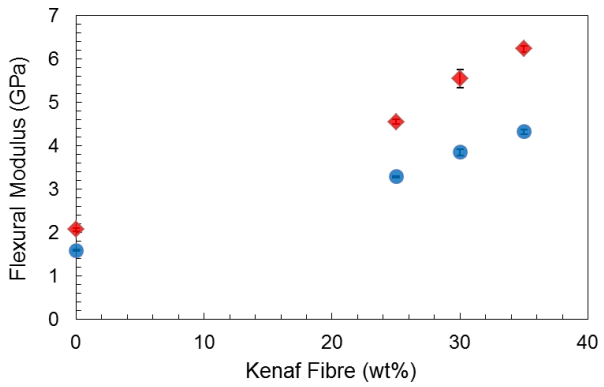

Figure 1 Flexural modulus vs fibre content

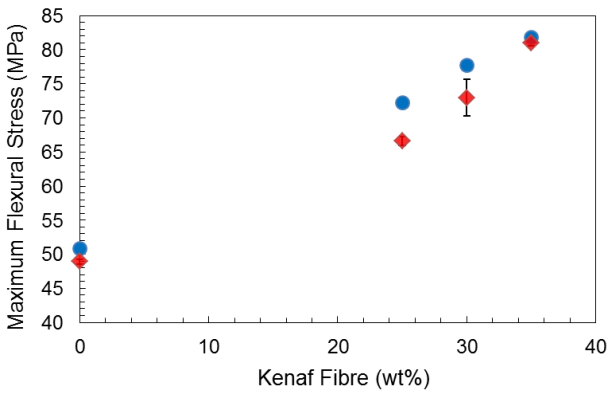

Figure 2 Maximum flexural stress vs fibre content

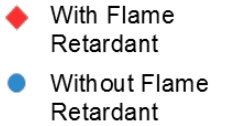

Figure 3 Legend for figures-1

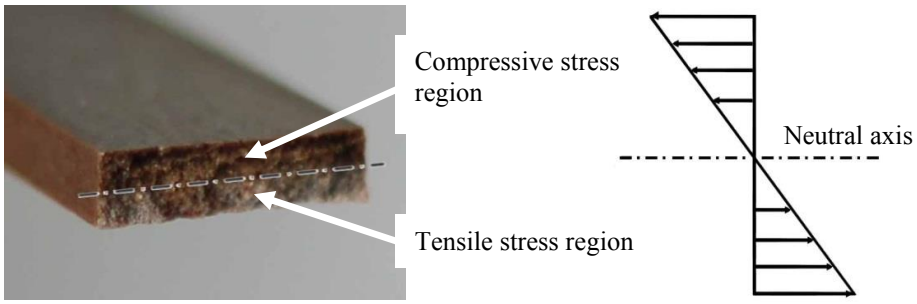

Figure 4 Flexural fracture surface showing two distinct regions

The following trends can be observed from the flexural tests:
(i) Increase in the composites' flexural properties, in terms of both flexural moduli and maximum flexural stress, as kenaf fibre loading increases;
(ii) Addition of the flame retardant increases the composites' flexural moduli between 38.7% to 44.2%;
(iii) Addition of the flame retardant decreases the composites' maximum flexural strength between 1.6% to 7.7%.

Kenaf fibres have superior mechanical properties compared to PP; hence the increase in both flexural modulus and maximum flexural stress with increasing fibre content. Adding the flame retardant further increases the flexural modulus, as the flame retardant acts like a particle reinforcement within the elastic region of the test, and

also, more PP is displaced. However, with regard to the maximum flexural stress, specimens without the flame retardant have better properties. The flexural test consists of both tensile and compressive components, as shown in Figure 4. Within the tensile part of the specimens, the weak bonds between the flame retardant and PP break in the plastic region of the test, resulting in the creation of micro voids and thus reducing the cross-sectional area able to withstand the imposed loading. (This isn't the case in the compressive part of the specimens). However, as the fibre content increases, this difference between the specimens without the flame retardant and those with the flame retardant is reduced. This is because the increased fibre percentage is able to withstand more of the load, thus compensating to some extent the loss of bonding between the flame retardant particles and the matrix, and also the micro voids created. In addition, the amount of PP is also reduced with increasing fibre fraction.

Charpy Impact Tests

The results from the Charpy impact test (Figure 5) show one distinct trend; the large reduction in impact resistance
with the addition of the flame retardant. This decrease in impact resistance is primarily due to the displacement of 30 wt% PP resulting from the addition of flame retardant particles. PP is the primary constituent material providing the composites with ductility and is therefore effectively responsible for the composites' impact resisting properties.
The effect of the flame retardant on the composites' ductility is highlighted in the flexural (and also tensile) tests. Prior to adding the flame retardant, the composite specimens do not fracture before 5% flexural strain. However, after adding the flame retardant, the kenaf blend specimens fracture at a flexural strain between 2.0% to 2.7%.

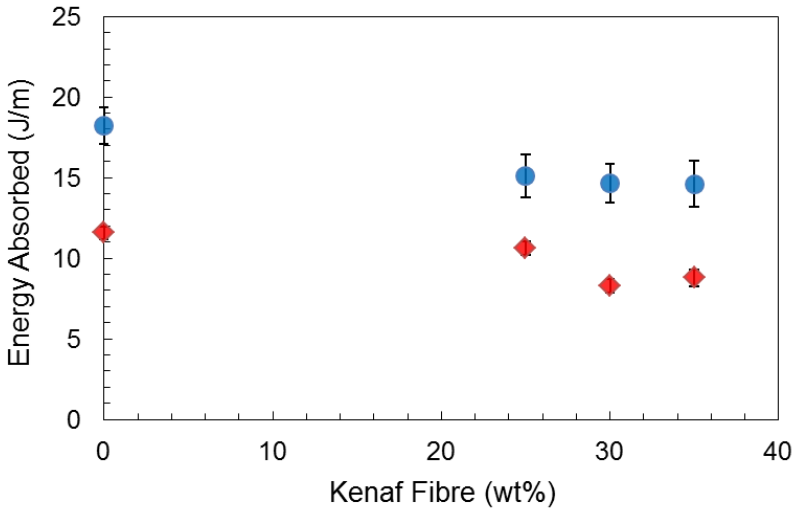

Figure 5 Charpy impact test results

The flame retardant particles act as reinforcements within the elastic region and thus, increase both the tensile and flexural moduli of the composites. This increase in tensile and flexural moduli correlates to a decrease in impact resistance of the composites. The flame retardant particles are essentially brittle materials, thus the large reduction in impact resistance once they are added. When the kenaf fibres are added, MAPP is used to enhance the interfacial bonding between the fibres and the PP, resulting in more effective load transfer. This explains why the drop in impact resistance between the specimens with and without kenaf fibre loading is less significant, when there is a PP reduction between 25 wt% to 35 wt%.

Vertical Burning Tests

The effect of kenaf fibre loading and the addition of the flame retardant on the composites' self-extinguishing abilities are summarised in Figure 6. The two horizontal lines indicate the benchmarks the worst performing specimen is required to be under for the blend to achieve the rating given by the line. The results show that the addition of the flame retardant significantly improves the composites' self-extinguishing fire properties. All the specimens without flame retardants failed to self-extinguish in less than 60 seconds and therefore, did not meet any of the UL94 ratings. Furthermore, burning material fell from all these specimens during the vertical burn test as shown in Figure 7, a very undesirable trait. The specimens with flame retardant performed much better, with only one blend, K25F, failing to achieve a UL94 rating. The Budit 3167 flame retardant is designed for PP.

Hence the fact that blend K0F passed the highest rating, with no specimens igniting during any of the tests, is not surprising. Blend K30F performed extremely well, with the worst specimen self-extinguishing in 9 seconds and therefore, also achieving the highest rating of UL94 V-0. Based on the poorest performing specimen self-extinguishing in 26 seconds, blend K35F achieved the second highest rating of UL94 V-1. Even though blend K35F did not pass with the highest rating overall, it should be noted that there were some specimens within this blend that, independently, would have achieved the UL94 V-0 rating. This variation is likely to be due to factors such as human error, for instance, and inconsistent burning and re-ignition times. Ignition occurs when there is a sufficient level of heat energy transferred to the specimens (Helwig and Paukszta 2000; Babrauskas and Peacock 1992). The UL94 vertical burn test stipulates that each specimen shall be ignited for 10 seconds, allowed to self-extinguish, then re-ignited for another 10 seconds. There is no mention of a wait period between when the flame self-extinguishes and re-ignition, and therefore, it was assumed to be instantaneous. This led to problems when the specimens did not cleanly self-extinguish, resulting in inconsistent re-ignition times. If specimens do not conduct sufficient levels of heat energy required for ignition, they will not ignite. During the down time before re-ignition, heat energy dissipates from the specimens. Therefore, if re-ignition is not instantaneous, heat energy is lost. The second period of ignition will build upon the existing levels of heat energy, and in most cases, induce ignition within the specimens. The variation in the results suggests that there is a fine line between the amount of heat energy required for some specimens, and the total amount of heat energy available in 20 seconds of ignition. As such, the loss in heat energy during the down time is likely to be influential.

Cone Calorimeter Tests

The cone calorimetry analysis determined the effect of kenaf fibre loading and the addition of the flame retardant on the composites' flammability-related properties. Numerous flammability characteristics were evaluated from the cone calorimetry test, some of which are discussed here. The heat release rate (HRR) results are illustrated in Figures 8 and 9. (Figure 10 shows the legend for these and other figures where composite blends are plotted against time as the independent variable). These two figures show two distinct trends once the flame retardants are added. The first is that the composite blends have a reduction of more than 50% in their peak HRRs. The second is that HRRs around 200 kW/m^2 are sustained for longer durations.

It is clear from Figure 8 that the composite blends form two separate groups, with the point of difference attributable to the addition of the flame retardant. Even though the peak HRRs of the blends containing flame retardants are lower, a moderate HRR was sustained for a longer duration and therefore, it is difficult to justify which is preferred. Calculation of the area under the HRR curves for each blend gives the total heat released (THR), providing a means of direct comparison, as shown in Figure 11. A large reduction in the THR is seen for the kenaf fibre blends once the flame retardants were added. This is because 30 wt% of PP, a combustible constituent, has been displaced by the flame retardant. The APP based flame retardant also has various flame retarding mechanisms which lower the HRR and thus, the THR (Xu et al. 2013). An inconsistent trend is seen for the blends without kenaf fibres, K0 and K0F. The THR of K0, the non-flame retardant blend, is actually lower than the blend with the flame retardant, K0F. Upon inspection of the events during the tests for K0, it was found that significant dripping occurred. This means a loss of material, explaining the inconsistent trend and

large variation in data. Due to this factor, data relating to blend K0 should be viewed with caution. The results of time to ignition (TTI) are summarised in Figure 12. These results show that the TTI increases for the kenaf blends once the flame retardants are added. This is due to the flame retarding mechanisms of the Budit 3167 flame retardant. Subject to high levels of heat, the flame retardants' first mode of action is the release of non-combustible gases. These gases form a blanket, preventing the access of oxygen to the composite (Xu et al. 2013) and therefore, delaying the TTI.

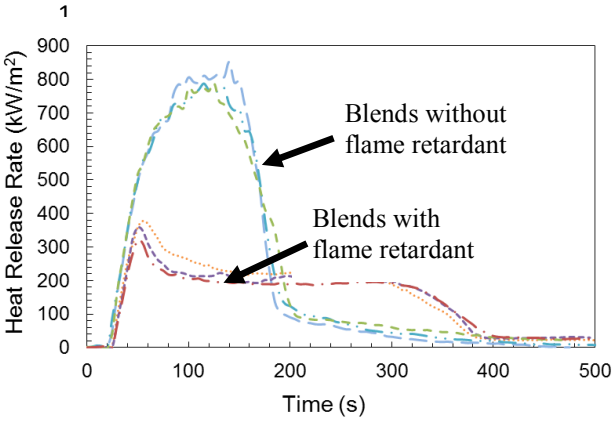

Figure 8 HRR of blends with kenaf fibres

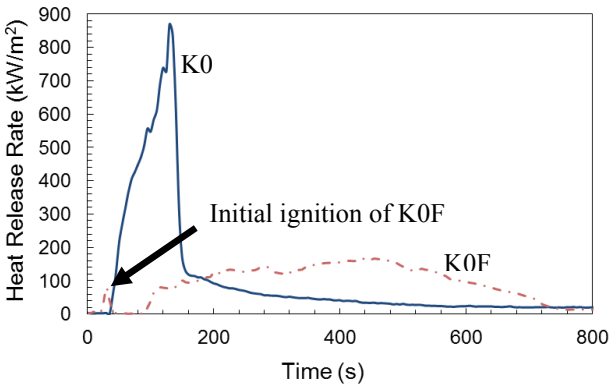

Figure 9 HRR of blends without kenaf fibres

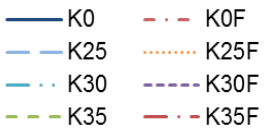

Figure 10 Legend for figures-2

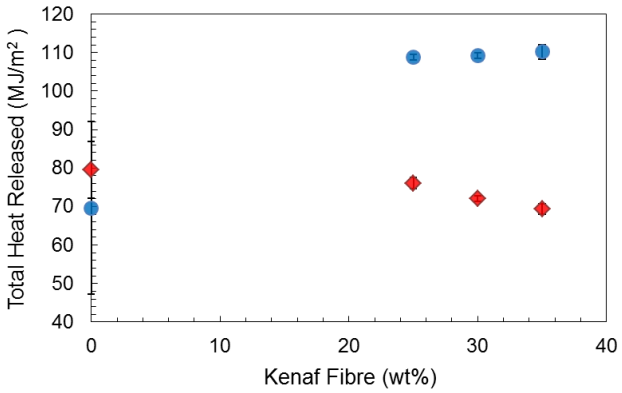

Figure 11 Summary of total heat released

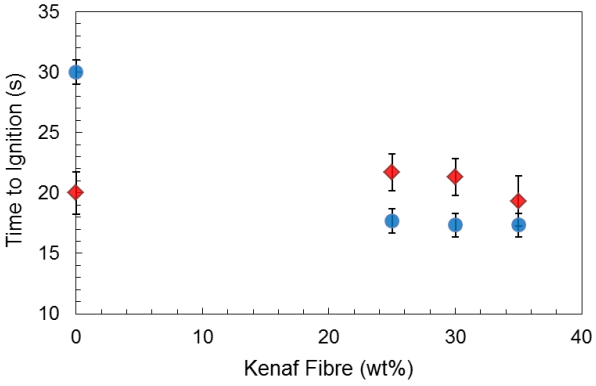

Figure 12 Summary of ignition times

The TTI decreases significantly once kenaf fibres are added to the composites without flame retardants. This is due to the poor thermal stability of natural fibres such as kenaf, inducing ignition. This trend is reinforced by a study conducted by Kozlowski et al. (Kozłowski and Władyka-Przybylak 2008). Kenaf fibre blends have lower TTIs than neat PP, even with the addition of flame retardants. This highlights the significance of the kenaf fibres' poor thermal stability on the overall composite.

The results for the blends without kenaf fibres reversed the trend that the addition of flame retardants increases the TTI. Once flame retardants are added to the pure PP blend, the composites' TTI decreases significantly. This is due to the flame retardants' second mode of flame retarding action, the formation of a char layer (Xu et al. 2013). During the initial stages of heating, heat energy is transferred to the surface of the composites quickly. The rate of heat transfer between the heat source and the composites' surface is much greater than the composites' ability to conduct the heat towards its interior. Coupled with the flame retardants, this forms a char layer. This char layer prevents both heat and oxygen from accessing the interior of the composites. This observation is reinforced in a study conducted by Su et al. (2012).

Another important flammability characteristic of the composites is the production of smoke and other gases. This is because most fire related deaths are due to the inhalation of combustion gases and particulates (Price et al. 2001). The smoke production rates (SPR) of the composites are shown in Figures 13 and 14. Once the flame

retardants are added, the SPR results show two distinct trends. The first is the reduction of the SPR peaks and the second is that SPRs around 0.035 m^2/s are sustained for longer durations, similar trends to those of the HRRs.

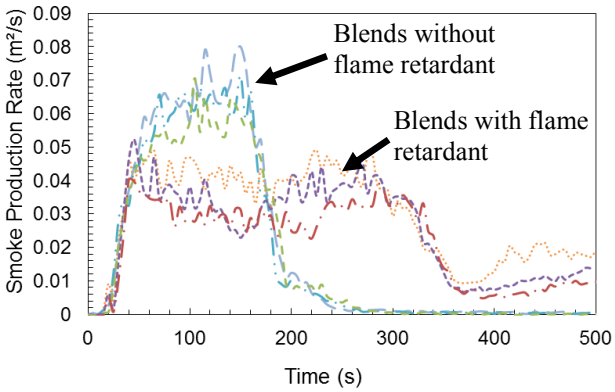

Figure 13 SPR of blends with kenaf fibres

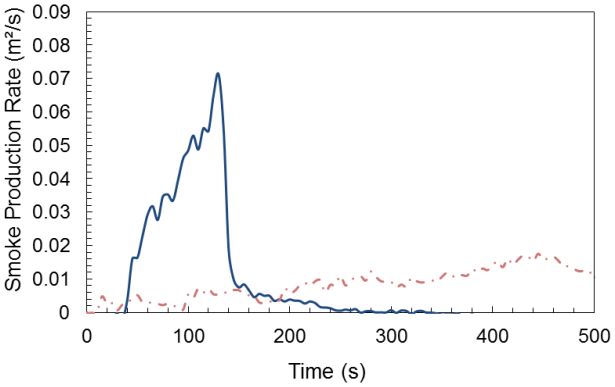

Figure 14 SPR of blends without kenaf fibres

Like the HRRs, two separate groups are formed, with the point of difference attributed to the addition of the flame retardant, as shown in Figure 13.Calculation of the area under the SPR curves gives the total smoke production (TSP), providing a means of direct comparison, as shown in Figure 15. An increase in the TSP is seen with the addition of the flame retardants, a trend opposite to that of the THR. This is due to the flame retardants' first mode of action, the release of non-combustible gases. The FTT cone calorimeter measures smoke production by utilising a light extinction method within a controlled duct and these gases affect the measurements. The TSP increases significantly once kenaf fibres are introduced to the composites. This is because of the volatile organic compounds within the kenaf fibres. When kenaf plants are living, they contain sap and other volatile hydrocarbons within their cells. These remain in the kenaf fibres unless a process has been carried out to remove them (Ismail et al. 2010). The kenaf fibres utilised had not undergone any process to remove the volatile organic compounds and therefore, the presence of these volatile organic compounds within the kenaf fibres explains the increase in TSP.

CONCLUDING REMARKS

Through the experimental results obtained, the following conclusions are drawn for the kenaf - PP composites evaluated:

- Budit 3167 flame retardant of 30 wt% improves the composites' tensile and flexural moduli; however, it reduces the composites' tensile, flexural and impact strengths.
- Budit 3167 of 30 wt% improves the kenaf - PP composites' flammability properties.
- Increases in kenaf fibre loading results in better tensile and flexural properties; however, they lead to decreases in impact properties of the composites.
- Increases in kenaf fibre loading results in a decline in flammability properties of the composites.
- No clear relationships were observed between the mechanical and flammability properties of the composites.

CRITICAL THINKING ON EFFLORESCENCE IN ALKALI ACTIVATED CEMENT (AAC)

Zuhua Zhang [1*], John L. Provis [2], and Hao Wang [1]

ABSTRACT

Alkali-activated cement (AAC), also known as "geopolymer", has been extensively investigated over the past 40 years and has been developed from laboratory mock ups to real structural usage in construction in the last decade. While numerous life cycle analyses and carbon accounting studies show the "green potential" of this material compared to Portland cement, some authors state that the high alkali concentration in AAC is a potentially unstable factor which may lead to, for example, efflorescence. This paper presents a critical thinking on the literature and some new experimental work regarding the possibility of efflorescence in AAC products. Subjects of the discussion include: (1) the role of alkalis in AACs, (2) the effect of alkali concentration on efflorescence, (3) the effect of solid precursor selection on efflorescence, (4) the effect of curing scheme and chemical additives on efflorescence, and (5) the impacts of efflorescence on the microstructural properties of AACs. Particular attention is given to the relationship between pore structure and efflorescence behaviour, and consequently the mechanical properties of AACs suffering from either efflorescence or alkali loss (by leaching). The changes in sodium aluminosilicate hydrate (N-A-S-H) gels due to efflorescence or alkali loss are critical to the durability of AACs. This paper emphasizes that the nature of the solid precursor and the pore structure of the resulting AAC are the two most important factors that control efflorescence rate. However, considering its alkaline nature, it seems difficult or impossible to avoid this issue in AAC products, although kinetically controlled diffusion of alkalis using phase transformation techniques may help to mitigate efflorescence. Efflorescence in AAC is a "skin issue" that needs to be carefully treated. It is recognized to be different from the visually similar, but chemically distinct, efflorescence that occurs in Portland cement based materials.

KEYWORDS

Alkali-activated cement (AAC), geopolymer, efflorescence, carbonation, durability.

INTRODUCTION

Alkali-activated cement (AAC) technology has shown potential in converting solid industrial wastes into greener cement. The environmental benefit of applying AAC technology mainly lies in the reduction of CO_2 emissions and energy consumption, which are issues of wide concern for the sustainable development of the cement and concrete industries (Damtoft *et al*. 2008). McLellan *et al*. (2011) pointed out that the unit emissions of greenhouse gas in making AAC binder depend on the source location, the energy source and the mode of transport. The counting of the four mixtures using typical Australian fly ashes indicated potential for a 44–64% reduction in greenhouse gas emissions. More recently, Heath *et al*. (2014) showed that AAC manufacture can reduce CO_2 emissions by about 40% when clay minerals are used to replace the widely used fly ash and slag. These have been the main forces driving the current research and development of AAC.

The use of AAC to fabricate concretes is still rare in industry compared to normal Portland cement concretes. Apart from the challenges in supplying consistent raw materials and the cost issues, there are still a variety of technical problems remaining, either unclear or un-solved (van Deventer J.S.J. et al., 2012). Efflorescence is one such problem which has been raised as a concern in some AAC formulations and this has been discussed briefly by Bernal et al. (2014), and more recently, systematically investigated by Zhang et al. (2014).

Looking back to efflorescence occurring in Portland cement based masonry and concrete, the most common efflorescence is formation of calcium carbonate, which involves six basic and coupled processes: dissolving of CO_2(g) in H_2O at air-water interface on the surface of products, conversion of CO_2 to aqueous species, release of alkali(s), dissolution of $Ca(OH)_2$, diffusion of reactants through solution and precipitation of calcium carbonate (Dow *et al*. 2003). The products are whitish, structurally harmless but aesthetically undesirable. To avoid and mitigate efflorescence, the first principle is to reduce the alkali concentration of cements so as to reduce the solubility and absorption rate of CO_2 from the ambient environment (Dow *et al*. 2003). However, in AAC systems, the concentrations of Na and K usually contain much higher soluble alkali metal concentrations than conventional cement. Burciaga-Díaz *et al*. (2010) mentioned that alkali-activated slag based materials show significant efflorescence and some have also shown negative impacts on the mechanical properties of the binders. It must be noted that alkali-activated slag contains higher concentration of calcium than alkali-activated metakaolin and fly ash systems, and this may lead to certain differences in the specific effects of efflorescence. Škvára *et al*. (2012) reviewed 25 fly ash-based mixes and reported that the total alkali content required in fly ash based AAC binders to meet reasonable workability and mild curing (>50°C) for strength development mainly ranges from 30 to150 g/kg (expressed as Na_2O to total mass of paste), which is 8.4 to 42 times higher than in Portland cement paste (assuming 0.5% Na_2O in cement and w/c = 0.4 for paste). This raises particular attention to the efflorescence issue in the application of AAC.

In literature and in our previous investigation, observations of many AAC mixes did find efflorescence that rapidly occurred on drying surfaces when samples were in contact with water and under highly humid atmosphere conditions. A number of factors have been reported to affect the extent of efflorescence in AAC: alkali metal type (Škvára *et al*. 2009; Škvára *et al*. 2012), raw materials (Temuujin *et al*. 2009; Najafi Kani *et al*. 2012) and reaction conditions (Burciaga-Díaz *et al*. 2010; Najafi Kani *et al*. 2012; Zhang *et al*. 2014).

The aim of this paper is to briefly discuss the results found in literature and our current experiments (not yet published). The role of alkalis in AACs (low calcium systems) and the effect of alkali concentration on efflorescence are discussed. Particular interest is given to the different efflorescence behaviours of AACs that were prepared with fly ashes sourced from different power stations. The suggestions are made based on the understanding of the effect of the curing scheme and chemical additives on efflorescence. The importance of this issue is highlighted by the observations of the microstructural properties of AACs which were subjected to efflorescence.

FACTORS AFFECTING EFFLORESCENCE

Roles and States of Alkalis in AACs

An AAC is usually formed by the reaction between the two parts of materials: an alkali activator and a reactive aluminosilicate precursor, which are usually metakaolin and fly ash or their blends. Slag is also very common in AAC manufacture but it can form high calcium gels, which are substantially different to low calcium gels that are formed in the AAC systems discussed. In this paper we mainly focus on the low calcium systems. There have been plenty of research into the molecular structure of AAC gels, a three-dimensional alumino-silicate network configured with SiO_4 and AlO_4 tetrahedrons and by oxygen bridges, with positive ions (Na^+, K^+) present to compensate the negative charge of Al that is present in coordination 4. This role is widely accepted and generally agreed on in most literature. However, there are some differences regarding the state of alkali metals.

According to Duxson et al. (2005), sodium has two states, with one present with aluminium inside gel structures and the other present in pore solutions, neutralizing the charge of $Al(OH)_4^-$ group. In other words, sodium can partially form Na-O-Al(Si) in gel structure, in which the Na-O bond is relatively intense, and partially form $Na(H_2O)_n^+$, in which Na is weakly associated with water molecules. This is in agreement with the leaching result and deconvolution of ^{23}Na MAS NMR spectra for alkali activated fly ash (Fernández-Jiménez *et al*. 2009). If it is assumed that the Na-O in gel structure is relatively stable in hydration conditions (contact with water molecules), similar to the Na-O in dehydrated zeolite, the soluble sodium must be limited, i.e. a certain fraction of sodium ions cannot be readily leached. Najafi Kani *et al*. (2012) ground AAC pastes (could be very fine) and used the stable leaching method at a water to solid ratio of 20:1 and reported that after 24 h the leached alkali is 1-7%, depending on the Si/Na and Na/Al ratios. Zhang *et al*. (2014) crushed alkali activated fly ash pastes into 1.25-1.5 mm particles, used the stable leaching method at water/solid ratio of 25:1 and found that after 24 h the leached sodium is 12-16%, depending on the activator type, curing temperature and slag replacement. These results are in agreement with the above hypothesis.

Škvára *et al*. (2012) crushed AAC pastes into particles under the size of 0.5 mm and used the dynamic leaching method (regularly change leaching solution with fresh water) and found that the alkalis can be almost completely leached from the binder after 150 days. In comparison with zeolite leaching behaviour (usually extremely slow in water), they concluded that the alkalis (Na and K) were only weakly bonded in the form of $Na(H_2O)_n^+$. This might not be true. Lloyd *et al*. (2010) measured the alkali concentration in the extracted pore solutions of typical alkali activated binders with 7% Na_2O provided from activator. If we assume that all of the sodium presents in the form of $Na(H_2O)_n^+$ in pore solution, and furthermore we assume that in 100 g binder, the pore water (free water) is 10 g and the structural water is 5 g, the sodium concentration is estimated to be higher than 20000 mM, which is far from the measured values of Lloyd et al. (2010), 600 to 1600 mM for the alkali activated fly ash systems. In fact, it is well known that the alkalis bound in zeolite frame structure may have different states, and each state having its own ion exchange capacity. Therefore, we state here the hypothesis that alkalis in AAC have different states (more than the two discussed above), and each state has its own leaching rate.

Nevertheless, a large amount of the alkalis are highly moveable, either due to the excessive utilization of activator or the inherent neutralization of $Al(OH)_4^-$ in pore solution, or both; hence the efflorescence can be potentially intense for AACs.

Effect of Alkali Concentration on Efflorescence

The results obtained by Najafi Kani *et al*. (2012) showed that the extent of leaching alkalis increased with Na/Al increasing from 0.61 to 1.23, and the severity of efflorescence of dry samples after immersion also increased. Fig.1 shows our current experiments of examining efflorescence rate on two fly ash-based AACs, GP(L) and GP(H), which were prepared by the activation of sodium silicate solution at different dosages: GP(L) contained 3.9% Na_2O (expressed as Na_2O to fly ash mass ratio, excluding the Na_2O originating from fly ash) while GP(H) contained 4.6% Na_2O. In GP(L) mixing a small amount of additional water was used to achieve similar workability as GP(H). The samples were cured in sealed moulds, initially 24 hours at RH = 90 ± 10%, 25 ± 1°C, followed by 12 hours curing at 75 ± 1°C and naturally cooled down to 25 ± 1°C and allowed further 7 days of ageing. Specimens were removed from the moulds and put in ambient air with the bottom immersed in water at a depth of 0.5-1 mm. Efflorescence occurs on the surface of GP(L) more rapidly. Tiny white products were observed after 1.5 hours (not presented here), and after only 2 hours, evidently efflorescence products could be seen on its surface above the wet line. In comparison, GP(H) started to exhibit visible efflorescence after 2 hours. The leaching analysis of the crushed samples, as a quantitative method of assessing efflorescence potential (Zhang *et al*. 2014), showed that the two AACs have very close sodium releasing rate and fraction (not shown). It means that GP(H) has higher efflorescence potential as the absolute amount of leached alkali is higher. This result indicates that lowering the alkali concentration in an AAC by reducing the amount of sodium silicate activator may not be a good practical method to mitigate efflorescence. In fact, other factors, such as gel composition (as a result of varied reaction extent of fly ash due to the change of activation conditions) and pore features (size and volume), can also influence the efflorescence rate.

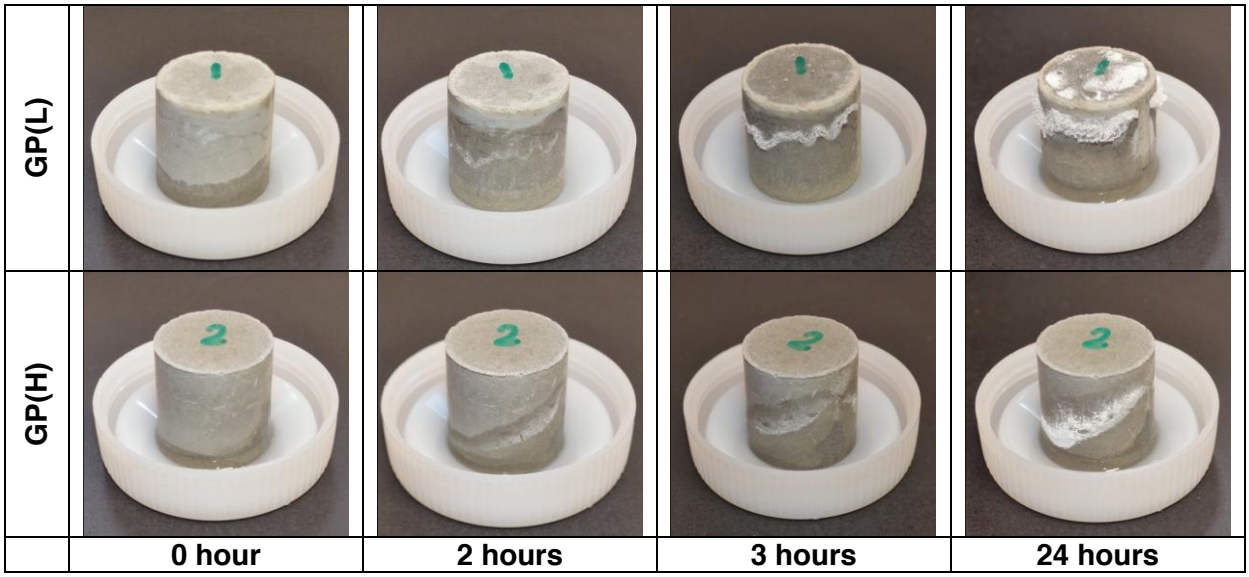

Figure 1 Efflorescence of hardened alkali-activated fly ash pastes in contact with water

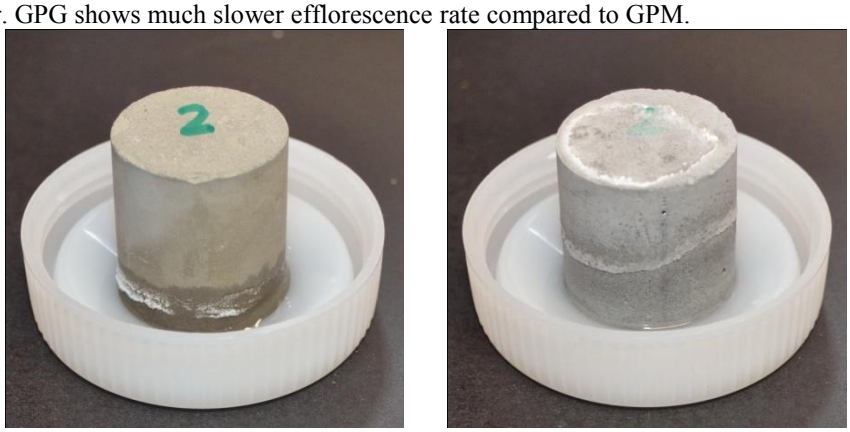
Effect of Solid Raw Materials and Curing Scheme

Fly ashes collected from different power stations vary substantially in their chemistry and physical nature, and the slow reaction of some fly ash sources leads to temptation to add excessive alkali to the mix to accelerate hardening, which can then lead to efflorescence. Figure 2 shows the efflorescence behaviour of AACs GPG and GPM, which were prepared by 12 M NaOH solution activation of fly ashes obtained from Gladstone and Millmerran power stations (Queensland, Australia), respectively. The curing conditions were the same as described earlier. GPG shows much slower efflorescence rate compared to GPM.



(a) GPG (b) GPM

Figure 2 Efflorescence of hardened AAC pastes in contact with water for 24 hours

The addition of slag into fly ash-based AACs has been shown to significantly reduce the efflorescence rate; however, it does not alter the efflorescence potential (Zhang *et al*. 2014). In fact it increases the total amount of leached alkali. Similar results were reported for natural pozzolan-based AAC (Najafi Kani *et al*. 2012). The addition of 6-8% slag increased the extent of alkali leaching. Therefore, the blending of slag is most likely to provide beneficial reductions in permeability rather than changing the binding nature of alkalis. Najafi Kani *et al*. (2012) suggested using alumina-rich admixtures, such as calcium aluminate cement, to reduce the efflorescence. This is probably because of the high reactivity of these additives and the high concentration of Al in the derived gels, which may require increased amount of alkali ions for charge balance. This mechanism is supported by the previous work by Temuujin *et al*. (2009). They reported that the efflorescence was more intensive in AACs that were prepared by preliminarily heated (500°C and 800°C) fly ashes, in which the quantities of amorphous phases were slightly reduced.

Curing scheme is one of the most critical factors that affects efflorescence of AACs. Najafi Kani *et al*. (2012) have shown that curing at $\geqslant$65°C provided a significant effect in efflorescence reduction. This was verified in a previous investigation (Zhang *et al*. 2014). This is because hydrothermal curing can change the local structure and improves the crystallinity of AAC gels. The transition of amorphous gels into more ordered or crystallized zeolite seems to reduce the alkali release rate and extent (Fernández-Jiménez *et al*. 2009). From this point of view, the use of some fine crystalline particles in raw materials as seeds to induce crystallization may help to reduce the efflorescence.

IMPACT OF EFFLORESCENCE

The Evolution of Microstructure

The effect of efflorescence on the microstructure of AACs GP(L) and GP(H) is shown in Figure 3. The observed areas are the surface parts of each sample after 28 days of ambient ageing (in air) and accelerating efflorescence (with bottom immersed in water as described above). The crushed particles near the surface were solidified using resin, polished and washed in acetone using an ultrasonic washer to remove lose particles.

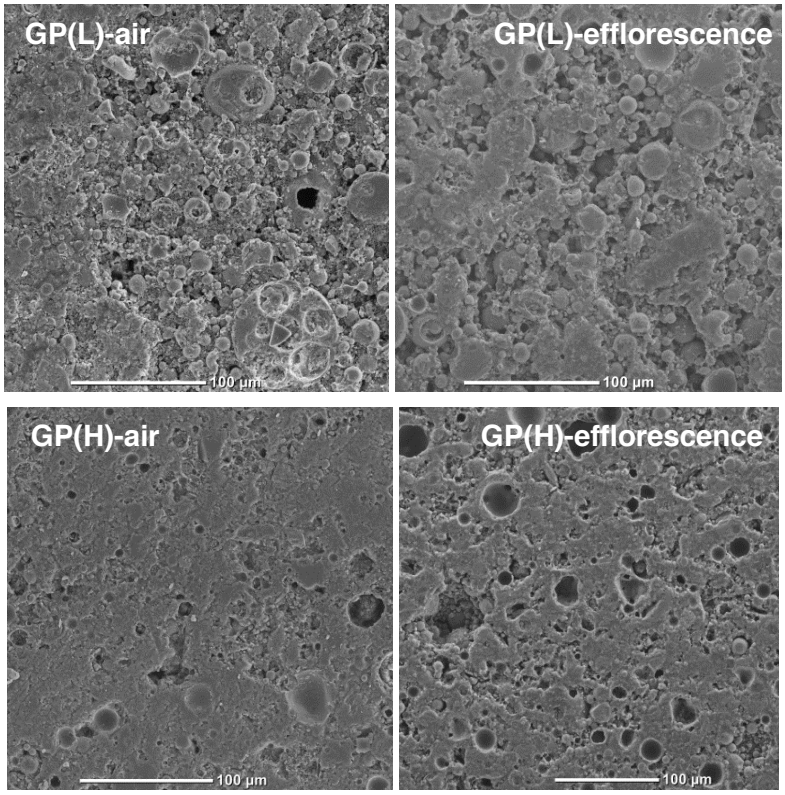


Figure 3 Scanning electron micrograph of AACs after 28 days of ageing under ambient air and accelerating efflorescence conditions

After the accelerating efflorescence procedure, GP(L) becomes more porous when compared to its corresponding samples after ageing in ambient air. Given that the same polishing and washing procedures were used for all the samples, the porous microstructure in cross-section implies the binder may be softer or less strong after efflorescence. The loss of alkalis due to the intensive efflorescence in these two binders is likely to be harmful for strength development. The cross-section of GP(H) after the accelerating efflorescence programme shows the same microstructural feature.

Compressive Strength Development

To date, there is very limited information about the effect of efflorescence on the mechanical properties of AACs. Burciaga-Díaz *et al*. (2010) have shown the degradation of alkali-activated slag binders due to efflorescence (mainly carbonation of excessive Na_2O) after 360 days of curing. Škvára *et al*. (2012) proposed that the leaching of alkalis from well matured AACs does not affect the strength significantly; they attributed the observed slight strength loss to the 'lower cohesion forces between the gel particles' when samples were immersed. We made direct comparison by measuring the specimens after demoulding, air-ageing and accelerating efflorescence recently. Figure 4 shows the compressive strengths of GP(L) and GP(H). After 28 days of ageing, the compressive strengths of the pastes in air all increase by 20 to 35% from their demoulding strengths, while the efflorescence samples show much less increase in strength compared to their strength at demoulding.

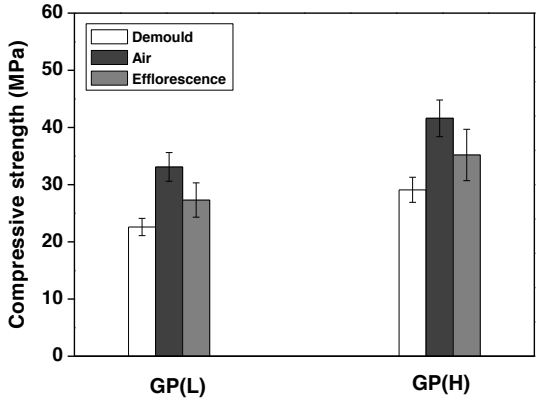

Figure 4 Compressive strengths of well matured AACs after demoulding, air-aging and accelerating efflorescence for 28 days

It is evident that efflorescence has a negative influence on strength development. When an AAC paste is placed in simulated efflorescence conditions, water can be drawn into the pores of the solid matrix by capillary suction, and evaporate from the sample surface. The internal alkalis are able to diffuse towards the surface, providing Na^+ for the precipitation of sodium carbonates, until an equilibrium (saturation) condition between the pore solution and the crystals is reached. The reduced alkali concentration in the matrix due to diffusion will affect or suppress the later activation of residual precursors. In addition, the crystallization pressure due to the precipitation of sodium carbonates in the pores of the binder may also introduce inner stress, and affect the mechanical properties of AAC. Further investigation is required to make a comparison of fully matured specimens (strength remains constant in air) and specimens subjected to efflorescence, to reveal the exact mechanical impact of efflorescence.

CONCLUSIONS

In this brief review paper we discussed efflorescence occurring in fly ash-based AACs. This phenomenon is distinct from that which occurs in Portland cement based materials. The high concentration and high mobility of alkalis in normal AAC systems make efflorescence an inborn process. Some progress has been made to understand these efflorescence mechanisms and the factors that influence them. It must be highlighted that the addition of Al-rich additives and the adoption of hydrothermal curing have been confirmed to be effective methods to reduce efflorescence rate. Other aspects, such as how efflorescence will affect the microstructure and properties, remain to be established.

ELEMENTARY KENAF FIBRE EXTRACTION

Niphaphun Soatthiyanon and Alan Crosky*
School of Materials Science and Engineering
UNSW Australia, Sydney, NSW 2052 Australia. *Email:a.crosky@unsw.edu.au

ABSTRACT

Elementary kenaf fibres were separated by the HNO_3 treatment and the H_2O_2/CH_3COOH treatment. It was found that the HNO_3 treatment caused fibre fragmentation causing a decrease in the fibre length and an increase in the fibre defect density. However, the H_2O_2/CH_3COOH treatment was not strong as the HNO_3 treatment and this had much less effect on the fibre length and the fibre defects. The fibres had an average length of 0.2 mm and 2.3 mm and an aspect ratio of 15 and 179 for the HNO_3 treated fibres and the H_2O_2/CH_3COOH treated fibres, respectively. The defect density of the HNO_3 treated fibres and the H_2O_2/CH_3COOH treated fibres was 21 and 14 defects/mm, respectively. Both the treatments removed lignin, pectin and waxes. They also increased cellulose crystallinity in the fibres, especially for the HNO_3 treatment. However, these treatments resulted in some oxidation of cellulose to occur.

Kenaf, elementary fibres, fibre extraction, fibre separation, fibre isolation.

INTRODUCTION

Natural fibres, particularly bast fibres, have been used as the reinforcement in polymer-matrix composites in recent years. These fibres have been developed to improve mechanical properties of the composites. Most methods found are to modify fibre surfaces. An another method found is to increase fibre aspect ratios by isolating natural fibres and this method is also more potential than the fibre surface modification conducted for enhancing mechanical properties of composites, especially strength (Hughes, 2012).

The objectives of this study were to develop an appropriate process for breaking down the kenaf fibre bundles into elementary fibres. Two chemical treatment methods used were nitric acid and a mixture of hydrogen peroxide and acetic acid. The fibres were physically characterized to determine their diameter, length and aspect ratio, and examine the defects present in the fibres. In addition, the fibres were characterised chemically using Fourier transform infrared spectroscopy (FTIR) while the level of cellulose crystallinity was determined by X-ray diffraction (XRD) and solid state ^{13}C nuclear magnetic resonance (NMR). NMR was also used for determining the degree of oxidation of cellulose in the fibres.

METHODOLOGY

Materials

Untreated kenaf fibres (UKF) were obtained by the Malaysian Agriculture Research and Development Institute (MARDI). Holocellulose, cellulose, hemicellulose, lignin, pentosan and ash which are the chemical composition of the UKF are 91%, 61%, 30%, 11%, 17% and 0.65%, respectively. The moisture content, alkali solubility and hot water solubility of the UKF are 10%, 19% and 1.2%, respectively (Zakaria, 2014). 70% Nitric acid (HNO_3), 30% hydrogen peroxide (H_2O_2) and glacial acetic acid (CH_3COOH) were supplied by Ajax Finechem. Alpha-cellulose was supplied by Sigma-Aldrich.

Isolation of Elementary Fibres

The fibre bundles were treated using two types of the chemical treatments, these being the nitric acid treatment and the hydrogen peroxide and acetic acid treatment. The nitric acid treatment was carried out using 60% HNO_3 in a 20:1 liquid to fibre ratio at 80 ± 2^oC for 30 minutes. The treatment was continued in the same solution at room temperature for a minimum of 5 weeks as the yield from this process was low. The hydrogen

peroxide/acetic acid treatment was carried out using a 50:50 mixture of 20% hydrogen peroxide and glacial acetic acid, in a 75:1 liquor to fibre ratio, at 98 ± 2°C for 7 hours. Both of the treated fibre types were then filtered, washed with water, until the pH of the solution was approximately 7.These fibres were subsequently frozen and then freeze dried using a Lyovac GT 2 freeze drier. The treated fibres are referred to hereafter as KFTN for the nitric acid treated fibres and KFTHA for the hydrogen peroxide/acetic acid treated fibres.

As cellulose is the main component in the fibres, α-cellulose (AC) was treated using the nitric acid and hydrogen peroxide/acetic acid treatments as explained above to study the effect of the treatments in the absence of the other components in the fibres. The nitric acid treated α-cellulose and the hydrogen peroxide/acetic acid treated α-cellulose are referred to hereafter as ACTN and ACTHA, respectively.

In addition, the untreated fibres were hand-cut to a length of approximately 2 mm and then manually separated. These chopped technical fibres were prepared for the purpose of comparison. These fibres are referred to hereafter as UKF.

Scanning Electron Microscopy (SEM)

The treated fibres were imaged using a Hitachi S3400-X scanning electron microscope. The fibre specimens were first sputter coated with gold using an Emitech K550x gold sputter. The SEM was operated in high vacuum at an accelerating voltage of 10 kV.

Fibre Length, Diameter and Aspect Ratios

The untreated and treated fibres were sprinkled onto glass slides and then examined using a Nikon Eclipse ME600 optical microscope. The length and diameter were then measured for 500 UKF, 500 KFTN and 50 KFTHA fibres using UTHSCSA ImageTool program. Subsequently, the aspect ratio was determined for each type of the fibres using the average values of these two parameters.

Defects in Elementary Fibres

The defects present in the KFTN and KFTHA fibres were assessed using a Hitachi S3400-X scanning electron microscope as described in the previous SEM section, but with an accelerating voltage of 15 kV. Ten fibres were examined in each case.

Fourier Transforms Infrared (FTIR) Spectroscopy

The kenaf fibres and α-cellulose in the untreated and treated conditions were analysed using FTIR spectroscopy. The analyses were carried out using a Perkin Elmer Spotlight 400 FTIR microscope in the range of 4,000-650 cm^{-1}, with a resolution of 4 cm^{-1}.

Cellulose Crystallinity

The level of crystallinity (crystallinity index) in the cellulose was determined for both the fibres and α-cellulose in both the untreated and treated conditions using a Philips X'pert Multipurpose XRD System. The specimens were scanned from 8° to 55° at 2Θ. A step size of 0.026°, a voltage of 45 kV and a current of 40 mA were used. Time per step was 51 seconds and revolution time was 4 seconds. Percentage crystallinity indexes were calculated using Segal's equation and multiplying by 100 (Sayeba et al., 2010). The Segal's equation is then given by

$$CrI = \frac{I_{002} - I_{am}}{I_{002}} \quad (1)$$

where I_{002} denotes the maximum intensity of the 002 peak at about 2Θ = 22.0-22.5° and I_{am} is the lowest intensity corresponding to 2Θ value near 18.0-18.5°(Segal et al., 1959; Wang et al., 2010).

The crystallinity index of cellulose was also determined for the same materials using a Bruker Avance III 300 Solid State NMR. The crystalline and amorphous peaks at 89 ppm and 84 ppm, respectively, in the C4 region (from 80 ppm to 93 ppm) were used for determining the crystallinity index of the cellulose (Park et al., 2010).

Degree of Oxidation

The degree of oxidation of cellulose in the treated kenaf fibres and treated α-cellulose was determined from NMR spectra by integrating the peak at 174 ppm (C6') corresponding to the carboxyl groups (Lasseuguette, 2008).

RESULTS AND DISCUSSION

Isolation of Elementary Fibres

Both of the HNO_3 and H_2O_2/CH_3COOH treatments were successful in isolating the elementary fibres. Both of the KFTN and KFTHA fibres had almost the same appearance (Figure 1). However, the KFTHA fibres had much longer length than the KFTN fibres. The KFTHA fibres had narrow tapered ends while the KFTN fibres had square ends.

The yield for the KFTN and KFTHA processes was 36% and 58%, respectively. However, these are slightly higher than the yields of 34% and 48% obtained by Mazumder et al. (2000) using similar treatments also on kenaf fibres.

From the present study, it is concluded that the H_2O_2/CH_3COOH treatment is better than the HNO_3 treatment in terms of both yield and treatment time. Moreover, this treatment is milder than the HNO_3 treatment and is less likely to degrade the cellulose in the fibres (Zhao et al., 2010).

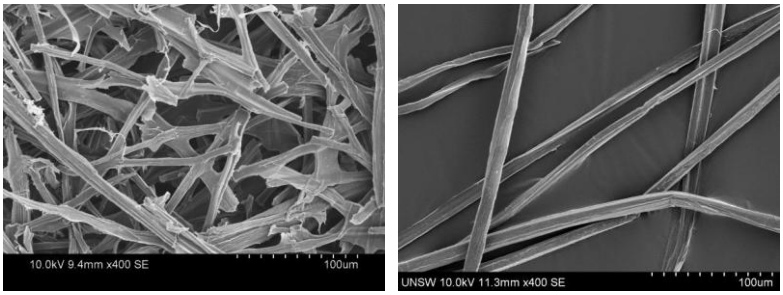

Figure 1SEM micrographs of KFTN (left) and KFTHA (right).

Aspect Ratios of Elementary Fibres

The mean length of the UKF, KFTN and KFTHA fibres was 730 µm (standard deviation 51%), 180 µm (standard deviation 53%), and 2312 µm (standard deviation 27%), respectively. The mean diameter was 97 µm (standard deviation 47%), 11.7 µm (standard deviation 26%), and 13.0 µm (standard deviation 23%) for the UKF, KFTN and KFTHA fibres, respectively. The aspect ratio of the UKF, KFTN and KFTHA fibres was 7.5, 15.3 and 179, respectively.

The average diameter of the treated fibres is within the range of 10-20 µm considered to be indicative of elementary fibres (Van den Oever et al., 2000) and this provides quantitative evidence that the treatments had been successful in converting the fibre bundles to elementary fibres. However, there was a very substantial difference in the fibre lengths, with the elementary fibres obtained from the H_2O_2/CH_3COOH treatment being an order of magnitude longer (average length of 2.3 mm) than that obtained from the HNO_3 treatment (average length of 0.18 mm). Accordingly, the aspect ratios also differed by an order of magnitude (179 compared with 15 for the two different types of treatment, respectively).

Calamari et al. (1999)also treated kenaf fibres with hydrogen peroxide/acetic acid, but in this case they used an alkali pretreatment. They obtained a fibre length of 2,450 µm and an aspect ratio of 204, again in good agreement with the results of the present study.

As noted above, the much shorter length of the HNO_3 treated fibres (KFTN) is considered to be due to fibre breakage resulting from acid attack at fibre defects. This occurs because the defects are chemically more active (Hughes, 2012).

Defect Density of Elementary Kenaf Fibres

The HNO_3 treated fibres (KFTN) and H_2O_2/CH_3COOH treated fibres (KFTHA) had fibre defects, such as kinks, micro-compressions, pits, nodes, dislocations and initial breaks. These are similar to the defects observed by Fan (2010) in elementary hemp fibres.

The average defect density was significantly higher for the KFTN fibres than for the KFTHA fibres with the values being 21 (standard deviation of 9) and 14 (standard deviation of 4) defects/mm, respectively.This is attributed to the higher level of hydrolysis produced by the stronger acid (Bailaret al., 1989).

FTIR Spectra

The assignments of peak positions of FTIR spectra of the kenaf fibres and α-cellulose in untreated and treated conditions are shown in Table 1.

The FTIR spectrum of the untreated fibres (UKF) was similar to that for the untreated α-cellulose (AC), expect for the absence of the 1716 cm^{-1}, 1593 cm^{-1}, 1500 cm^{-1}, and 1238 cm^{-1} peaks. The peaks in the spectrum of the untreated fibres at 3329 cm^{-1}, 2900 cm^{-1} and 1102 cm^{-1} are seen not only in cellulose, but also in hemicellulose and lignin. The spectrum of the untreated fibres also contained the same absorption peaks as the spectrum for a kenaf stem published previously by Öztürk et al. (2010).

The spectrum from the HNO_3 treated fibres (KFTN) contained the same peaks as the α-cellulose treated with HNO_3 (ACTN), except for the addition a peak at 1716 cm^{-1}, which is attributed to the presence of some oxidized cellulose.

The spectrum from the H_2O_2/CH_3COOH treated fibres (KFTHA) contained the same peaks as the H_2O_2/CH_3COOH treated α-cellulose (ACTHA).

Crystallinity of Cellulose

The crystallinity indexes of the cellulose in the untreated and treated α-cellulose and fibres examined using XRD and NMR are shown in Figure 2.

The crystallinity indexes examined using XRD range from 75% to 97%. The values are generally lower for α-cellulose than for the fibres. They are also lower for the untreated than for the treated materials. The crystallinity index for the untreated α-cellulose was 75% compared with 83% for the untreated fibres. The HNO_3 treatment substantially increased the crystallinity index with values of 97% and 96% being obtained for the ACTN and KFTN materials, respectively. The H_2O_2/CH_3COOH treatment also increased the level of crystallinity, but to a lesser extent, especially in the α-cellulose. Park et al. (2010) determined the crystallinity index of α-cellulose and obtained a value of 78% which is in good agreement with the value of 75% obtained in the present study.

The crystallinity indexes for the untreated and treated α-cellulose and fibres examined using NMR are much lower than those obtained by XRD, ranging from 30-56% compared with 75-97%. However, the trends were generally similar. The untreated cellulose and fibres had the lowest crystallinity indexes (30% and 36%, respectively) while the HNO_3 treated samples had the highest crystallinity indexes (55% and 56%, respectively). The crystallinity indexes were intermediate for the H_2O_2/CH_3COOHtreatment (38% and 39%, respectively) but there was now no difference in the crystallinity levels in the α-cellulose and fibre samples. Park et al. (2010) used NMR to determine the crystallinity index of α-cellulose and obtained a value of 42%, which is in reasonable agreement with the value of 30% obtained in the present study. Focheret al. (2001)determined the crystallinity index of cellulose extracted from kenaf using NMR, and obtained a value of 42%. This is again in reasonable agreement with the value of 36% obtained here.

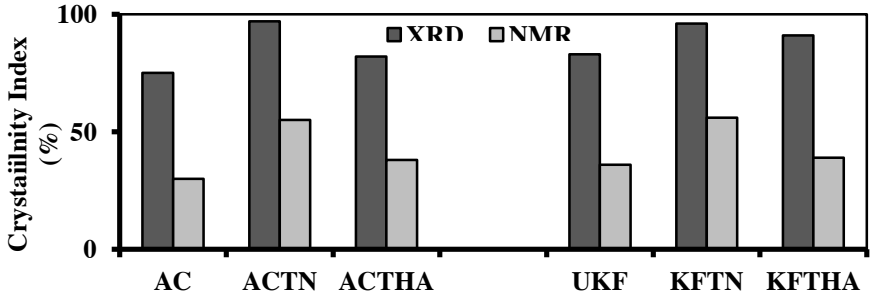

Figure 2 Crystallinity indexes of cellulose in the untreated and treated α-cellulose and fibres examined using XRD and NMR.

The increase in crystallinity as determined by XRD and NMR was 16% and 56%, respectively, for the HNO_3 treated fibres (KFTN), 10% and 8%, respectively, for the H_2O_2/CH_3COOH treated fibres (KFTHA). The increase in crystallinity is attributed to oxidation of the cellulose (Abdel Moteleb & El Akabawy, 1999). In addition, oxidation would reduce the degree of polymerisation (DP) by constraining movement of cellulose molecules, which would lead to an increase in cellulose crystallinity,(Sandy et al., 2010).

Degree of Oxidation

The degree of oxidation of cellulose of the treated samples for the α-cellulose and fibres ranges from 4-15%. The results for the HNO_3 treatment (ACTN and KFTN) were 14.5% (standard deviation of 0.8%) and 7.4% (standard deviation of 0.4%) for the α-cellulose and fibres, respectively. Substantially lower values of 4.4% (standard deviation of 0.3%) and 6.9% (standard deviation of 0.3%), respectively, were obtained from the H_2O_2/CH_3COOH treatment (ACTHA and KFTHA).

CONCLUSIONS

Elementary kenaf fibres were successfully isolated using HNO_3 and a mixture of H_2O_2 and CH_3COOH. The main findings are as follows:

- The H_2O_2/CH_3COOH treatment required a shorter treatment time and gave a 60% higher yield than the HNO_3 treatment.
- The average length and aspect ratio were 2.31 mm and 179, respectively, for the H_2O_2/CH_3COOH treated fibres (KFTHA) while those of the HNO_3 treated fibres (KFTN) were 0.18 mm and 15.3, respectively. The reduced length of the HNO_3 treated fibres is considered to be due to fibre breakage arising from chemical attack at defects in the fibres.
- The defect density in the HNO_3 treated fibres (KFTN) was double that found in the H_2O_2/CH_3COOH treated fibres (KFTHA). This is again considered to be due to chemical attack of the fibres during the harsher HNO_3 treatment.
- Both the treatments removed lignin, pectin and waxes, as would be expected in elementary fibreisolation. However, they caused some cellulose oxidation to happen.
- Both of the treatments increased the level of cellulose crystallinity in the fibres which is beneficial to their mechanical properties. The increase in crystallinity in the fibres was higher for using the HNO_3 treatment than the H_2O_2/CH_3COOH treatment.

ABSTRACT

Buildings contribute substantially to our greenhouse gas emissions and energy demands both in their occupation and construction. Their construction also consumes large volumes of finite resources. Sustainable, low embodied energy, high performance crop based materials therefore offer great potential. Hemp-lime is a bio-composite concrete, mass infill material with a greatly lower embodied energy than equivalent traditional constructions. It also exhibits beneficial hygrothermal properties that can improve both a building's energy performance and the comfort of its occupants by buffering humidity and temperature. It is however widely considered insufficient structurally, limiting its scope for application. A lack of understanding and acknowledgment that hemp-lime and other similar bio-composites are anisotropic, but instead have a directional internal structure, has hindered the development of stronger and more versatile products. In this work a range of methods based on digital image analysis and computer tomography were trialled with the aim of identifying the nature of hemp-lime's internal structure and providing a methodology to classify it. The results from both digital imaging and computer tomography scanning indicate that the internal structure of the specimens considered was highly anisotropic; a strong directionality in the hemp particles was found to be induced by the construction process. The novel assessment methods developed to allow the numerical classification the internal structure that may be used in the future to allow the structural optimisation and modelling of bio-composites.

INTRODUCTION

Currently the world relies heavily on fossil fuels for the production of useful energy; this production is unsustainable and therefore it is increasingly important to use the energy produced efficiently. Burning fossil fuels also produces carbon dioxide (CO_2), the accumulation of which is driving climate change, the effects of which are already being felt(Field et al. 2014).

Buildings are a major contributor to the amount of energy we use and CO_2 we emit; they therefore represent an area of great potential savings(Huovila 2007). Large efficiency gains in the operation of buildings can be made by improving their performance thermally. Ironically however many building insulation products are derived from the very non-renewable fossil fuels that we are trying to preserve and are energy intensive to produce(Harvey 2007). Natural insulation materials often have a very low or even negative embodied carbon and so offer large embodied savings as well as other ecological benefits. Given their potential, many natural insulation materials have become the focus of research including: straw(Alcorn and Donn 2010; Wall et al. 2012), sheep's wool(Zach et al. 2012) and hemp-lime(Benfratello et al. 2013; Murphy et al. 2010).

Hemp is a fast growing and ecologically beneficial break crop that enhances the soil and supresses weeds. It requires minimal fertiliser, pesticides and herbicides and yields multiple products(Allin 2012). The woody internal stalk, or shiv, is a cheap co-product commonly used as animal bedding. When mixed with a lime based binder the shiv forms a low strength composite, hemp-lime, that is most commonly used as a non-load bearing mass infill walling material, cast or sprayed into place(Bevan et al. 2008). The unique porosity of hemp-lime means it buffers humidity and provides both insulation and effective thermal mass through a phase change phenomenon, significantly enhancing thermal efficiency(Arnaud et al. 2013b; Collet and Pretot 2014; Nordby and Shea 2013). As hemp grows it sequesters CO_2 from the atmosphere and thus hemp-lime can be considered

carbon negative: effectively removing almost 300kg of CO_2 from the environment per cubic meter used(Boutin et al. 2006; Ip and Miller 2012).

Hemp-lime's application on site is hindered by its variability and a long drying time. Pre-casting and off site drying of hemp-lime components are plausible ways of circumventing these issues(Walker and Thomson 2013). The low strength and poor durability of the material however has restricted this to either high density formulations or as a component in structural insulated panels. This has been at the cost of the thermal performance and design flexibility respectively and has limited application. Refining the production of precast elements to produce stronger and more uniform components is therefore critical in order to improve the uptake of this high potential material.

The internal layout of the shiv particles is unquestionably a contributing factor in the mechanical properties of the composite. This is however a topic which has to date been the subject of little research. In this work a novel analysis and classification method for the internal structure was developed. Data were gathered from 15 specimens using two data collection procedures: computed tomography scanning (CT scanning) and two-dimensional digital imaging of cut sections. Image enhancement and analysis techniques where then implemented to allow the orientation of the shiv to be represented as a frequency distribution to enable classification of the structure. From this analysis, the research aims to discover if hemp-lime should be considered as an anisotropic material in future works relating to the physical testing and theoretical modelling of structural and thermal properties and provide a methodology enabling further investigation.

FACTORS INFLUENCING THE MECHANICAL PROPERTIES OF HEMP-LIME

The mechanical properties of hemp-lime have been studied as part of the fundamental characterisation of this novel material, but few studies have accounted for the impact of orientation on these properties.. What research has alluded to the influence of particle orientation is reviewed in this section.

Compressive Behaviour

The compressive behaviour of hemp-lime is the most widely reported mechanical property and is considered indicative of durability. In addition it is the only mechanical property specified in the world's singular design guide (Lanos et al. 2013).

It is generally considered that the binder is the sole structural element and compressive strength and stiffness are therefore proportional to the amount used(Arnaud et al. 2013a). For common mix designs and construction methods this pattern has indeed been observed widely(Arnaud and Gourlay 2012; Hirst et al. 2010; Murphy et al. 2010). The opposite was observed however by Nguyen et al. (2009) who considered highly compressed materials. This was attributed to a lower free-water content, hindering the hydraulic set of the binder. The formulation of binder has also been considered in respect of compressive behaviour with inconclusive results (Hirst et al. 2010; Magniont et al. 2012).Competition for moisture between the highly hydroscopic shiv and the binder can hinder setting of hydraulic components. As a result "stronger" binders will not necessarily produce composites of higher compressive strength and stiffness(Bevan et al. 2008).

The particle size distribution (PSD)of the shiv has been studied in relation to compressive behaviour by Gourlay, reported in (Arnaud et al. 2013a), and Arnaud and Gourlay (2012) who found that a finer shiv produced material that was slower to acquire strength but obtained higher values after a period of time. This was attributed to a greater degree of natural consolidation occurring with finer particles, providing a stronger geometrical structure but slowing carbonation. Conversely it has been observed elsewhere that in compressed material a coarser shiv will produce higher compressive strength, attributed to an increased overlap and friction between particles(Nguyen et al. 2009).

The manufacturing process has also been found to affect the compressive behaviour. Currently all forms of manufacture involve a degree of consolidation: tamping or vibration in the case of cast material and projection force in the case of sprayed material. The degree of consolidation has been shown to have an impact on the compressive strength and stiffness and this is attributed to increased contact between particles(Nguyen et al. 2009). As both consolidation and binder content directly affect the density, it is often reported simply that compressive strength is proportional to density(Hustache and Arnaud 2008).

It is suggested in many studies that the manufacturing process produces anisotropy in the shiv structure and thus anisotropic mechanical behaviour (Arnaud et al. 2013a; Duffy et al. 2014). This has however, to the authors'

knowledge, only been tested by two researchers. The work of Mounanga, reported in Arnaud et al. (2013a), observed that the nature of compressive failure changes with orientation. However no statistically significant difference in capacity was observed. Gross (2013), as part of a wider investigation into the enhancement that hemp-lime can have on timber frames, performed a direct comparison of two casting directions and observed that in compressive tests orientation influenced the result by as much as 50%.

Flexural Behaviour

The flexural behaviour of hemp-lime has been studied considerably less but is relevant to the durability of elongated or flat precast objects. Flexural failure in hemp-lime is reported consistently as a failure of the tensile face and at a much lower stress levels than compressive failure(Benfratello et al. 2013; Gross 2013; Walker et al. 2014). This has been attributed to the lower tensile strength of the binder. Studies byElfordy et al. (2008)and Murphy et al. (2010)however found results for flexural strength comparable to those for compressive strength. Elfordy proposed that a preferable orientation of the shiv was induced in the construction which was perpendicular to the direction of the compacting force and enhanced the flexural properties.

Summary

It can be concluded that whilst several factors that impact the mechanical properties of these materials have been identified, a full understanding of the behaviour is lacking. It is generally considered that the internal structure of hemp-lime is not homogenous and that its formation will be influenced by the production method and consolidation. It is also likely that the mechanical properties are influenced at least as much by particle orientation as they are byother factors such as PSD and binder content.

METHODOLOGY

The aim of this study is to develop a means of numerical classification of the orientation preference of shiv within the material. Two methods for data acquisition, or digitisation, were considered. Both have been successfully applied for similar assessment of other materials and for the assessment of other characteristics of loose hemp particles.

Two dimensional digital image analysis has already been used for accessing the PSD of hemp shiv through imaging samples of loose materials(Nozahic et al. 2012). It has also been used to a lesser extent to analyse the porosity of loose “poured” shiv in consideration of the acoustical properties(Glé et al. 2013). While to the authors’ knowledge this concept has not been used for the assessment of the orientation of shiv in cast material, it has been used to assess the orientation and layout of aggregates in other materials- notably asphalt(Coenen et al. 2012; Yue and Morin 1996) and soil(Shi et al. 1998).

CT scanning produces a volume of 3D pixels (voxels) where assigned value represents the material’s X-ray absorption. CT scanning has been used successfully to classify the distribution of fibre reinforcement in concretes(Liu et al. 2013) and splits in timber (Wehrhausen et al. 2012)amongst other aspects of building materials internal structure. Again itdoes not appear to have been used to classify hemp-lime.

In this study five sets of hemp-lime specimens were produced.Each set comprised three specimens produced to differing mix designs representing an industry standard “wall” mix (mix ID 330), a more compacted mix (mix ID 400) and a lower binder to hemp ratio mix (mix ID 275). The mixes are detailed in table 1. Specimens were produced by initially mixing the binder and water in a pan mixer to form a slurry, the shiv was then incorporated mixed briefly to combine. A predetermined amount of mixture was then weighed into a 150mm cube moulds with a collar and consolidated to 150mm high using a 25mm square tamp. The samples were conditioned at 20°C, 60% relative humidity for a minimum of 28 days prior to analysis.

Table 1 Mix design details

Mix ID	Binder: Tradical HB (% mass)	Hemp: UK sourced (% mass)	Water (% mass)	Quantity of wet mix used (kg)	Target equilibrium density (kg/m^3)	Actual equilibrium density (kg/m^3)
275	36	21	43	1.48	275	284
330	36	16	48	2.00	330	353
400	36	16	48	2.41	400	422

Digitisation

Four sets of specimens were digitised using 2D digital scanning. These were first sectioned using a fine toothed band saw to produce 6 cut faces per specimen; two sets of specimens were sectioned parallel to the tamping direction and two perpendicular to allow for comparison.

When compared to other materials which have been subjected to2D digital image analysis, hemp-lime is more voided and more uniform of colour making reliable identification of particles more difficult. Two physical processes were trailed to enhance the quality of images produced: the addition of a red pigment to the lime to improve definition between the binder and the hemp, and the encasement of the cut faces in a coloured casting resin to fill inter-particle voids. The resin also improves the durability of the cut surface allowing sanding of the surface, removing marks made by the cutting. The resulting four variations of specimen are shown in figure 1. The prepared faces were scanned using a flatbed scanner set to 2400dpi.

The final set of specimens were digitised using a Nikon XTEK, XTH 225 ST computer tomography scanner at 165kV and 165uA. Due to the nature of the scanning process, the data captured was of a central 150mm diameter cylinder within each sample. The scanning process and the reconstructed volume are shown in figure 2. The flow chart, figure 3, summarises the processes used to digitise the specimens and lists the data sets gathered.

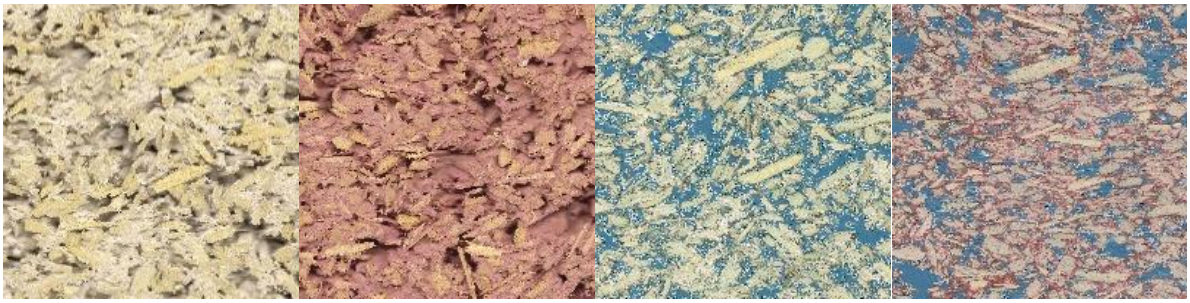

Figure 1 Comparison freshly cut hemp-lime, freshly cut pigmented hemp-lime, resin encased hemp-lime, and pigmented & resin encased hemp-lime

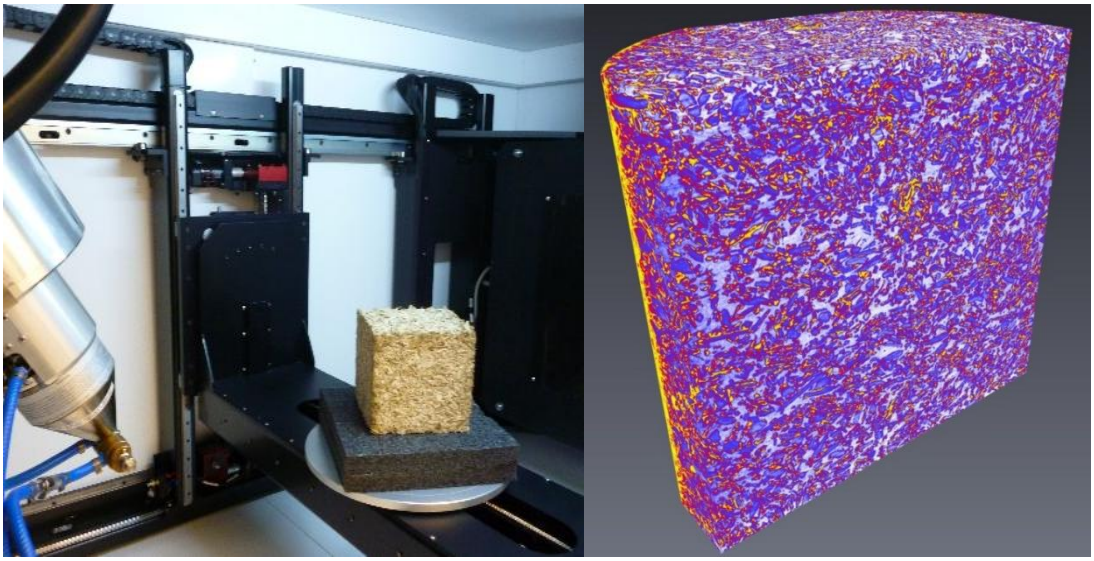

Figure 2 Hemp-lime being scanned in the Nikon XTEK, reconstructed 3D volume in Avizo Fire 8

Data Analysis

To produce usable data the 2D and 3D images were enhanced and filtered to identify the shiv. The enhancement and filtering methods used were based on those used in similar techniques for other materials(Coenen et al. 2012; Yue and Morin 1996) and the PSD analysis of hemp shiv (Nozahic et al. 2012).

The image enhancement of all 2D scans was carried out using the program ImageJ. A median filter (which replaces each pixel with the median of those within a radius) was first applied to remove noise and anomalies. A hue threshold filter was then applied to segregate the shiv and convert the image into a binary form. Finally an

opening algorithm(which successively removes and adds pixels from the edge of a binary object) was applied to help clean and separate connected objects. The stages of image enhancement are demonstrated in figure 4. As all these processes are controlled by user selected settings, a range for each setting was trialled giving a total of 288 permutations to be considered. The range of setting used is detailed in table 2. To produce a distribution of particle orientations, ImageJ's particle analysis tool was used to index all discrete binary objects and calculate the orientation of their maximum calliper diameter.

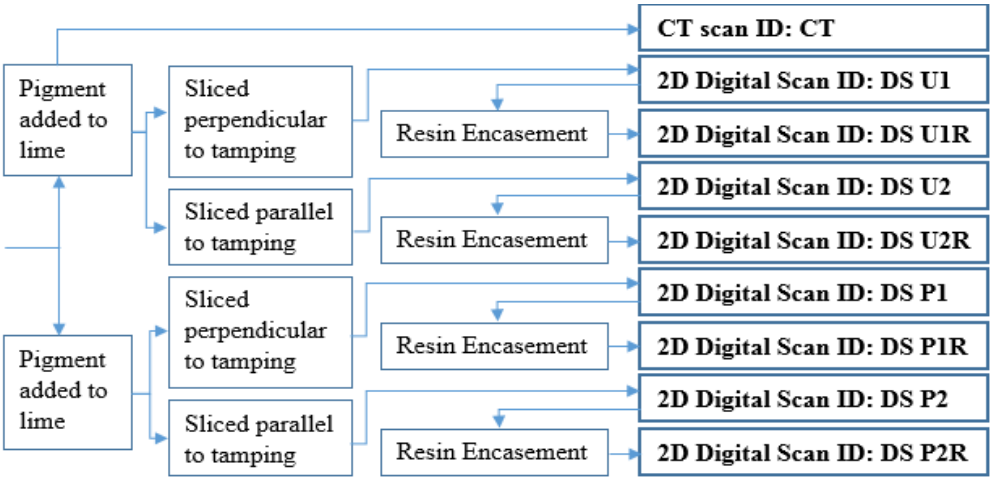

Figure 3 Flow chart of processes and resulting data set IDs

The 3D images were enhanced and analysed using the program Avizo Fire 8 with equivalent 3D versions of the same processes. As the software only allows for a single radius median filter, a varying number of iterations were instead trialled. A brightness threshold filter was used in place of a hue threshold filter as the images are grey scale as opposed to colour. As the overall density of the scans where different, a single range of threshold values was not appropriate and so an individual range of 9 variations was considered for each specimen. As the software only allows one iteration of opening algorithm, various kernel sizes were instead trialled. A total of 81permutations were considered and the range of setting used are summarised in table 2. The Label Analysis Module in Avizo Fire 8 was used to identify and measure the discrete binary objects. For each identified particle the orientation was calculated using the Orientation Theta and Orientation Phi measures. As the particles are considered in 3D space, the orientation is therefore defined by two angles with reference to the horizontal plane, Theta, and vertical axis, Phi.

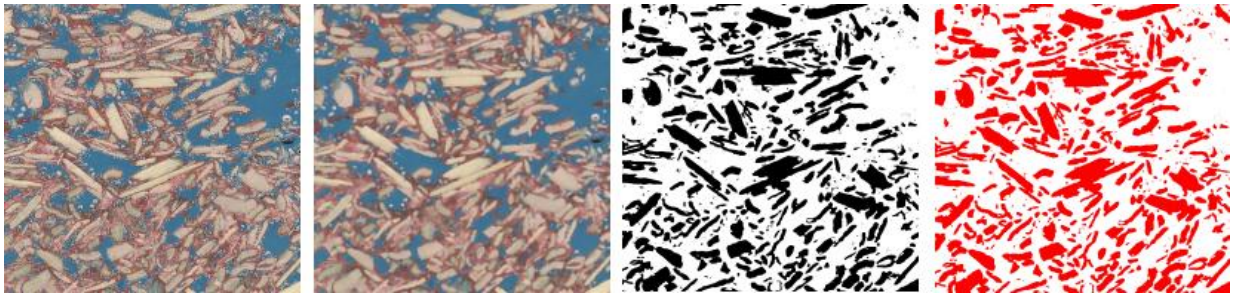

Figure 4Stages of 2D image enhancement: raw image, median filtered, threshold filtered, open algorithm applied

Table 2 Variables used in image enhancement of the 2D and 3D scans

Digitisation method	Range of median filters trailed	Range of thresholds trailed	Range of opening algorithms trailed
2D digital scanning	Radius of 5,10,15,20,25 and 30 pixels	Hue threshold of 10-50, 12-50, 14-50, 16-50, 18-50, 20-50	1, 2, 3, 5, 10, 15, 20, 25 iterations
CT scanning	5, 6 and 7 iterations	Brightness Threshold of 4, 4.5 or 5- 8, 8.5 or 9 (275 mix) 4, 5 or 6- 28, 29 or 30 (330 mix) 6, 7 or 8- 28, 29 or 30 (400 mix)	Radius of 1, 2, 3

RESULTS

Two Dimensional Digital Image Analysis

To assess the effect of the enhancement settings used and to establish the most appropriate settings for correct identification of particles, the frequency distribution of particle orientations for all 288 versions of one image from each data set were produced using 10 degree groupings. A cosine curve (Eq. 1), was then fitted to the distribution by finding the values of α and β that minimise the sum of the squared differences between the modelled and actual distributions. Figure 5 shows the sum of the squared difference plotted for all enhancement variations for the data set DS UR2. If the continuous distribution of any given data set is assumed to follow Eq. 1, the sum of the squared difference represents the effectiveness of the settings used. Using this as a guide the assumed most effective combinations of setting were identified. A visual inspection of these images was then used to confirm their accuracy and assess the most appropriate settings.

$$y = \alpha + \beta \cos(2x) \tag{1}$$

A similar approach was taken to assess the most effective physical processing. Using the settings identified for each data set, the images were assessed visually for their ability to correctly identify individual particles of shiv. From this the most effective combination of physical processes and image enhancements for the identification of shiv particles using 2D scanning was assessed to be as follows: pigment should be added to the binder during forming; the sliced specimen should have the face cast in low viscosity resin and then be sanded to a smooth surface; the image should be median filtered with a radius of 20px; threshold filtered with a 8 bit hue value of 14-50; and an opening algorithm should be applied with 3 iterations. Data sets DS P1R and DS P2R were therefore considered for assessment.

A comparison of the DS P1R and DS P2R data sets was conducted in order to compare the results from two orientations. The individual frequency distributions for all 6 imaged sections for each mix as well as the best fitting cosine curve for all slices are shown for both parallel and perpendicular slices in figure 6.

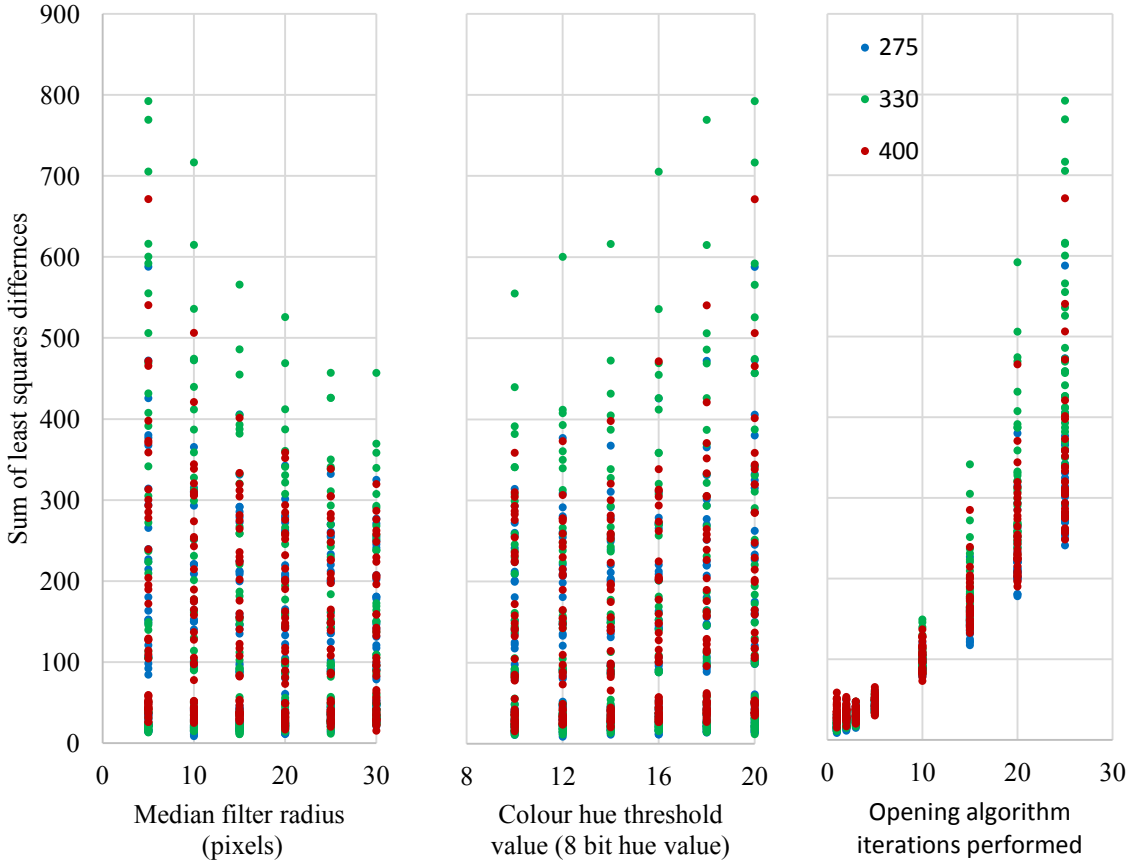

Figure 5 Sum of the least squares differences for the DS UR2 data set

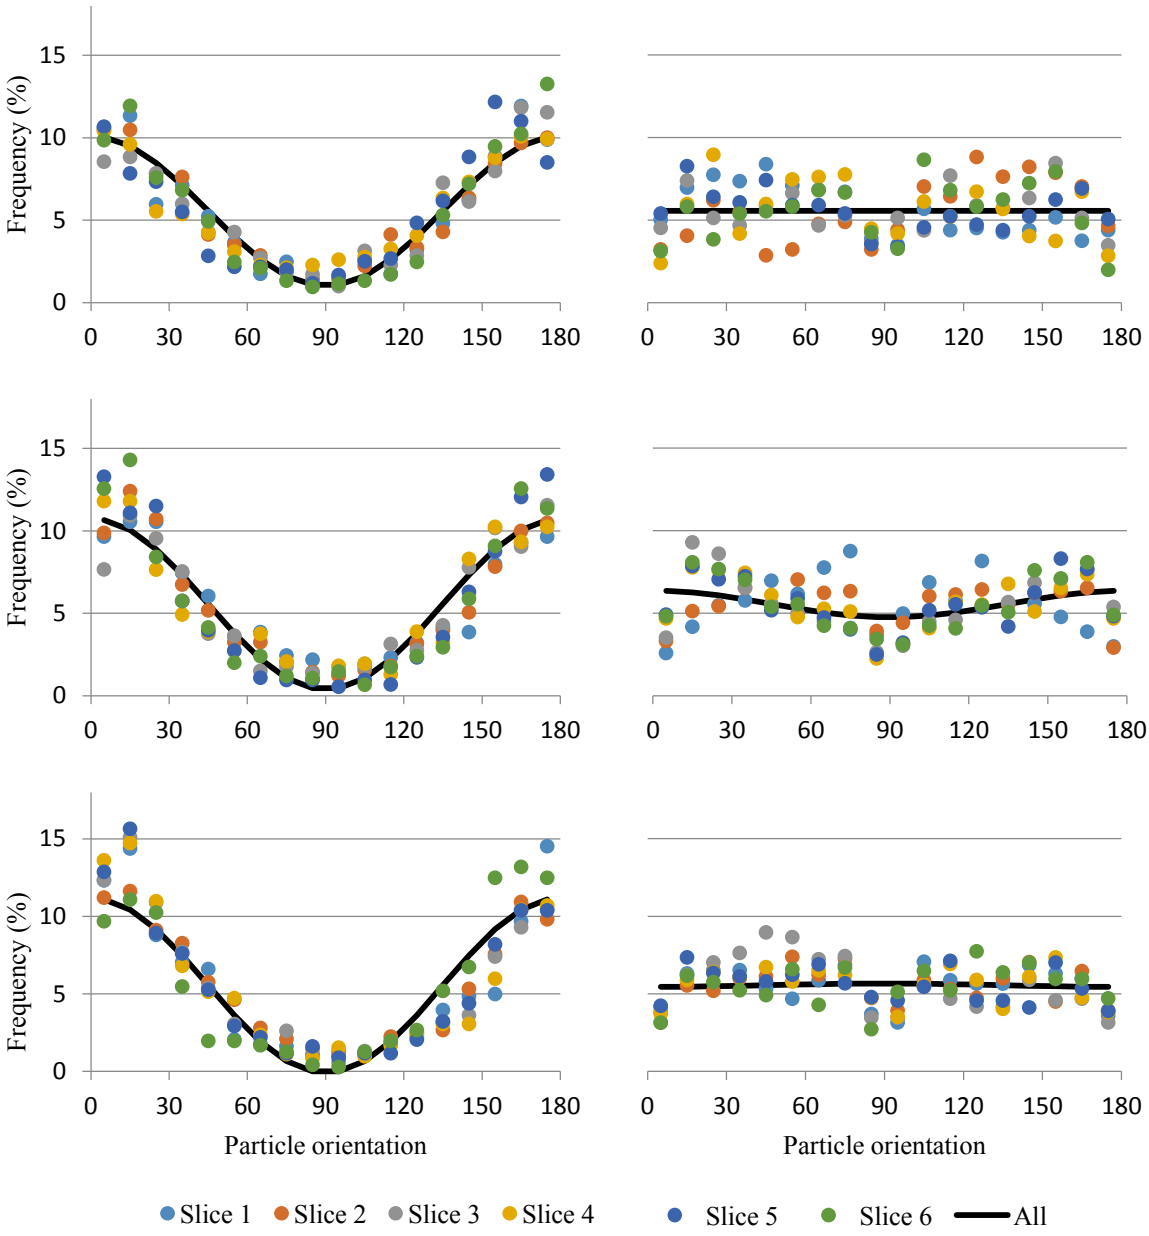

Figure 6 Frequency distributions of DSP1R (left) and DSP2R (right) data sets for the 275 mix (top), 330 mix (middle, and the 400 mix (bottom)

Computer Tomography Scanning

The results from the CT scan data were interpreted using the same frequency groupings. The results from all 81 combinations of enhancement where inspected for perceived accuracy of particle detection by visually inspecting random slices taken from the volume. Six iterations of median filter and opening with a radius of three were the settings perceived to give the most reliable identification of particles for all mix designs. Brightness threshold setting of 5-9.5, 4-29 and 7-29 were perceived to the most appropriate for the 275, 330 and 400 mixes respectively. The frequency distributions of orientation for both directions using these enhancement parameters are given in figure 7.

DISCUSSION

The strong agreement between the results obtained from two dimensional imaging and CT scanning indicates that both methods of data collection are successful way of assessing the orientations of the shiv particle within hemp-lime and could be applied easily to other bio-composite concretes.

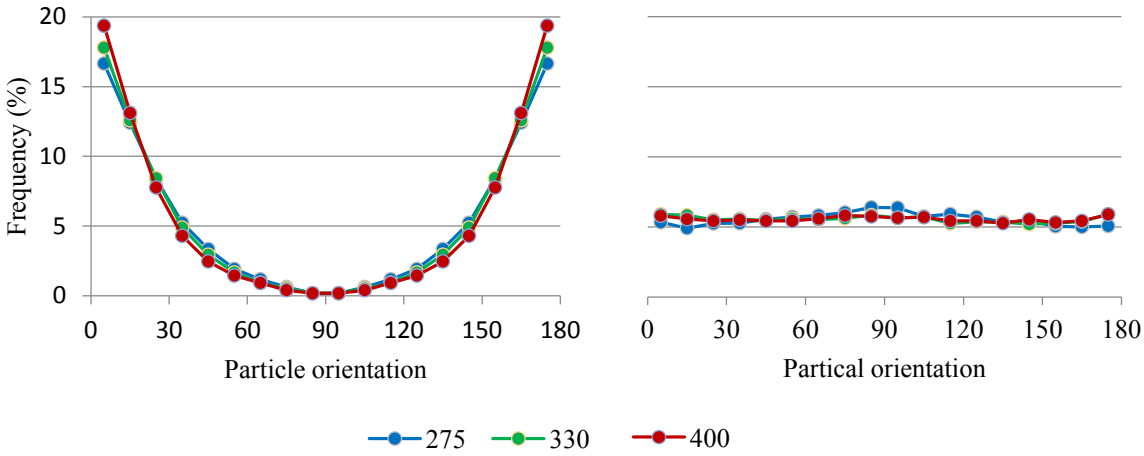

Figure 7 Frequency distributions of particles in the Phi orientation (left) and Theta orientation (right) for the CT data set.

In the case of two dimensional imaging, two physical treatments were identified as essential in order for the technique to be applied accurately: a coloured pigment added to the binder and encasement of the face in coloured resin. Both of these increase the visual contrast between the hemp and the surroundings and enable the software to accurately identify the particles.

For both methods it was observed that accurate identification of a particle is dependent on the enhancement processes applied to the image. In the case of two dimensional imaging, the number of iterations used with the opening algorithm was observed to have the largest single effect in this respect. It is unclear why this might be the case however it was observed that the nature of the algorithm reshapes binary objects towards a circular form that could increase the likelihood of the orientation becoming misinterpreted. This operation should therefore be used with caution in the analysis of these images.

The assumption that the frequency distribution of particle orientation can be modelled by Eq. 1 was useful to enable the easy identification of likely optimal enhancement settings for the 2D images. It is not justifiable to use this method solely however as the true form of the distribution is unknown and there is a high level of natural variation. From the visual inspection of images for both CT scan data and 2D scan data it was possible to identify the most appropriate enhancement parameters and to have a good degree of confidence in the software's ability to correctly identify particles. The comparatively smoother distribution for the CT scan data can be attributed to the larger effective sample size of particles considered.

It is clearly visible from both figure 6 and 7 that there is a distinct difference in the particle orientation distribution of the material when viewed in different directions. When viewed in the direction of compaction force, a relatively flat frequency distribution is observed indicating a random orientation. It is unclear why there should be apparently lower frequencies of orientations around 90° and 0/180° regions in figure 6 and the opposite in figure 7 however this could be in part related to the influences of the mould edges that are aligned in these directions.

When viewed in a direction perpendicular to the direction of compaction there is a very strong indication of directionality within the particles with a strong tendency towards the horizontal. It is a logical assumption, widely mentioned in the literature, that compaction in a given direction will encourage particles to rotate towards planes perpendicular to the force. These results directly support this assumption, providing clear evidence that process of tamping will produce an anisotropic internal structure governed by the direction of force applied. The degree of directionality observed indicates that it is inappropriate to consider the material as homogenous and that future work should clearly state the orientation from which results have been obtained, particularly with reference to mechanical and thermal properties.

From figures 6 and 7 it appears that the specimens of higher density may have higher degrees of orientation. Figure 8 shows the particle distributions for the DS P1R data set and the CT data set (Phi orientations) reduced into a distribution between 0° (horizontal) and 90° (vertical). This increases the effective sample size for the two dimensional image data making trends more obvious. A similar form of distribution is observed for data collected using each method as is a perceived increase in the amount of orientation as density increases. By

considering the 330 mix and the 400 mix it is considered likely that as the level of compaction is increased so is the degree of internal orientation. The 275 mix was perceived to have the same compaction level as the 330 mix when produced and so it is unclear why this should have a lower degree of orientation however it is likely that the initial assumption of equivalent compaction is incorrect. The generally lower degree of orientation in the two dimensional data is also unexplained however considered to be a likely result of the different ways the programs assess orientation. The dip in frequency in the lowest value grouping in the two dimensional image analysis is unexplained however considered possibly to be an effect of the calliper diameter orientation being used or the influence of mould edges; not observed in the CT scan data due to the nature of the process only producing an image of a central cylinder. This difference will be studied in greater depth in future work.

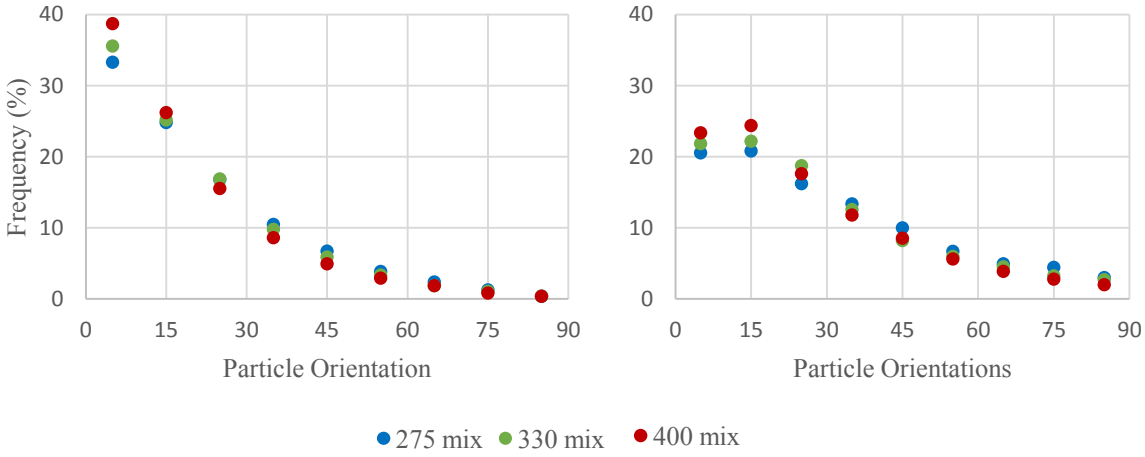

Figure 8 Particle orientation frequency distribution between horizontal (0) and vertical (90) for the DS P1R and CT (Phi orientation) data sets

CONCLUSION

Two methods of producing digital images of the internal structure of the bio-concrete hemp-lime were trialled using a number of image enhancement methods. With the exception of possible edge effects identified by the 2D digital scanning method, both techniques produced very similar frequency distributions. Both CT scanning and the 2D digital scanning methods were able to produce usable data pertaining to the orientation of the hemp particles within the specimens and the optimum methods of image enhancement and specimen processing were established. The results indicate that hemp-lime exhibits a high degree of preferential internal orientation with the shiv tending towards stratified layers perpendicular to the direction of tamping. It is considered that this has a large bearing on the mechanical properties and would explain the anisotropic behaviour of physical properties observed by others. It is therefore important that future research on the mechanical and thermal properties of hemp-lime or other bio-composites should make reference to the direction of compaction.

ABSTRACT

Concrete Filled Steel Tube (CFST) columns are popular in high rise buildings due to their superior strength, seismic and fire resistance capacities and construction simplicity. Structural framing systems in high rise buildings are commonly coupled with reinforced concrete outrigger and belt systems to facilitate lateral load resistance. When axial shortenings of vertical elements occur due to time dependent phenomena of creep, shrinkage and elastic deformations, the horizontal stiff elements balance the shortening differentials in the vertical elements and cause load redistributing among them dynamically. This can result in high transfer stresses induced in the stiff outrigger and belt systems which need to be considered in design or mitigated during construction. To plan mitigation strategies such as the time to connect the shear core to the structural frame to effectively reduce time dependent transfer stresses, it is necessary to quantify current and future differential axial shortenings. This paper first quantifies the differential axial shortening (DAS) between the shear core and columns, considering effects of construction sequence, time dependent material properties and reinforcement and then quantifies the transfer stresses built up in outrigger and belt systems in CFST high rise buildings. This information will be useful in mitigating the adverse effects of these high transfer stresses.

KEYWORDS

Concrete Filled Tubes, Creep, Elastic deformation, Time Dependent structural performance.

INTRODUCTION

Concrete Filled Steel Tube (CFST) columns have been successfully used in many high rise buildings such as the Taipei 101 tower in Taipei, the Two Union Square in Seattle USA, Shimizu Super High Rise Building in Tokyo, Guangzhou New TV Tower, China and 111 Eagle street, Australia. Axial shortenings of these structural components occur due to time dependent phenomena of basic creep, shrinkage and elastic deformation. Due to different gravity loads supported by these load bearing components they undergo differential settlements.

The structural systems in high rise buildings, with either reinforced concrete or CFST columns are commonly coupled with reinforced concrete outrigger and belt systems for lateral load resistance due to the unique combination of architectural flexibility and structural efficiency they offer compared to tubular systems. The outrigger and belt systems that link the core system to the column are therefore displaced by differential movements which can result in high transfer stresses in the lateral resistance system. In some cases these transfer forces are believed to amount up to the forces generated by the applied design lateral loads (Choi *et al*. 2012).

Although outrigger systems have been extensively used, one area that needs further investigation is the effects of differential shortening on these systems and the accurate prediction of these effects (Choi *et al*. 2012). Research will enhance the understanding in this area and will provide engineers some guidance on the following: (i) feasibility of changing and delaying the entire construction cycle times, (ii) using delayed connection of outrigger belt systems and planning connection times considering the risk of adverse lateral loading events that could occur during construction and (iii) determining the need for or effectiveness of detailed control measures such as sliding friction joints at the intersection of the walls as used in the Water Front Place Brisbane, Australia or damped outriggers developed by ARUP (Choi *et al*. 2012) or design the outrigger and belt systems to the combined effects of lateral loads and differential axial shortening while designing the structural frame system for possible load redistributions.

The accuracy of the predictions of the outrigger transfer stresses and construction planning inevitably depends on the accuracy of the differential axial shortening predictions. Therefore it is important to conduct the axial shortening analysis with adequate detail. The factors that need to be considered are accurate inclusion of the time dependent properties of creep and shrinkage and corresponding loading conditions, global structural effects caused by specific members such as outriggers, raking columns and transfers, effect of construction sequence on the deflection and importantly concrete levelling during construction (Moragaspitiya *et al*. 2010). In addition, previous research on reinforced concrete structural components confirmed that load migration occurs between concrete and steel due to the creep and shrinkage and this has significant effects on the axial shortening of these components (Wang *et al*. 2008) in which the effects of reinforcement need to be considered. This study incorporates all these in the numerical procedure that was developed and applied to quantify axial shortening of CFST columns and shear core walls. This comprehensive procedure can hence be used to accurately predict the stresses developed in the outrigger system due the interactive differential shortenings and control in the high rise structure caused by these horizontal rigid structural components.

METHODOLOGY

A comprehensive and rigorous methodology has been developed in this research incorporating all the time dependent phenomena occurring in the real-life situations. The methodology is based on material models presented in Euro code2 (EC2) which are well established among the practicing engineers and the finite element technique (FET). The creep calculation included in the methodology is based on the Age Adjusted Effective Modulus method (AAEM) developed by Trost and Bazant (Bazant and Baweja 2000) which includes the aging of concrete and can be applied to analyse high rise building accurately with limited computational demand. This combination was selected based on the outcomes of the previous research by Geng et al (Geng *et al*. 2012) who compared several creep material models, except that in AS3600, with results of 81 experimental tests on creep and shrinkage behaviour of CFST for a range of normal and high strength concretes. They used the largest test data on CFSTs and recommended the use of EC2 for the axial shortening predictions and the use of AAEM with coefficients suggested by Bazant and Baweja (Bazant and Baweja 2000).

Creep and Shrinkage Model of Concrete

Creep and shrinkage material models presented in EC2 have been incorporated into the methodology developed and presented in this paper through MPCHG command in the ANSYS finite element code. This command changes the material number attributes of the elements to include the relevant age adjusted elastic modulus value at the considered time step as the material elastic modulus for both column and shear wall elements. In the creep calculation, time-dependent concrete behaviour is modelled by the age adjusted effective modulus method developed by Trost and Bazant (Bazant and Baweja 2000). The age adjusted effective modulus; $\overline{E_c}(t,t_0)$ at any time t for first loading at t_0, is expressed by Equation (1). The aging coefficient; $\chi(t,t_0)$ as defined by Trost and Bazant is in Equation (2) and relaxation function $R(t,t_0)$ in Equations (3) and (3.1).

$$\overline{E_c}(t,t_0)=\frac{E_c(t_0)}{1+\chi(t,t_0)\ \phi(t,t_0)} \tag{1}$$

$$\chi(t,t_0)=\frac{E(t_0)}{E(t_0)-R(t,t_0)}-\frac{1}{\phi(t,t_0)} \tag{2}$$

$$R(t,t_0)=\frac{0.992}{J(t,t_0)}-\frac{0.115}{J_0}\left[\frac{J(t_0+\zeta,t_0)}{J(t,t-\zeta)}-1\right] \tag{3}$$

$$J(t,t_0)=\frac{1}{E_c(t_0)}+\frac{\phi(t,t_0)}{1.05\times E_{ci}} \tag{3.1}$$

Where; t_0 is the time of first loading, $E_c(t_0)$ is the Young's modulus of elasticity at the time of first loading, $\phi(t,t_0)$ is the creep coefficient from EC2 as presented below in Equation (4), $E_{ci}=E_{c0}[f_{cm28}/f_{cm0}]^{0.3}$, $E_{c0}=2.2\times10^4$, $f_{cm0}=10$, $\xi=(t-t_0)/2$ and $J_0=J(\xi+t_0,\xi+t_0-1)$

The creep coefficient; $\phi(t,t_0)$ as obtained from EC2 recommendation gives (BSI, Eurocode2 2004):

$$\phi(t,t_0)=\phi_{RH}\cdot\beta(f_{cm28})\cdot\beta(t_0)\cdot\beta(t-t_0) \tag{4}$$

where ϕ_{RH} , $\beta(f_{cm28})$ and $\beta(t_0)$ are factors to allow for the effects of relative humidity, concrete strength and concrete age at loading on the notional creep coefficient,

$\beta(t-t_0)=\left[\frac{(t-t_0)}{(\beta_H+t-t_0)}\right]^{0.3}$ is the time function of creep development that depends on relative humidity and notional member size $h_0=\frac{2A_c}{u}$ (A_c-concrete cross-sectional area, u is exposed perimeter).

Concrete shrinkage comprises of two components: drying $\varepsilon_{cd}(t)$and autogenous $\varepsilon_{ca}(t)$. The drying shrinkage depends on the notional size, environmental conditions such as relative humidity and temperature, strength of concrete and type of cement used while the autogenous shrinkage depends only on the strength of concrete.

The drying shrinkage component can be represented by Equation (5) below, while the autogenous shrinkage component is as given in Equation (6) below.

$$\varepsilon_{cd}(t)=\beta_{ds}(t,t_s)\cdot k_h\cdot\varepsilon_{cd,0} \tag{5}$$

$$\varepsilon_{ca}(t)=\beta_{as}(t)\cdot\varepsilon_{ca}(\infty) \tag{6}$$

In drying shrinkage, the basic shrinkage strain $\varepsilon_{cd,0}$ is modified with k_h, a coefficient depending on the notional size h_0 and the time function for drying shrinkage $\beta_{ds}(t,t_s)$. Whereas in autogenous shrinkage $\varepsilon_{ca}(\infty)$ *and* $\beta_{as}(t)$ are the basic autogenous shrinkage strain and the time function for shrinkage development respectively.

The procedure developed and presented in this paper uses an infinite value for the hypothetical thickness or notional size of the CFST components in order to eliminate drying components in both shrinkage and creep, which do not influence the axial shortening of CFST. Also, the relative humidity has been considered as 100% to account for the non-exposure of the concrete to the outer environment due to the presence of the steel tube.

The computational technique including the material modal presented above has been validated using experimental data published on Kwon et al (Kwon *et al*. 2005) which presents outcomes of the axial shortening behaviour of CFST columns. Details on the validation are reported elsewhere (Samarakkody *et al*. 2014).

FEM of the High Rise Building

The 60 storey CFST building in this study comprises of a reinforced concrete core shear wall system and belt and outrigger systems which are commonly used in high rise buildings. The building lay out is shown in Figure 2. 80MPa concrete (mean compressive strength at 28 days based on cylinder strength) has been used for outrigger and belt systems, 65MPa concrete has been used for the walls and 40 MPa concrete has been used for the floor plates (thickness -200mm). The reinforcement content of the walls is 3% of the cross sectional area. Sizes of the structural components are presented in Tables 1 and 2. "D" and "t" in Table 1 are the external diameter and the steel tube thickness of CFST columns respectively.

Table 1 Sizes of columns and thicknesses of core shear walls

Floor number	CFST column sizes D x t (mm)	Shear Wall thickness (m)
1-21	1150 x 16	1.2
22-41	900 x 12	1.0
42-60	800 x 8	0.75

Table 2 Size of walls of outrigger and belt systems

Floor number	Outrigger wall size (m)
20-21	0.8
40-41	0.6

The analyses have been conducted incorporating the influences of the self-weight, superimposed dead load (1.8 kPa) and live load (2.5 kPa) and environmental conditions such as 50% humidity (for RC components) and 30^{0}C temperature. A finite element model has been developed for the structural framing system shown in Figure 1. In this model, the columns and beams have been modelled using BEAM188 elements while the shear core walls, slabs and the outrigger- belt system have been modelled using SHELL181 elements.

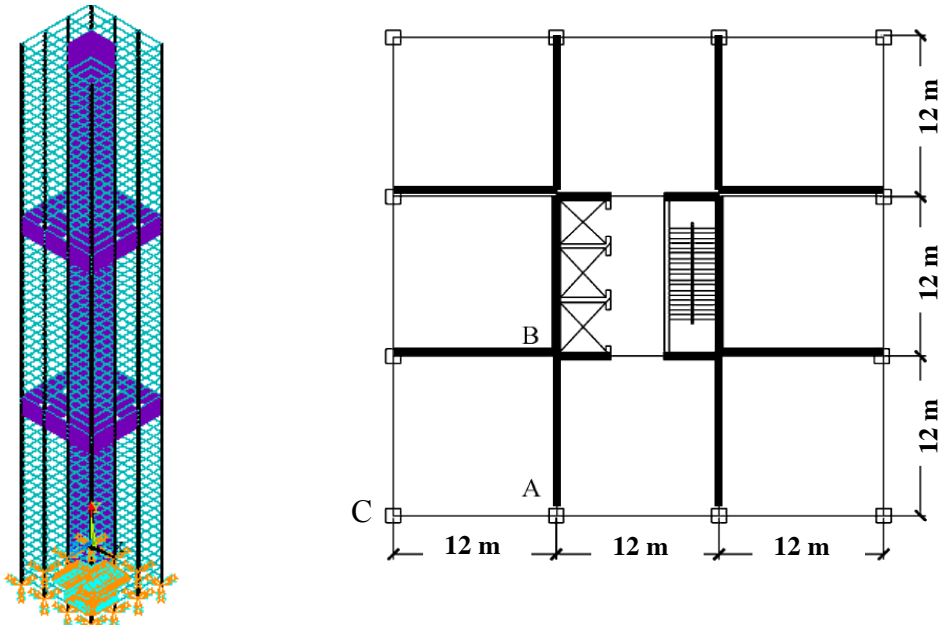

Figure 1 High rise building Isometric View (left) Plan View (right)

Simulation of Construction Sequence

During construction stage of building, structural components are incorporated into the whole structural system following the construction schedule and hence the stiffness and the self-weight for the system vary during construction. “Birth and Death of elements” option with geometric nonlinearity available in ANSYS is utilised to simulate these construction stages accurately. At the beginning of the analysis, all components of the system are killed (or deactivated) and all degrees of freedom (DOF) of these floating elements are fixed. The structural components are then gradually added (activated) according to the construction sequence while releasing the relevant DOF.

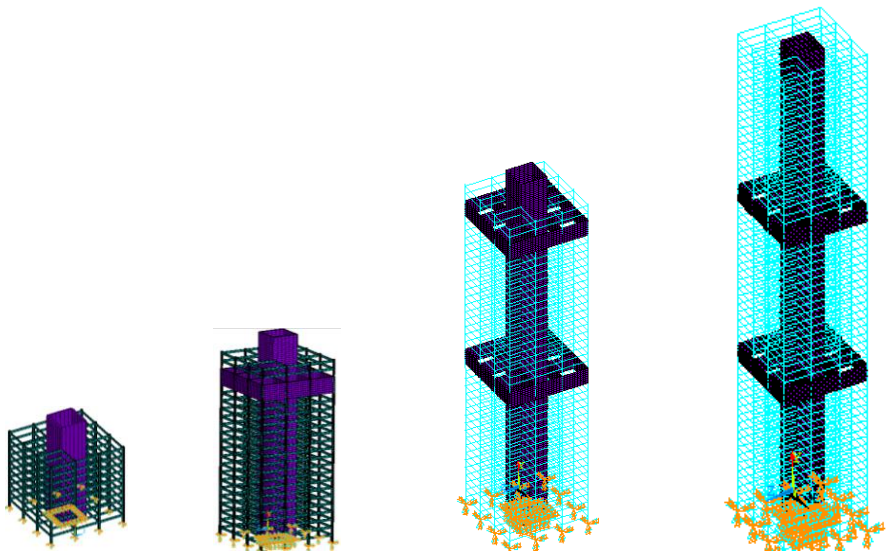

Figure 2 Modelling construction sequence

To achieve the "element death" effect in the ANSYS program, the stiffness of the structural components is multiplied by a very high reduction factor. Element loads associated with deactivated elements are zeroed (removed) out of the load vector. An element's strain is also set to zero when the element is killed. Similarly when an element is reactivated, all these return to their full original values. In addition, elements are reactivated with no record of strain history (ANSYS 2010). Figure 2 above shows the activated elements in a few representative construction steps such as after the construction of (a) 10th story, (b) 23rd story, (c) 43rd story and (d) 60th story.

RESULTS AND DISCUSSIONS

Time dependent behaviour of structural components during and after the construction has been studied. The variation of elastic, creep and shrinkage strains in the CFST column C (Figure 1) at levels 10, 30 and 50 are shown in Figure 3. The EC2 concrete creep modal for these columns predicted a maximum creep coefficient of 0.76, as opposed to the creep coefficient range of 2.0 to 3.0 for normal strength concrete. The present value seems to be close to that observed in the experiments of Uy (Uy 2001) who obtained an average creep coefficient value of 1.0, while testing 6 HSCFT column specimens with concrete having a 28 days compressive strength of 52 MPa. Further, Yisuo Ma (Ma and Wang 2012) observed maximum final creep coefficients of 0.75 and 0.57 at the age of 126 days for specimens with compressive strengths of 75.5 MPa and 85.5 MPa respectively which is closer to the concrete grade of 80 used for the columns in the structural system analysed and presented in this paper. Moreover, the maximum shrinkage strain obtained by EC2 for the CFST columns was 150 micro strains which is comparable with the tests of Uy et al (Uy 2001). After 140 days, they observed a total shrinkage strain of 160 micro strains, for the composite column as opposed to that of 600 micro strains of concrete cylinders which then approached a plateau after 140 days of results. The information above highlights the accuracy of the material models and computational technique used in the analysis.

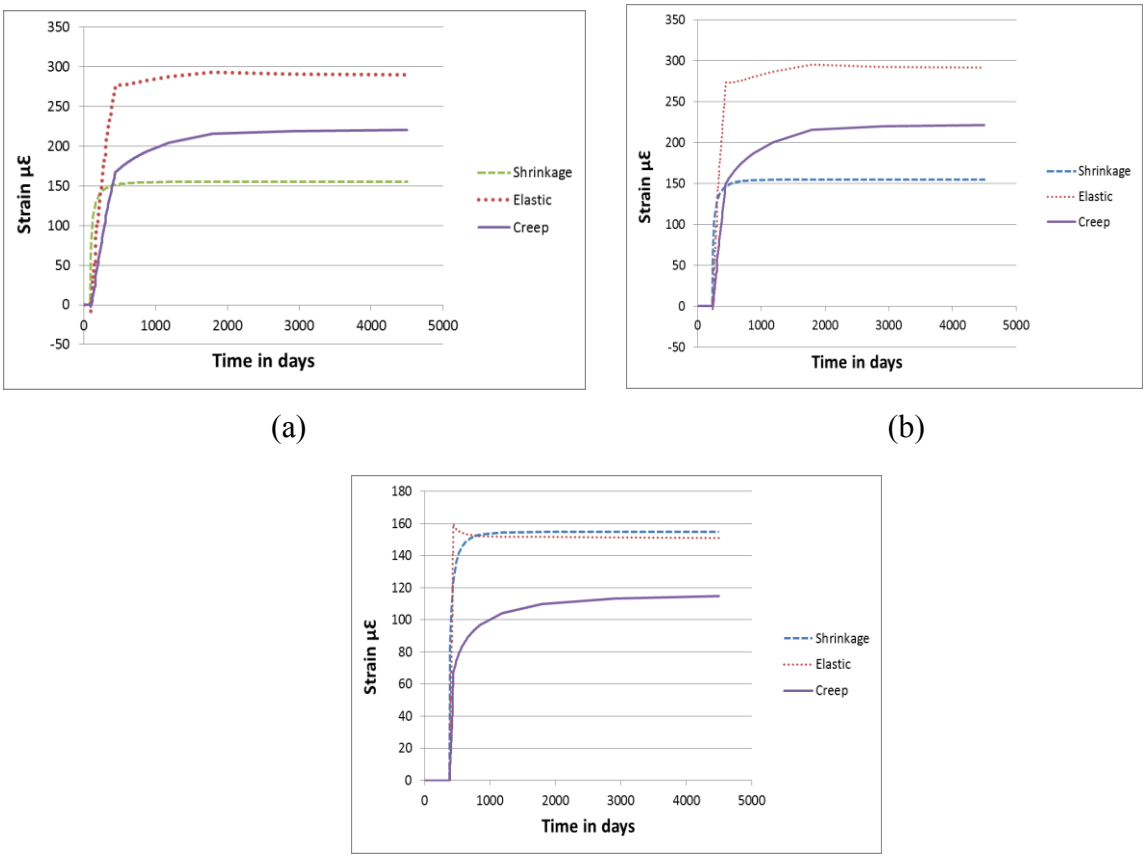

Figure 3 Variation of elastic, creep and shrinkage strains in column C for level (a) 10, (b) 30 and (c) 50

The axial shortening due to time dependent elastic, creep and shrinkage strains of CFST columns and the reinforced concrete shear core walls along the building height are presented in Figure 4. Figure 4(a) and 4(b) show the axial shortening of the CFST column on grids A and C together with the Shear walls at point B (see Figure 1) at each storey level of the building at 483 days (end of construction) and after 4500 days from start of construction respectively. As shown in these Figures, the axial shortening of the column at storey 32 (with a maximum of 51.48 mm) is higher than that of the walls with a maximum value of 44mm at storey 45 due to the fact that the gravity load tributary area of the column is higher compared to that of the walls. However, axial shortening of the top most three storeys of shear wall surpasses that of columns due to higher shrinkage and creep of the reinforced concrete shear wall resulting from drying and the columns being lightly loaded than at the lower levels. The axial shortening of the vertical load bearing structural components are equal at the outrigger floor levels of 19-21 and 39-41 as indicated in Figure 4 confirming that the load migration between the structural components at these locations occurs due to the outrigger systems.

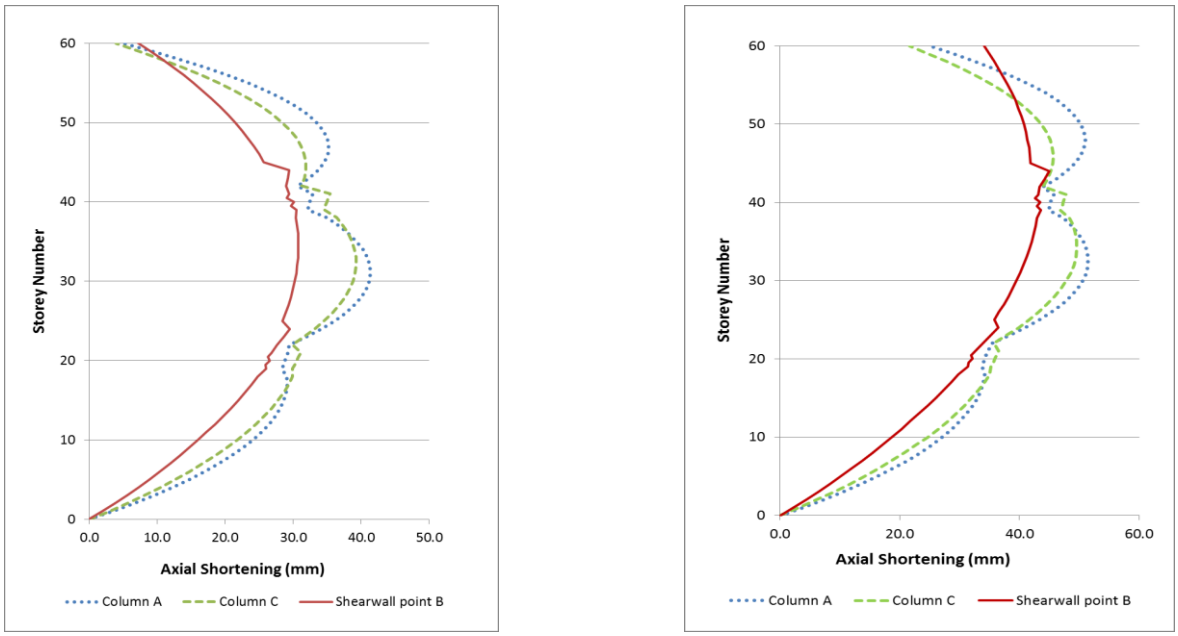

Figure 4 Axial shortening of vertical load bearing elements (a) at the end of construction, (b) at 4500 days from start of construction

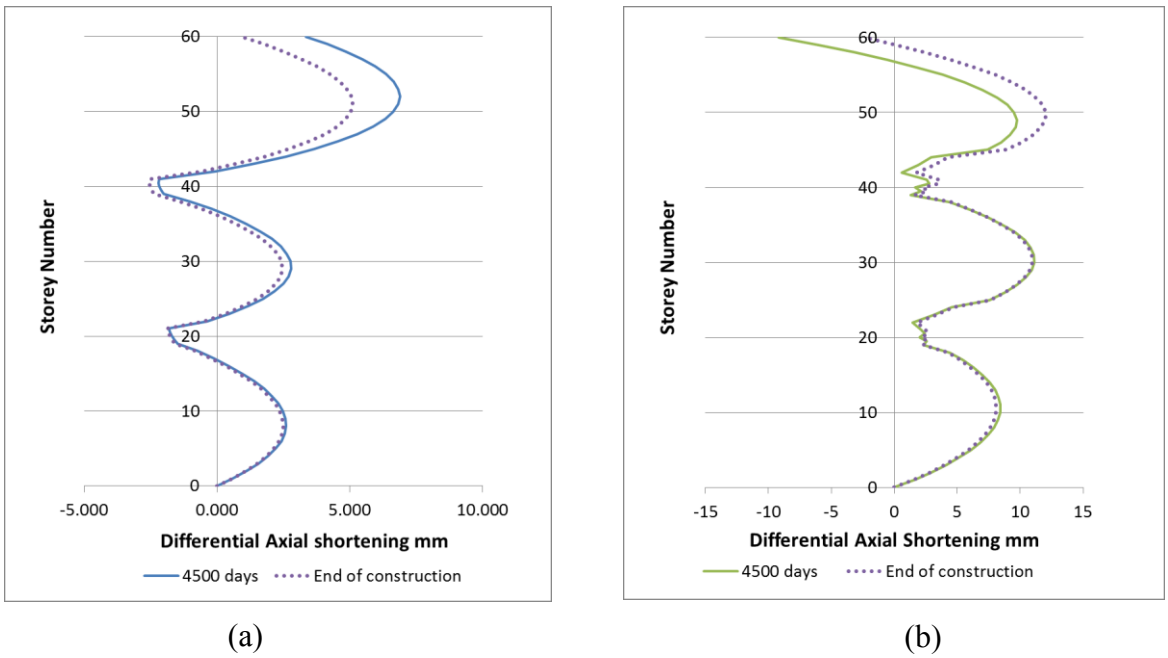

Figure 5 Differential Axial shortening (a) between column A and C, (b) between column A and shear wall at B

Differential Axial shortening between the CFST columns A and B is presented in Figure 5(a) and that between the shear core and the columns linked to it by outrigger is given in Figure 5(b). The maximum differential shortening is about 12mm which is at level 50 of the building and is between the shear core walls and the column connected to it. As evident from the above Figures, differential shortening between the two columns increases with time while that between the perimeter column and shear wall connected with outriggers decreases with the time and reverse in direction due to the load migration occurring through the outrigger and the higher creep and shrinkage occurring in shear walls due to drying.

The above mentioned linkage between columns and shear walls through the outrigger which leads to partial gravity load transfer from columns to shear walls, results in controlling the differential shortening between the structural components. As a result, the outrigger and belt systems are subjected to high gravity transfer stresses. The stress increment due to the load migration, impacts significantly on the performance of the lateral load resisting system of the whole building. This increment is evident in the stress plots in Figure 6 and 7 shown below. Figure 6 (a) and (c) illustrate the horizontal membrane stresses and (b) and (d), the transverse shear stresses of the bottom outrigger located between floor levels 19-21. The first on each set shows the stresses at the end of outrigger construction and the next shows the stresses at the end of 4500 days from the start of construction. Similarly Figure 7 (a), (b), (c) and (d) illustrate these stress distributions for the top outrigger located between floor levels 39-41.

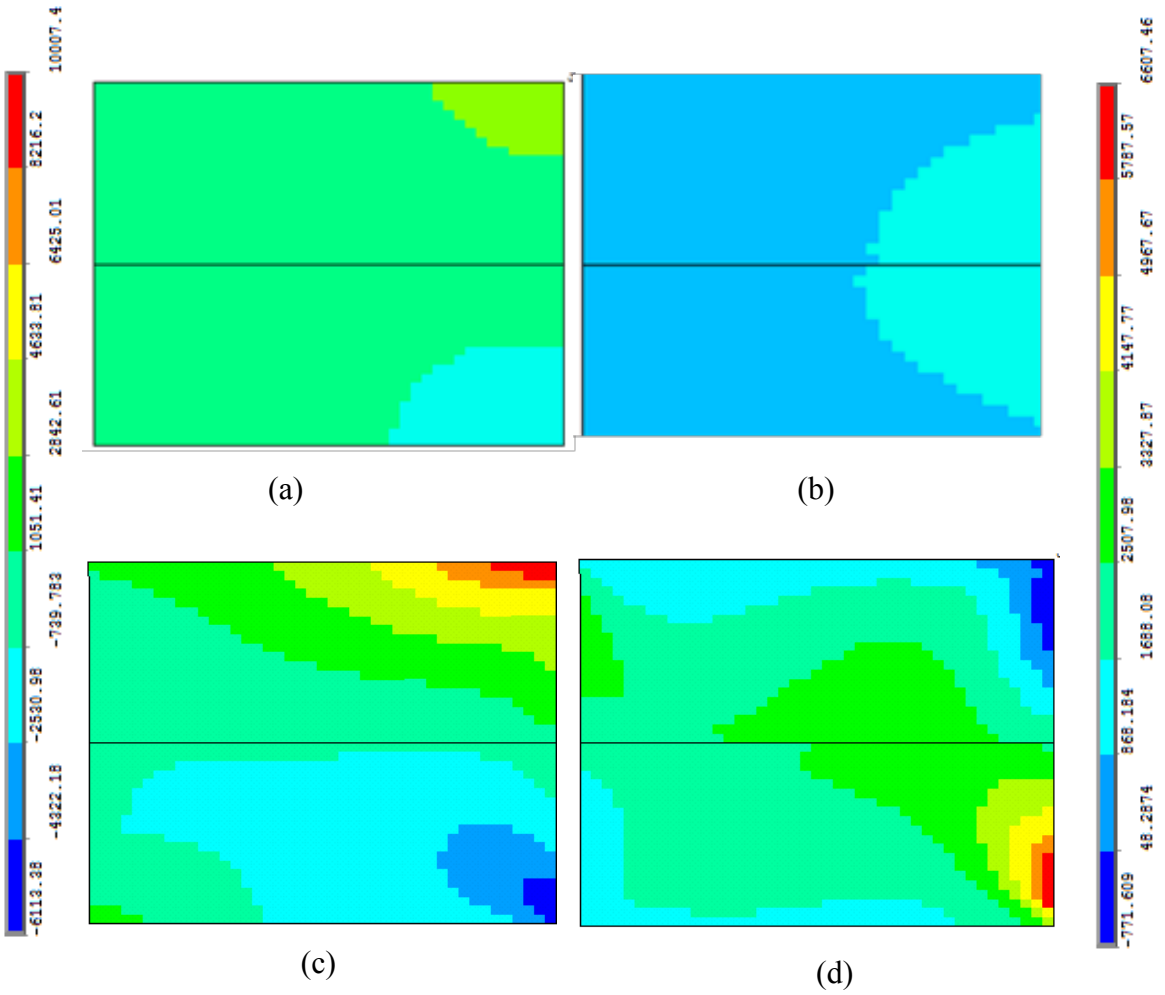

Figure 6 (a) Horizontal membrane stresses, (b) transverse shear stresses at the end of construction of outrigger and (c) horizontal membrane stresses, (d) transverse shear stresses at 4500 days of the bottom outrigger in kN/m^2

Figure 6 illustrates that the maximum horizontal membrane stress of the bottom of the outrigger increases from 2.3MPa (at end of construction) to 10 MPa (after 4500 days) which is an increase of 335%. The transverse shear stresses also increases from 1.3 MPa to 6.6 MPa during the time from removal of formwork of outrigger till end

of 4500 days. Correspondingly the top outrigger horizontal membrane stresses and transverse shear stresses increased by 381% and 340% respectively each rising from 2.451 MPa to 11.8 MPa and 1.57 MPa to 6.9 MPa. Therefore for the specific building considered, there is a 3-4 times increment in outrigger stresses from construction till end of 4500 days due to differential axial shortening of vertical load bearing elements. However, considering the outrigger concrete strength which is 80MPa, the final stresses due to gravity loading and the differential axial shortening are about 14% of the concrete strength therefore doesn't exceed the safety limits.

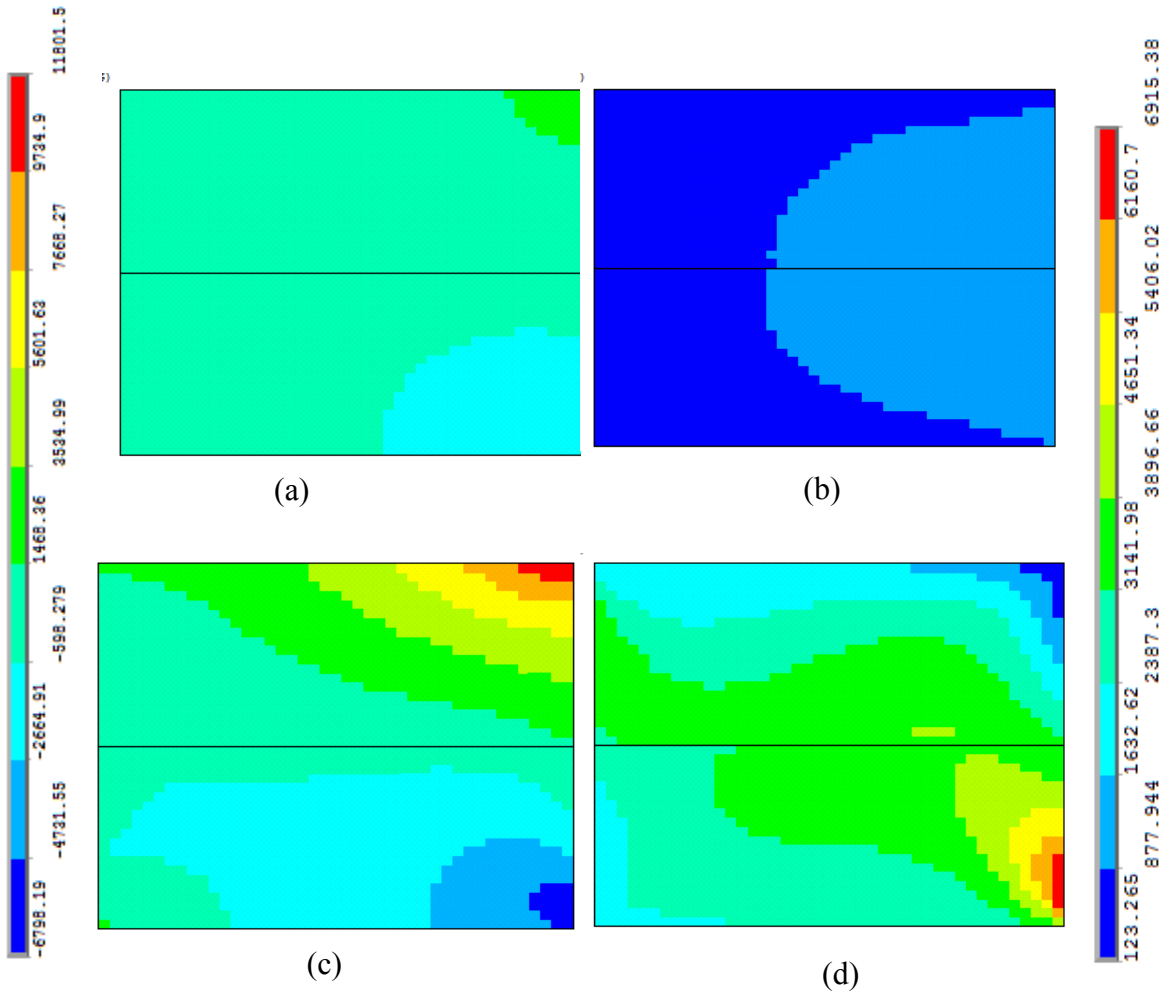

Figure 7 (a) Horizontal membrane stresses, (b) transverse shear stresses at the end of construction of outrigger and (c) horizontal membrane stresses, (d) transverse shear stresses at 4500 days of the top outrigger in kN/m^2

Figure 8 (a) and (b) below show the distribution of horizontal membrane stresses along the outrigger height at a line 1m away from the (a) column end and (b) shear wall end. Also Figures 8 (c) and (d) show and transverse shear stresses at these same locations respectively. These Figures further illustrate the increment in the membrane stresses due to increased bending moments and the transverse shear stresses with time owing to the creep and shrinkage deformations in the building column and wall elements that was discussed above. Initially both the bottom outrigger and the top outrigger are under similar stresses just after the removal of formwork, with the axial shortening of vertical elements at both outrigger levels being similar in magnitude. However at 4500 days, the stresses in the top outrigger have surpassed those at the bottom outrigger due to the higher deformation differentials at levels 39-41 compared to those at the bottom outrigger which is at levels 19-21.

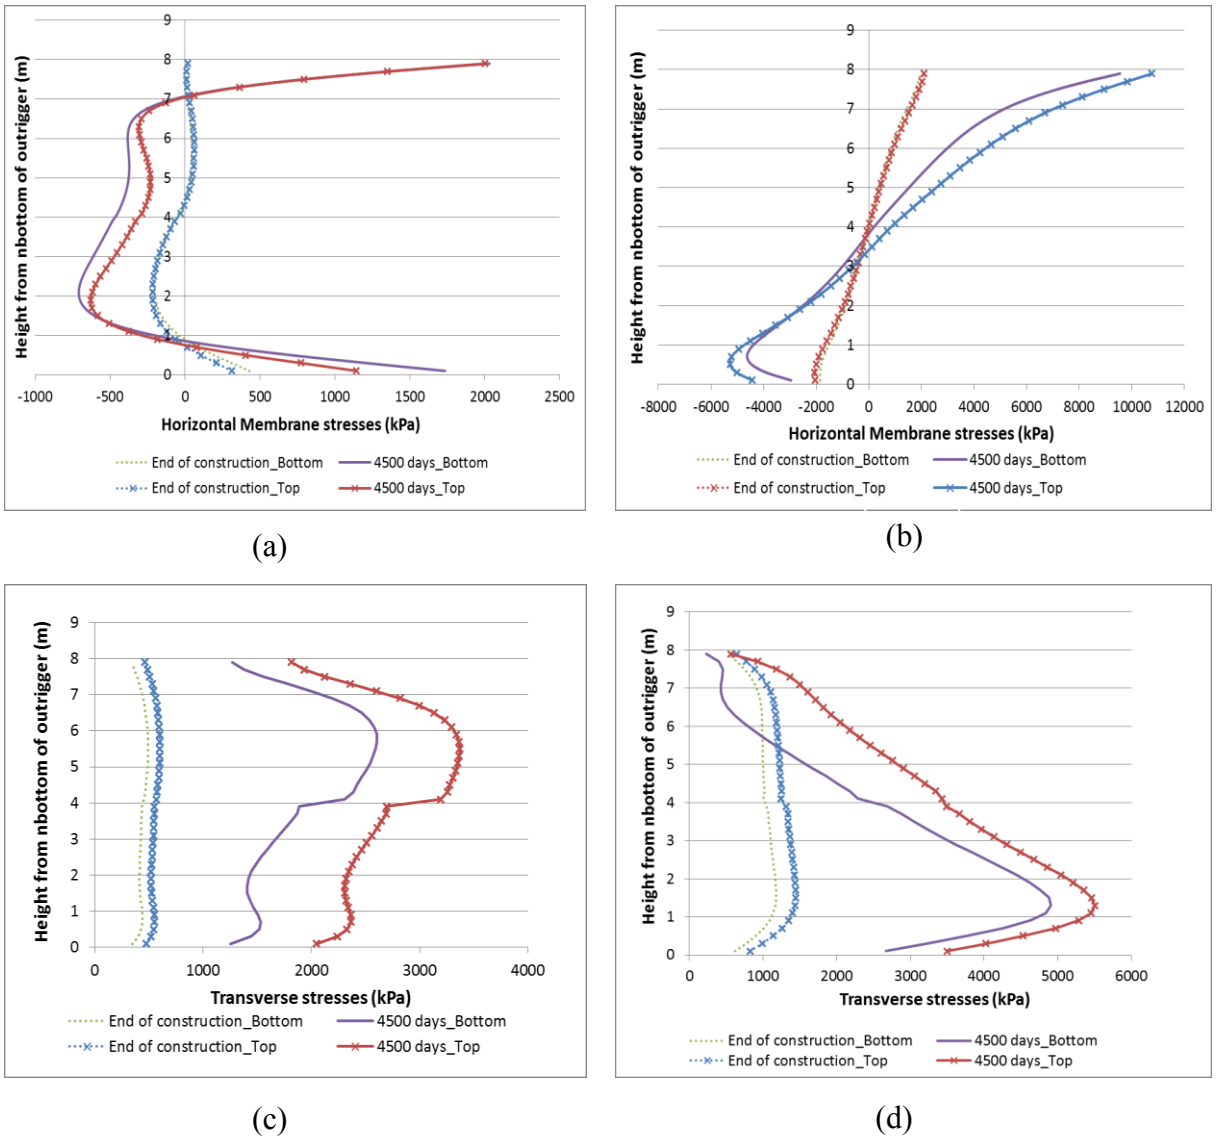

Figure 8 Horizontal membrane stresses at (a) column end, (b) shear wall end and transverse shear stresses at (c) column end, (d) shear wall end

CONCLUSIONS

A detailed analysis of a high rise building with CFST columns, reinforced concrete shear walls and outrigger belt system has been carried out using the developed method with FET to quantify the stress development in the outrigger system due to the differential shortening between columns and the shear wall structure. This modelling procedure also included the effects of reinforcement, time dependent material properties, construction sequence and interaction of outrigger and belt system with the structural frame on and during DAS. There is a 3-4 times increment in outrigger stresses from construction till the end of 4500 days due to differential axial shortening of vertical load bearing elements for the specific case studied.

The procedure can be conveniently used by practicing engineers to estimate the axial shortening of a CFST building and the expected transfer stresses in the outrigger and belt systems due to this differential shortening of the columns and shear walls. This information will provide guidance on outrigger connection timing and the need for complex control systems and enable them to make a decision on whether to design the outrigger and belt system incorporating the stress increment due to the control of differentials in displacements of linked vertical load bearing elements.

ABSTRACT

This paper presents research work that aims at developing a robust method for condition assessment of real-life concrete structures for the detection of small cracks at an early stage of development. A method is presented that utilises an unsupervised one-class support vector machine (SVM).Measured acceleration data from the current state of a structure are used as input parameter. The first singular value of the measured response data is utilized for training and testing of new data sets. Two damage identification approaches are demonstrated, one implementing the SVM for each measurement sensor separately, and another one implementing the SVM for all sensors combined. The use of one-class SVM is well suited for the condition assessment in structural health monitoring since they can detect the advancement of cracks by assigning progressively negative decision values. The presented method is based on unsupervised and non-model-based approaches, and hence there is no need for any representative numerical/finite element model of the structure to be created. To demonstrate the feasibility of the method in the detection and assessment of gradually evolving deterioration, it is tested on a replicate structure of a concrete jack arch which is a main structural component on the Sydney Harbor Bridge – one of Australia's iconic structures. The test structure is a concrete cantilever beam with an arch section which is located on the eastern side of the bridge underneath the bus lane. A cut is introduced to the structure using a saw and its length is progressively increased in four stages while the depth is kept constant; these four damage cases correspond to less than 0.5% reduction in the first three vibrational modes of the structure which is considered a very small damage. It is demonstrated that the presented method can reliably detect the progression of the crack in the structure and thus can enable the real-time monitoring of infrastructures.

INTRODUCTION

All civil structures have finite lives, and they begin to deteriorate as soon as they are put into service, due to processes such as corrosion, fatigue, erosion, wear and overloading. To ensure the safety and reliability of ageing infrastructures, the concept of structural health monitoring (SHM) was developed in the 1960s and is applied today by infrastructure owners and authorities to assess the health condition of a structure. SHM enables early and reliable damage detection and health assessment, and thereby prevents catastrophic failures and allows the extension of a structure's lifespan. In general, SHM covers continuous, global and automated monitoring practices that aim at detecting, locating and estimating any introduced damaged or any growth of inherent faults in a structure and enables the decision making on actions of safety measures and the predication on a structure's residual life, following Rytter's hierarchy (Rytter, 1993).

The fundamental questions for the design of a SHM system are, as stated in (Cross et al. 2013); what can be measured that correlates to damage, how to measure it, and, importantly, how to use the raw measurements to make inferences and decisions about structural condition. To date, the most common measurements for SHM systems are the vibration responses of a structure (Makki Alamdari et al. 2014). These global measurements contain information about the mass, stiffness and damping of a structure and can thereby reflect structural changes due to damage. Measurements of acceleration along with strain are the most commonly used quantities

in SHM systems, but also other measurements such as acoustic emissions, electrical impedance are being employed. An ideal SHM system comprises of a large number of heterogeneous sensors installed across the structure at various locations.
After the collection of raw measurements, a SHM system faces two challenges, one is feature extraction and the other is pattern recognition. Since damage fingerprints are typically deeply embedded in the raw measurements, a parameter must be formulated that extracts the damage features from the measured raw data. This feature extraction process usually also involves dimensional reduction. Some traditional damage sensitive parameters are resonant frequencies, mode shapes, modal flexibilities, modal stiffness and modal strain energy. Feature extraction methods include modal analysis and statistical methods such as principal component analysis or singular value decomposition.

Once a particular feature has been extracted, it must be classified using pattern recognition techniques to determine whether it has arisen from the damaged or undamaged structure, and at higher levels of SHM, classified as to the location, type and severity of the damage if present (Cross et al., 2013). Pattern recognition techniques include supervised learning approaches such as neural networks, support vector machines and Gaussian processes (Worden et al., 2011) and novelty detection such as outlier analysis and the use of statistical process control charts(Worden et al., 2004). While supervised learning approaches require data from damaged states of a structure, novelty detection methods only rely on data from the undamaged condition of a structure, which is most often the case for practical applications of in-situ structures.

This paper presents a damage identification method that is applicable to SHM systems of in-situ structures where only data of the current (undamaged) state is available. The method uses acceleration response measurements as raw data and applies single value decomposition (SVD) as feature extraction technique and one-class support vector machine for pattern recognition. The method is validated on experimental data from a laboratory test structure that represents a replica of a concrete jack arch from the Sydney Harbor Bridge. Progressive damage of four stages is inflicted to the test structure and the vibrational responses are captured by a number of accelerometers at the healthy and each damaged state. Two damage identification approaches using the presented method are demonstrated, one approach implements the SVM for each measurement sensor separately, and the other approach implements it for all sensors combined. The results show that both approaches are robust in detecting the presence of damage. The second approach is also successful in reliably indicating the progression of damage.

BACKGROUND

Support Vector Machine

Support Vector Machine (SVM) (Cortes & Vapnik, 1995) is a supervised learning technique with strong theoretical foundations based on the Vapnik-Chervonenkis theory. It has a strong regularization property, which is the ability to generalize a model to new data. These characteristics help to overcome overfitting, which is a common issue for neural networks. Furthermore, SVM can unify different types of discriminant functions such as linear, polynomial, radial basic functions in the same framework.

In the context of this paper, **x**is a feature vector extracted from sensor data, $y \in \{-1,1\}$ the label of **x**, where $y = -1$ means that **x** is recorded from a damaged bridge component and $y = +1$ means that **x** is measured from a healthy component. We want to find a hyperplane with maximum margin that separates the points with labels $y = +1$ from those having $y = -1$.

The classification model is a function, $f: R^d \rightarrow \{-1,1\}$. It is in the form: $f(x) = \mathrm{sgn}(w \cdot x - b)$ where '.' is the dot product, $\mathrm{sgn}(x) = +1$ if $x > 0$ and $\mathrm{sgn}(x) = -1$ otherwise. **w** and b are the parameters of the model and can be learned from training data. Given a set of *n* training samples, $\{(x_i, y_i)\}_{i=1}^{n}$, the training process determines the model parameters **w** and b by minimizing the classification error on the training set while still maximizing the margin. Mathematically, it is equivalent to the following minimization problem:

$$\min_{w,\xi,b} \frac{1}{2}\|w\|^2 + C\sum_{i=1}^{n}\xi_i \quad (1)$$

$$\text{such that} \quad y_i(w \cdot x_i - b) \geq 1 - \xi_i, \;\; \xi_i \geq 0, \;\; i = 1, \cdots, n, \quad (2)$$

where ξ_i is a slack variable for controlling how much training error is allowed and C is the variable for controlling the balance between ξ_i (the training error) and **w** (the margin). The problem can be transformed to the dual form using Lagrangian multiplier:

$$\max_{\alpha_1,\cdots,\alpha_n} \sum_{i=1}^{n} \alpha_i - \frac{1}{2}\sum_{i,j} \alpha_i\alpha_j y_i y_j x_i.x_j \quad (3)$$

such that $$\sum_i \alpha_i y_i = 0,\ 0 \le \alpha_i \le C,\ i = 1,\cdots,n. \quad (4)$$

This problem can be solved using quadratic programming. The learned classification model $f(x) = \mathrm{sgn}(w \cdot x - b) = \mathrm{sgn}(\sum_i \alpha_i y_i x_i x - b)$ will be used to determine if a new data instance is coming from a healthy or damaged bridge component. A health score for a new data instance, denoted as $\mathbf{x_{new}}$, can be generated as $\sum_i \alpha_i y_i x_i x_{new} - b$.

One-class Support Vector Machine

Due to the limited availability of damaged data for supervised learning, unsupervised or one-class approach is more practical. In this work, we use one-class SVM (Schölkopf et al. 2001), (Schölkopf et al., 1999) for damage detection. The algorithm is to find a small region containing most of healthy data points. They do that by mapping data into a feature space using a kernel function and then separating them from the origin with maximum margin. The Kernel function is a function that corresponds to an inner product in the feature space. This makes the algorithm to fit the hyperplane in a transformed high-dimensional feature space although we cannot linearly separate the two classes in the original feature space. Using the settings of supervised SVM learning with the origin as a second class, the one-class learning process can be formed as the following optimization problem:

$$\min_{w,\xi,b} \frac{1}{2}\|w\|^2 + \frac{1}{vn}\sum_{i=1}^{n} \xi_i - \rho \quad (5)$$

such that $$\mathbf{w} \cdot \mathbf{x_i} \ge \rho - \xi_i,\ \xi_i \ge 0,\ i = 1,\cdots,n, \quad (6)$$

where *v* has similar function as *C* in supervised SVM and *n* represents the number of training examples.

It is worth noting that the training dataset $\{x_i\}_{i=1}^{n}$ in this case only contains feature vectors and no label information is provided. Once the model is obtained, health score can be created in the same way as the supervised learning as $f(x) = \mathrm{sgn}(\sum_i \alpha_i x_i x - \rho)$. A negative health score from a new data instance will indicate it is an anomaly, which is likely damage.

Feature Extraction

The method used in this paper is based on the Frequency Domain Decomposition (FDD) technique, which uses Singular Value Decomposition (SVD) of the spectral matrix. This section aims to provide a theoretical background of FDD.

Suppose a system under white Gaussian excitation. The relation between an unknown input and the measured response can be expressed by:

$$G_{xx}(\omega) = H(\omega)G_{ff}(\omega)H^T(\omega) \quad (7)$$

where G_{xx} is a $m \times m$ Power Spectral Density (PSD) matrix of the responses and G_{ff} is a $n \times n$PSD matrix of the input excitation. $H$is a$m \times n$ Frequency Response Function (FRF) matrix. Under assumption of a white Gaussian input and lightly damped system, it can be proved that the PSD of response corresponds to Eigen-parameters of the system [(Brincker et al., 2000)].

In FDD, the first step is to estimate the PSD matrix of the response. At each frequency, the PSD matrix is decomposed by taking the SVD of the matrix as:

$$G_{xx}(\omega) = U\Sigma U^H \quad (8)$$

Where U and Σ are $m \times m$ unitary matrix of singular vectors and diagonal matrix of singular values, respectively. In this study, the first singular value of Σ at each frequency coordinate is utilized as damage sensitive feature and training of the model is performed according to the estimated first singular values of the measured responses at the healthy state of the structure.

EXPERIMENTAL CASE STUDY

The experimental set-up for this study is a reinforced concrete jack arch, which is one of the major structural components of the Sydney Harbor Bridge. There are 800 concrete jack arches on the underside of the deck of the bus lane, see Figure.1(a). For the bridge management, it is critical to detect any structural deterioration in the arches as early as possible in order to schedule the required inspection and repair. A steel reinforced concrete beam was manufactured with a similar geometry to those on the Sydney Harbor Bridge, see Figure.1(b). The length of the specimen was 2000 mm, the width was 1000 mm and the depth was 374 mm, see Figure.2(a) and (b).

A 16-channel NI PCI-6133 data acquisition was used to capture the force and resultant acceleration time histories. To measure the structure's vibrational response, the structure was excited using an impact hammer with steel tip, which was applied on the top surface of the specimen just above the sensor A9, see Figure.2 (a). The acceleration response of the structure was collected by 10 uniaxial PCB 352C34 accelerometers placed at the front face of the jack arch termed A1, A2, …, A10, see Figure.2(a). Measurement were recorded for 2 seconds at a sampling rate of 8 kHz, resulting in 16000 samples for each event.

After testing the benchmark structure in its healthy condition, a crack was gradually introduced to the specimen between sensors A2 and A3 with four levels of crack dimensions: (75 × 50) mm, (150 × 50) mm, (225 × 50) mm and (270 × 50) mm, see Figure.2 (c), (d), (e) and (f). A total of 190 impact test responses were collected from the healthy condition and at each level of damage severity.

In order to investigate the impact of damage on the natural frequencies, at each damage case, a comparison was made on the measured frequency responses. Figure.3 compares the Fast Fourier Transform (FFT) of four damage cases and the healthy state. As expected, the discrepancy is more obvious at higher frequencies, higher than 500 Hz, in this case, and there is not much distinguishable difference in frequencies lower than 500 Hz. It was realized that the change in the first three natural frequencies between the healthy state and all damage cases was less than 0.5% which corresponds to very small damage.

DAMAGE IDENTIFICATION RESULTS

First Approach: Implementation of SVM for Each Sensor Location

Two different approaches were implemented to build and train a model utilizing one-class support vector machine. In the first approach, for each sensor location and for all events, 190×5 (190 events for each state of the structure including one healthy state and four damage states), the features in the frequency domain were created as follows. For every vibration event, the data from each accelerometer were standardized to have zero mean and one standard deviation. Then the data were converted to the frequency domain to generate the power spectral density. Only half of the samples (8000) were used since the frequency spectra were mirrored with respect to the Nyquist frequency; hence, there were 8000 feature elements for each event. All 190 events from the healthy state of the structure were implemented to train the model. A separate model was constructed for each sensor location. The remaining data from four damage cases were implemented for the testing and an accuracy of 99% was effectively obtained for all sensor locations showing that all damage cases were correctly identified as a separate class. Then testing was separately performed for each damage case. All 190 events from each damage case were utilized for testing to detect the

progress of damage in the structure. The results of the testing for all 10 sensors locations and four damage states are depicted in Figure 4.

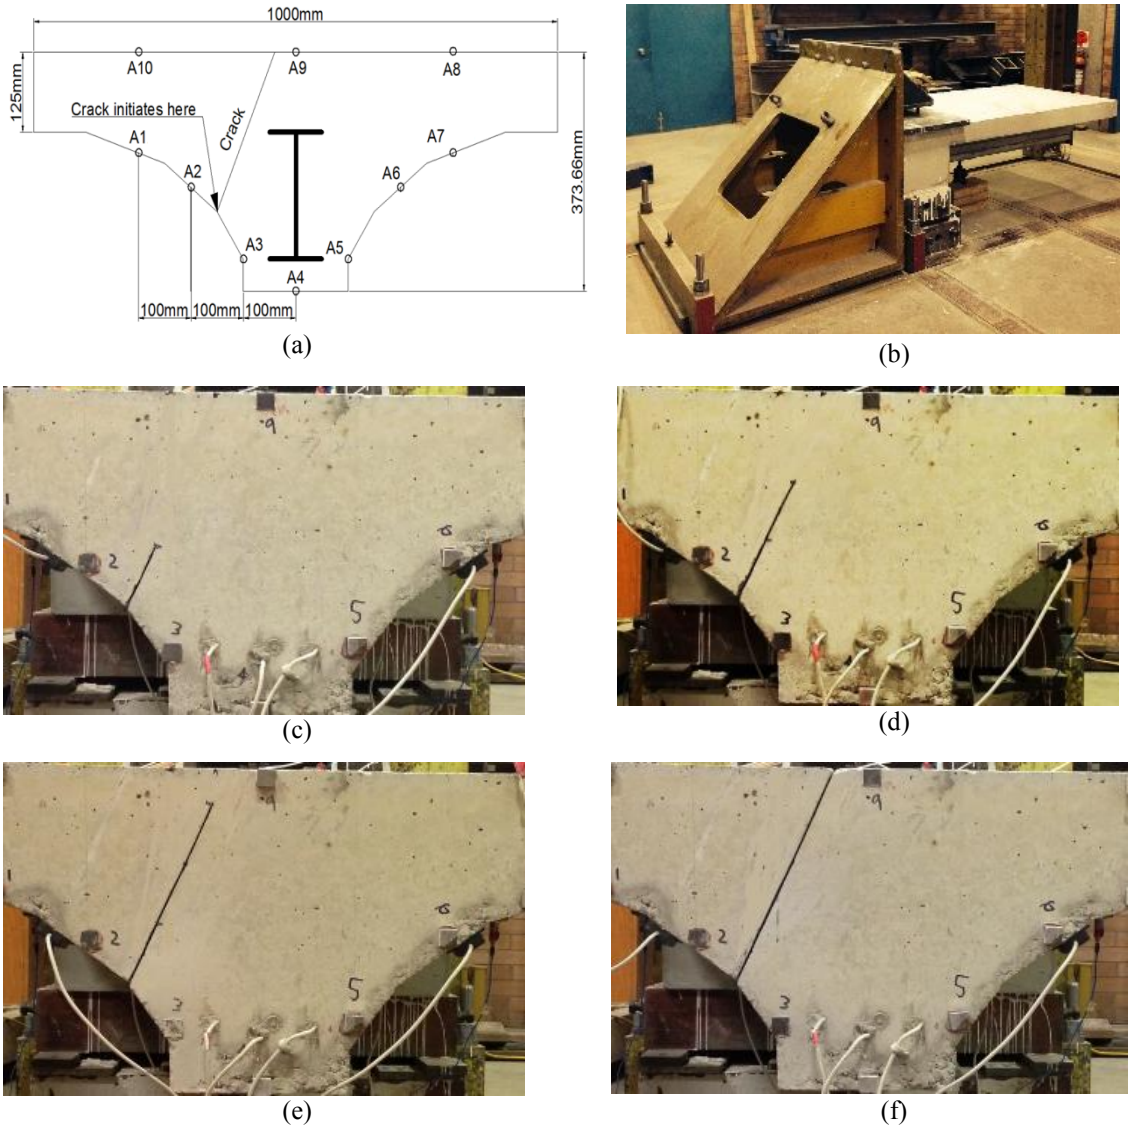

Figure 2. Test specimen: (a) intact structure with arrow indicating the cut, (b) support of the structure, (c) damage case 1: 75 mm damage cut, (d) damage case 2: 150 mm damage cut, (e) damage case 3: 225 mm damage cut and (f) damage case 4: 270 mm damage cut.

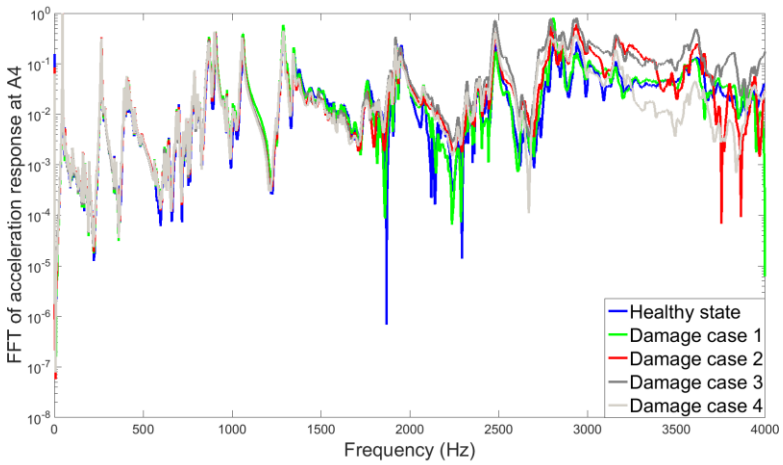

Figure 3. Comparison of the FFT of response in the healthy case and four damage cases for sensor location A4

The horizontal axis in each graph indicates the event index including 190×4= 760 events in total and each circle refers to one of these events. The vertical axis refers to the decision values. The four damage cases are differentiated by four colours. The first 190 events refer to damage case 1, the second 190 events refer to damage case 2, the third 190 events refer to damage case 3 and the last 190 events refer to damage case 4. The average of all decision values for each damage case is calculated and illustrated by a big black point. A line connects the averages of all decision values at each damage case as shown in Figure 4.

As illustrated, almost all obtained decision values are negative which indicates the fact that the testing data are not from the same class as the trained data which corresponds to the healthy state of the structure. On the other hand, it can be observed that with an increasing damage severity, an overall decrement trend in decision values is obtained, however, this is not the case for sensor A2 from damage case 1 to damage case 2. Also, it can be seen that there is very small variation in the connecting line at most sensors from damage case 3 to damage case 4 meaning that most sensors cannot detect the progress of the crack in the structure from case 3 to case 4.

From this demonstration, it can be concluded that an individually trained ML model for each sensor is able to detect the presence of damage in the structure (a negative decision value is obtained for an event from a damaged state). Moreover, the progress of the crack in the structure can also be identified for most sensors.

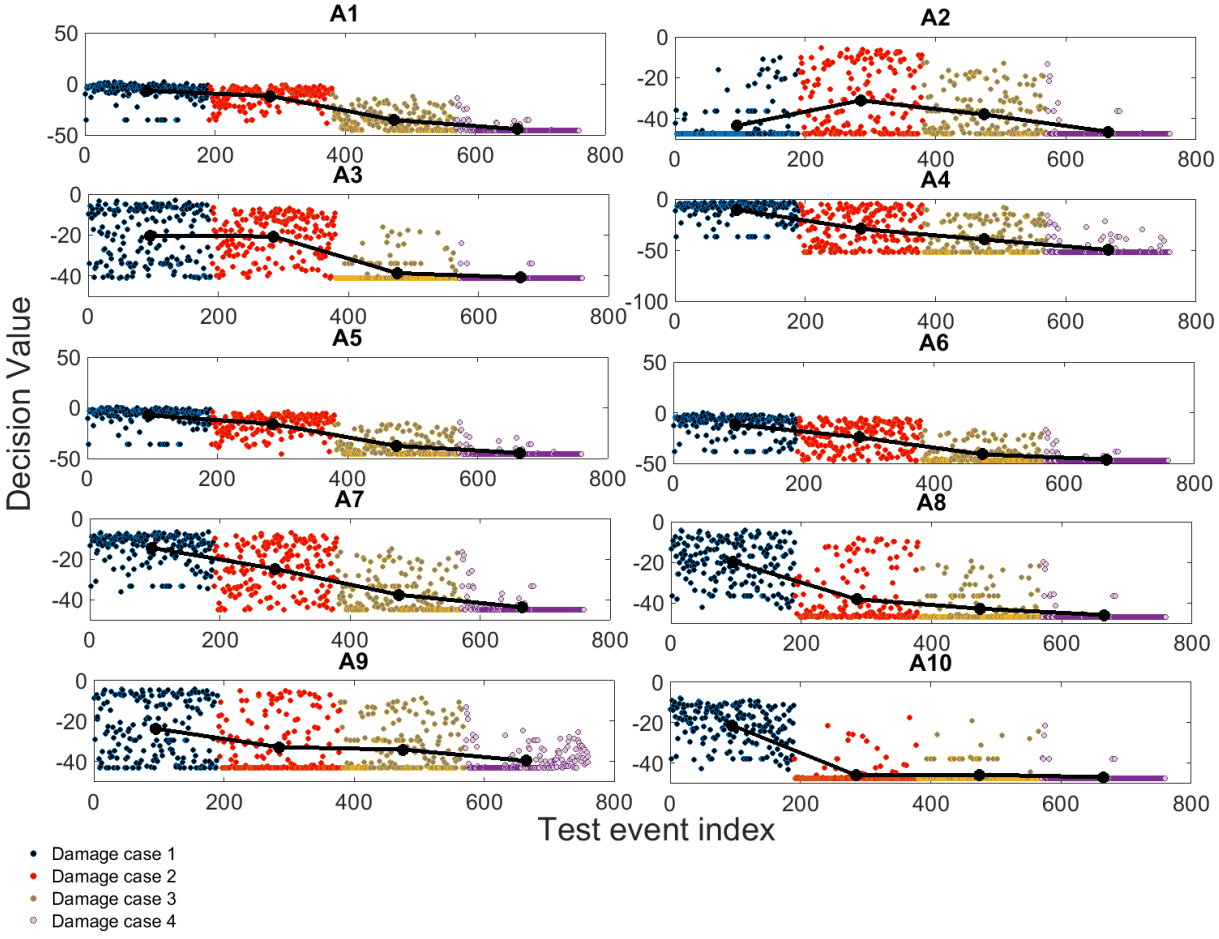

Figure 4. Damage identification results applying SVM for each sensor location

Second Approach: Implementation of SVM for All Sensor Locations

In the second exercise, the SVD approach was implemented as follows. At each frequency coordinated, the power spectral matrix was constructed. This matrix will be a 10 by 10 symmetric matrix. Then by applying SVD, the singular values of the constructed matrix were estimated for each frequency spectrum. The first and second singular values from the healthy state of the structure were utilised to train the model and then testing was conducted using the first and second singular values of each damage case. The obtained decision values are

presented in Figure 5 and Figure 6 for first and second singular values, respectively. The set-up of the graphs is the same as for Figure.4.

As illustrated, almost 99% of the tested data is correctly identified as unhealthy event since the obtained decision value is negative. In addition, using this approach, the progress of damage is correctly identified as a decreasing trend in the damage index line is obtained.

This demonstration illustrates that training and testing the model using all sensor data results in a more robust indication of the crack progression in the structure. An interesting finding is that not only the first singular value can successfully assess the crack growth in the structure but also the second singular value can reliably detect its progression.

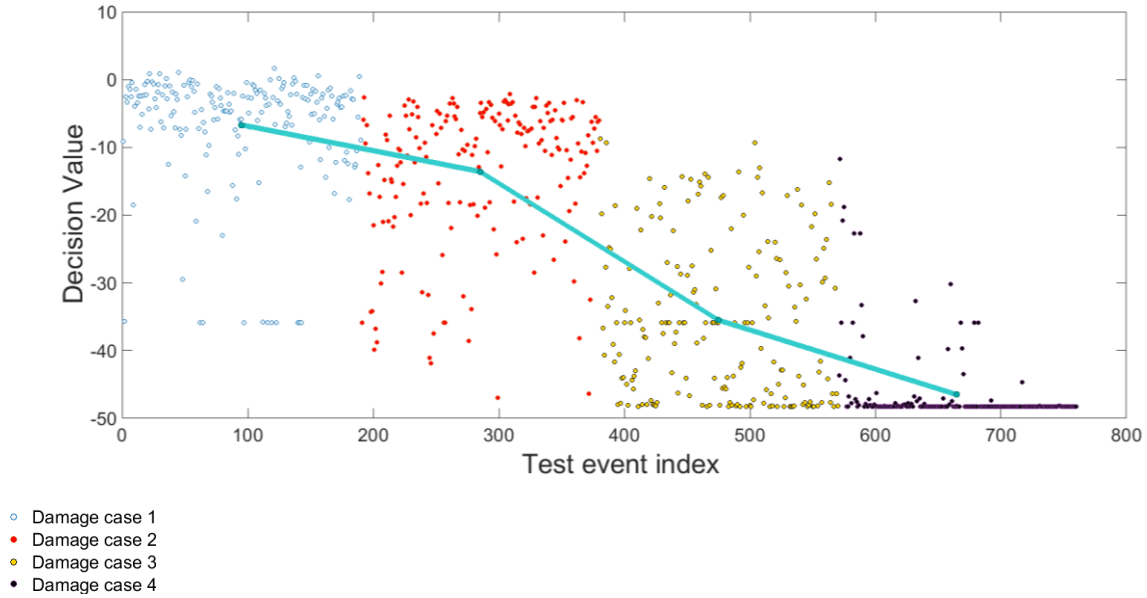

Figure 5. Damage identification results using first singular value

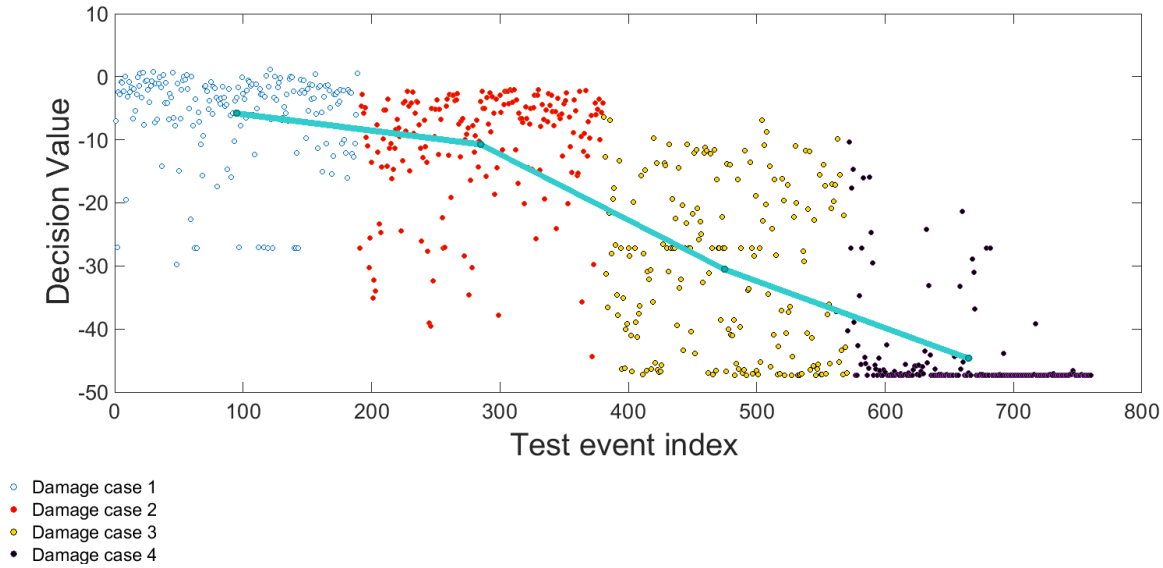

Figure 6. Damage identification results using second singular value

CONCLUSION

This work presented a damage detection methodology using a machine learning algorithm. A structural benchmark model was learnt using one-class SVM on a structural component of the Sydney Harbor Bridge and then was tested

with data from damaged states of the structure. This approach suits real situations where data from a damaged state are not available for supervised learning. To demonstrate the method, an artificial damage was inflicted to the test structure and its severity was increased in four stages. Then new events were tested against the benchmark model to detect damage. Two different exercises were conducted to detect the presence and progress of damage in the structure. In the first approach, a model was constructed for each sensor location and in the second approach a model was constructed using the first and second singular value of the power spectral matrix. It was demonstrated that both approaches can reliably detect the presence of damage in the structure; however, the second approach is more superior in the detection of the crack progression in the structure. These findings indicate that the application of unsupervised learning along with the implementation of one-class SVM can provide a robust separation of two states of a structure (healthy and damaged) and can successfully evaluate the progression of damage, which is critical for structural condition assessment.

ACKNOWLEDGEMENT

ABSTRACT

Usage of new smart materials in retrofitting of structures has become popular within last decade. Carbon fiber reinforced polymer (CFRP) has been widely used in retrofitting and strengthening of concrete structures and its usage in metallic structures is still in the developing stage. The variation of mechanical properties of CFRP and the consequent effects on strengthening and retrofitting CFRP systems are yet to be investigated under different loading and environmental conditions. This paper presents the results of CFRP strengthened and retrofitted corroded steel plate double strap joints under tension. An accelerated corrosion cell has been developed to accelerate the corrosion of the steel samples and CFRP strengthened samples. The results show a direct comparison of bond characteristics of CFRP strengthened and retrofitted steel double strap joints.

KEYWORDS

CFRP, accelerated corrosion, retrofitting, strengthening.

INTRODUCTION

A large proportion of existing steel infrastructures can suffer deterioration with time due to various effects. The number is increasing as more structures reach the end of their service life, which has been shortened by increased loading, material degradation, and structural fatigue. Galvanic corrosion is one of the prevalent issues with all steel members, and although extensive research has been conducted on the issue and several methods have been developed to reduce or eliminate the effects of corrosion, it remains a prevalent concern. Demolition and reconstruction of such infrastructure may involve a significant cost and structural rehabilitation is becoming the preferred solution.

A popular, and increasingly common strengthening technique employed by engineers to rehabilitate structures is carbon fibre reinforced polymer (CFRP) systems. The process has been derived from a traditional retroactive strengthening of steel beams using steel plates. Several studies have been conducted on the performance of fibre composites bonded to concrete surfaces; however a comparatively lesser amount of research has been conducted on the application to steel surfaces.

Studies carried out in early stage, have proven that the CFRP systems effectively enhance the structural performance of structures (Vatovac et al. 2002, Jiao et al. 2004,Colombi et al. 2006, Dawood et al. 2006,Photiou et al. 2006,Fawziaet al. 2007).Research was further extended to determine the bond characteristics between CFRP and steel because majority of the failure was observed at the CFRP-steel interface (Fawzia et al. 2005, 2006, Matta et al, 2005).As a result of further investigation, it is known that a major cause of failure in steel to CFRP joints is composite delamination (Nozaka et al. 2005) and design guidelines have been developed to assist the development of methodologies for applying CFRP to steel surfaces (Schnerch et al. 2007, Fernando et al. 2013) .

All of the above research focused on the performance and effectiveness of CFRP systems.Researchers extended their scope to determine durability of CFRP/steel systems. Many studies have been conducted on the environmental durability of CFRP strengthened members. The effects of cold conditions (Kimet al. 2012, Humayunet al. 2015), warm conditions(Gamage et al. 2009, Nguyen et al. 2013), freeze-thaw, warm-cold, and wet-dry cycles(Smith et al. 2005, Kim et al. 2012, Nguyen et al. 2012), humidity(Gamage et al. 2009, Nguyen et al. 2013), UV radiation and fire(Smith et al. 2005)and submersion in water(Zanni-Deffarges and Shanahan 1995, Nguyen et al. 2012), have been extensively studied.

Although, it is well known that carbon fibre can facilitate galvanic corrosion by acting as an electrical conductor(Tavakkolizadeh and Saadatmanesh 2001), a comparatively lower number of studies have examined the effect of corrosion on joint strength. They investigated the galvanic corrosion between steel and a CFRP

sheet. It was concluded that galvanic action will only occur when the carbon fibre is in direct contact with the steel, and the galvanic corrosion rate is directly related to the epoxy coating thickness. A study by Nguyen et al. 2012(Nguyen et al. 2012)showed that the performance of steel/CFRP double-strap joints were significantly affected by the ingress of water into the adhesive layer and further suggested that corrosion may present itself between the adhesive and steel interface. One proposed method of resisting galvanic action which has been suggested by a number of sources (Mertz and Gillespie 1996, Gillespie and West 2002, Dawood and Rizkalla 2010)is to place an insulating material such as glass fibre between the carbon fibre sheets and the steel surface. It was found by Dawood and Rizkalla (Dawood and Rizkalla 2010) that the glass fibre sheet did not increase the long term durability of the bond. However, it enhanced the initial bond strength of the specimens.
Literature clearly suggests that CFRP/steel systems are vulnerable to galvanic corrosion. Presence of sea water can accelerate the corrosion in steel. However, the behavior of CFRP/steel interface under accelerated corrosion is yet to be investigated.
In this research, corrosion cell is developed to accelerate the corrosion of strengthened and retrofitted steel double strap joints specimens. This paper presents the results of an experimental study based on the strengthened and retrofitted CFRP/steel double strap joints subjected to galvanic corrosion. The joint capacity is experimentally determined by applying direct tensile loads and the results are compared and discussed.

MATERIAL PROPERTIES

The steel had a nominal elastic modulus of 200GPa, and an ultimate strength of 300MPa. Properties of the unidirectional CFRP, primer and the epoxy adhesive as provided by the manufacturer are listed in Table 1.

Table 1: Material properties (Manufacturer provided)

Property	MBrace CF130 (CFRP)	MBrace two-part epoxy adhesive	MBrace two-part epoxy primer
Elastic Modulus (MPa)	227000	3000	>700
Tensile Strength (MPa)	3800	>50	>12
Compressive Strength (MPa)	-	>80	-
Fibre Weight (g/m^2)	300	-	-
Fibre Density (g/cm^3)	1.7	-	-
Thickness (mm)	0.176	-	-
Ultimate Strain	0.0167	0.025	0.030
Glass Transition Temp. (^OC)	-	55.5	-

EXPERIMENTAL PROGRAMME

Experimental programme was conducted in two phases. Phase 1 (Class R): exposure to accelerated corrosion before applying CFRP, Phase 2 (Class S): exposure to corrosion after strengthened with CFRP. Also two control specimens were prepared (Class C) for the comparison of results. Specimen labelling and experimental parameters are listed in Table 2. Fourteen steel-CFRP double strap specimens were tested to evaluate the joint capacity. Typical test specimen consists of two 6 mm thick × 25 mm wide steel flat bars bond together using 25 mm width CFRP sheet. CFRP-steel joint consist of three layers of CFRP each side. Three CFRP layers were used to increase the joint stiffness. The bond configuration considered in the experimental programme is shown in Figure 1.Bond lengths considered in this experiment were 120 mm and 75 mm. shorter bond length was used to initiate the failure in the corroded end of the joint. To maintain consistency of the test specimens, a standard fabrication process was adopted. The samples were cured under room temperature for 10 days as recommended by the manufacturer to develop its full strength. Important steps in specimen preparation are illustrated in Figure 2.

Retrofitted Specimens (Class R)

Steel samples were exposed to accelerated corrosion prior to applying CFRP. Corrosion resistive priming layer was applied to prevent the corrosion of un-bonded and longer bond length. Shorter bond length was exposed to accelerated corrosion conditions to obtain failure in the shorter bond length side. After exposed to required period, the samples were removed from corrosion tank. The specimens were sand blasted prior to retrofit with CFRP.
All the retrofitted specimens were fabricated simultaneously. Sand blasted steel specimens were cleaned with acetone and then aligned together with epoxy adhesive and left 24 hours. Then priming agent was applied using

a brush on the steel surface according to the manufacturer's recommendations and allowed it to dry for approximately 1 hour.
The CFRP sheets were cut in to required dimensions and cleaned with methylated spirit to remove any residual dust. The adhesive was mixed thoroughly by hand and applied on primed steel surface. Then, the CFRP sheet was placed on and pressed in to the adhesive. A ribbed roller was used to impregnate adhesive properly in to CFRP layer. Another adhesive layer was applied on top of the existing CFRP layer and pressed again using the ribbed roller. Smooth round roller is then used to maintain even adhesive thickness throughout the sample. Second and third CFRP layers were bonded following the same procedure.

Strengthened Specimens (Class S)

Steel samples were sand blasted and then strengthened with CFRP. All the strengthened specimens were fabricated simultaneously. Sand blasted steel specimens were cleaned with acetone and then aligned together with epoxy adhesive and left 24 hours. Then priming agent was applied using a brush on the steel surface according to the manufacturer's recommendations and allowed it to dry for approximately 1 hour. Applying CFRP layers to the samples was similar to the procedure mentioned above in retrofitted specimens. Corrosion resistive priming layer was applied to prevent the corrosion of un-bonded and longer bond length. Shorter bond length was exposed to accelerated corrosion conditions to obtain failure in the shorter bond length side. After exposed to required period, the samples were removed from corrosion tank.

Table 2: Specimen matrix

	Specimen ID	Mass loss ratio based to determine current	Exposure duration (days)	Corrosion condition
Class C	C1	0%	none	No corrosion
	C2	0%		
Class R	R1A	5%	2	Exposure to corrosion before strengthening
	R1B	5%	2	
	R2A	15%	6	
	R2B	15%	6	
	R3A	10%	4	
	R3B	10%	4	
Class S	S1	10%	4	Exposure to corrosion after strengthening
	S2	10%	4	
	S3	5%	2	
	S4	15%	6	
	S5	15%	6	
	S6	5%	2	

Accelerated Corrosion Cell Setup

The corrosion cell was developed to accelerate the corrosion process and shown in Figure 3. 5% NaCl solution was used as the electrolyte. DC power supply was set up and the negative terminal was connected to two stainless steel bars to act as cathodes. Specimens were connected to the positive terminal of the power supply to act as anodes. By inducing a current through the cell, the specimens lose mass in the form of ions to the cathodes through the solution. Each of the specimens was impressed with the same current (170mA) for different exposure durations to induce proportional quantities of mass loss. The current and exposure durations have been calculated by the method proposed in ASTM G102-89 (ASTM 2010). This method is based on the Faraday's law using Equation 1.

$$I = \frac{mass\ loss\ (g) \times 2 \times 96{,}487\ (coulomb)}{t(s) \times 55.847(g/mol\ for\ iron)} \quad (1)$$

Where t is the time, I is the current, 55.847 (g/mol) is the molar mass for iron and 96,487 (coulomb) is the Faraday's constant.

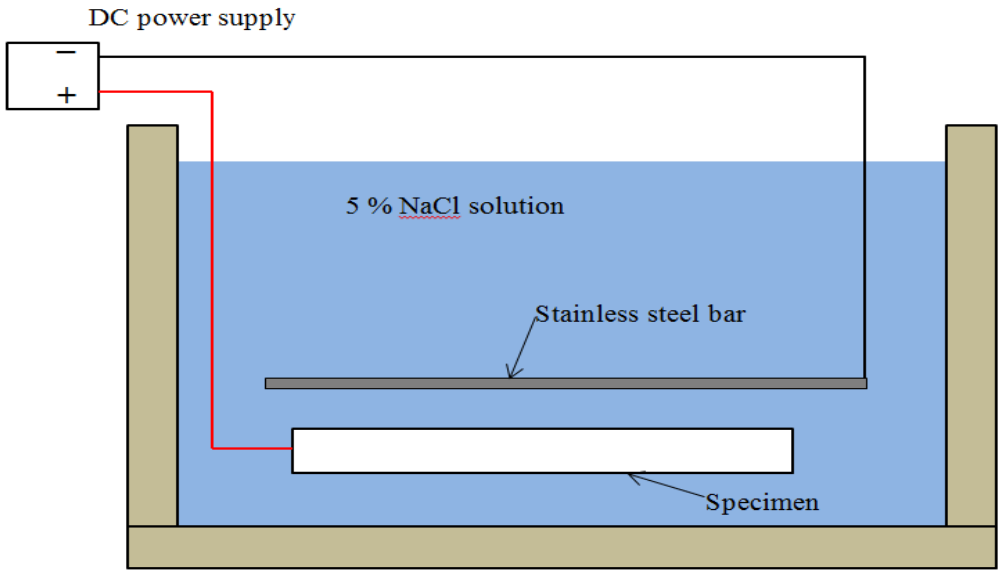

Figure 3: Corrosion cell setup

RESULTS AND DISCUSSIONS

All the double strap joints were tested under direct tension in an Instron Tension machine at a constant displacement rate of 1mm/min (Figure 4). The tests were carried out until delamination of the carbon fibre layers or a complete failure of strength observed.

Figure 4: Test setup

Ultimate Load

It was observed that all the joints failed by debonding of CFRP from the steel surface. Class R specimens experienced debonding at an average load of 10.52kN, while the class C and class S specimens failed at an average load of 16.73kN and 16.59kN respectively. The ultimate load on each of the specimens is summarised in Table 4, and the load-displacement graphs for each specimen are given in Figures5 to 7.

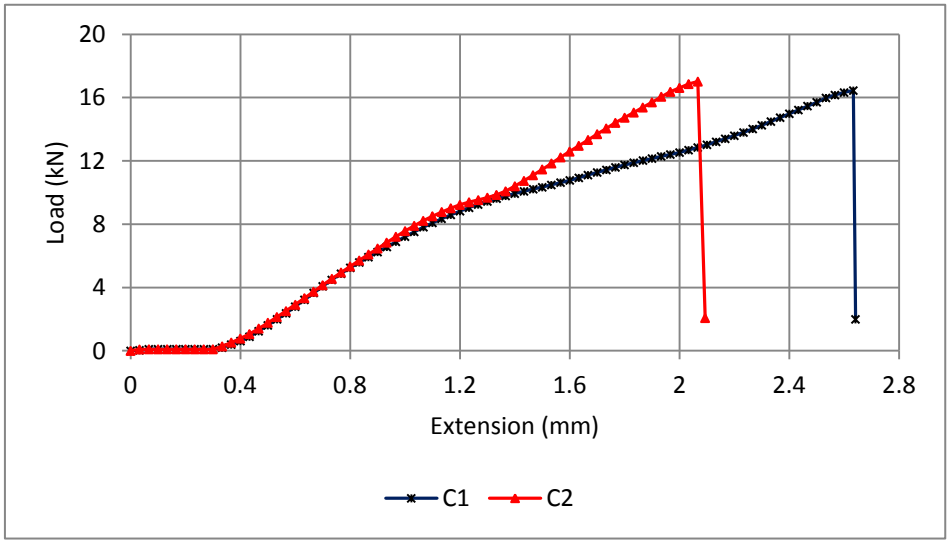

Figure 5: Load-displacement relationship for control specimens (Class C)

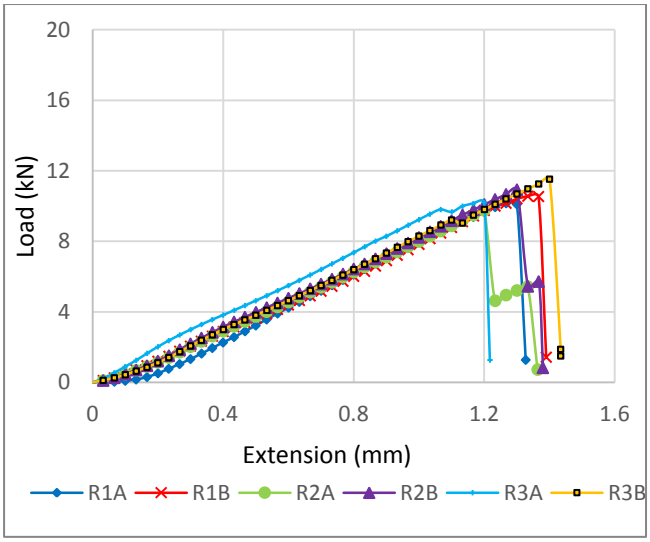

Figure 6: Load-displacement relationship for retrofitted specimens (Class R)

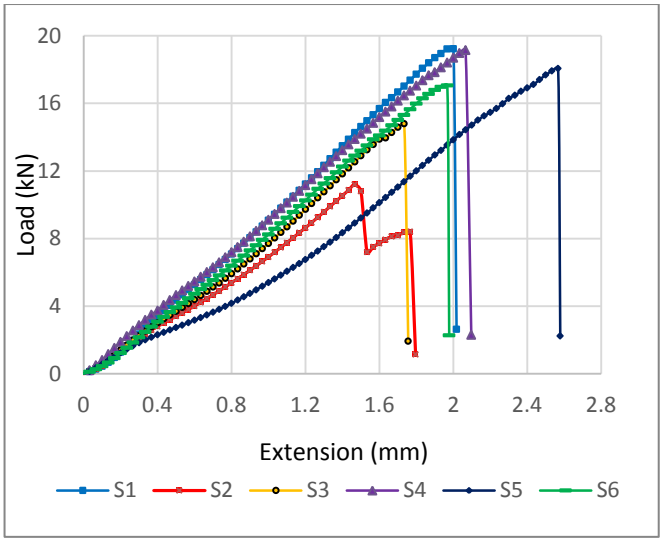

Figure7: Load-displacement relationship for strengthened specimens (Class S)

Initial slip can be observed in control specimens (Figure 5). Strengthened and retrofitted specimens did not show any slippage during the initial loading (Figures 6 and 7).

Failure Mode

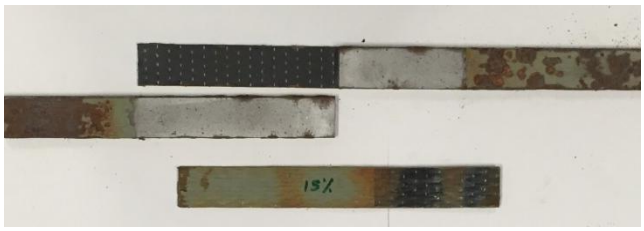
Summary of each of the specimen's failure bond lengths and the resulting failure modes are presented in Table 3 and the typical failure of double strap joint is shown in Figure 8. All the joint failures were due to bond failure between steel surface and CFRP termed as debonding failure.

Table 3: Failure modes of double strap joints

	ID	Mass loss	Ultimate load (kN)	Bond length			
				Side 1		Side 2	
				75mm	120mm	75mm	120mm
Class C	C1	0%	16.45	Debonded	Debonded	Debonded	-
	C2	0%	17.01	-	Debonded	Debonded	-
Class R	R1A	5%	10.16	Debonded	-	-	Debonded
	R1B	5%	10.56	-	Debonded	Debonded	-
	R2A	15%	9.76	Debonded	Debonded	Debonded	-
	R2B	15%	10.93	Debonded	-	Debonded	-
	R3A	10%	10.20	-	Debonded	-	Debonded
	R3B	10%	11.53	-	Debonded	-	Debonded
Class S	S1	10%	19.24	Debonded	Debonded	Debonded	-
	S2	10%	11.20	Debonded	-	Debonded	-
	S3	5%	14.80	Debonded	-	Debonded	-
	S4	15%	19.16	Debonded	-	Debonded	-
	S5	15%	18.07	-	Debonded	Debonded	Debonded
	S6	5%	17.07	Debonded	-	Debonded	Debonded

It was observed that for a number of specimens (S2, R1B, and R2B) the failure occurred in two steps, with one side of the bond delaminating while the other maintained strength. Most of the specimens experienced initialisation of delamination process from the shorter bond length where the failure was designed to occur.

(a) Strengthened specimen



(b) Retrofitted specimen

(C) Un-corroded CFRP/steel interface of strengthened specimens

Figure 8: Typical failure of a double strap joint

Discussion

Figure 6 illustrates the load vs deflection relationship for strengthened specimens of different corrosion mass loss. Specimen S2 showed the lowest joint capacity among all the strengthened specimens and it can be observed that all the other ultimate load values are in the same range. It is observed that a twisting occurred during the testing of specimen S2 and this might be the cause for lower ultimate load. However, the applied current and exposure duration wasn't able to produce any degradation within CFRP-steel interface. Inspecting the specimens after delamination showed that the class S specimens experienced almost no corrosion mass loss below the carbon fibre layers and underneath the painted steel (Figure 8). This helps to describe the maintained strength of the class S joints, as the bond area appeared comparatively undisturbed.

It was observed that there was a significant disparity between the strength of the class C and class R joints; while the class S joints exhibited no significant loss of strength when compared to the class C joints. It was observed that the joints of class R experienced premature failure at around 60% of the original bond strength (as given by the average of class C specimens). Theoretically the ultimate load of retrofitted joints should be in the same range of control specimens. After analysing the geometry of the joint configuration, the reason causing for lower ultimate load can be described as follows.

A significant amount of mass loss was noted on the shorter bond length, as designed. The corrosion was observed to be uniform, with very few pits were observed and those which were present had only penetrated to a shallow depth. As a result of the mass loss, when the two lengths of steel were adhered together a small level difference of approximately 1mm was created, with a larger discrepancy being present on the two R2 type specimens (Figure 9). This level difference may cause for premature failure, introducing a stress concentration at the location of the joint.

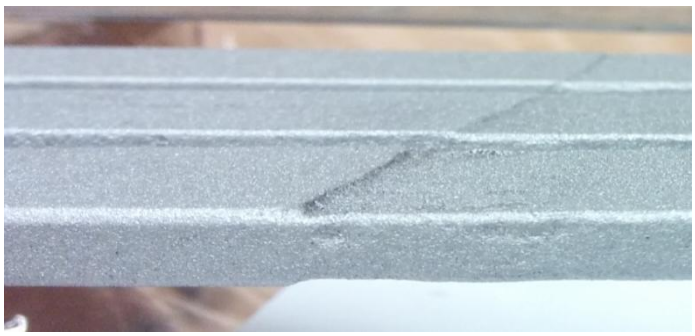


Figure9: Level difference resulting from corrosion mass loss

CONCLUSIONS

This paper presents the findings of an experimental programme conducted to evaluate the bond behaviour of CFRP strengthened and retrofitted double strap joints under accelerated corrosion. Ultimate joint capacity of

each specimen was determined under direct tensile load and compared. Based on the results following conclusions can be drawn.

1. The applied accelerated corrosion on the strengthened double strap joints which were related to 5%, 10% and 15% mass loss respectively did not have any effect on the strengthened joint strength. Interface between CFRP and steel was not affected by the applied current and resulted in the same joint strength as control specimens. It may be necessary to increase the galvanic current or the duration to get sufficient ion penetration through CFRP layers to determine the bond characteristics between CFRP and steel under accelerated corrosion environment.

2. Retrofitted joints, which were corroded prior to strengthening, exhibited a significant loss of strength of 37% as an average. This loss of strength can be attributed to the different level of the steel surface to which the carbon fibre was bonded. The reduction in joint strength is due to the level difference of the two steel parts and not due to the corrosion effect. This level difference may lead to stress concentration near the joint hence resulted a joint failure under a lower load. It is recommended to have flat level for retrofitted joints to achieve the ultimate joint capacity in direct tension.

3. Strengthened joints exhibited no noticeable loss of strength, maintaining on average 99% of the original strength. This is mainly due to un-corroded steel surface beneath the CFRP layers. The surface of the steel which was designed to be corroded appeared to have experienced no corrosion under applied direct current and exposure duration considered under this experimental programme.

ABSTRACT

The number of carbon fibre reinforced polymer (CFRP) layer and their orientation generallyaffect the strength and stiffness of the steel circular hollow section (CHS) members primarily when they are subjected to bending. In this study, numerical investigation is carried out to find the effect of number and orientation of CFRP composites layer on strength and stiffness of CHS members under bending. In numerical investigation, cohesive element is adopted to model interface element (adhesive) and an 8-node quadrilateral in-plane general-purpose continuum shell is used to model CFRP elements. The validity of the FE models is ascertained by comparing the ultimate load, stiffness and failure mode from experimental results. The results of FE analyses show that the strength and stiffness increase with the increase of number of CFRP layer. The three layer configured CFRP strengthened steel CHS beams are found cost effective with respect to strength increment than four layer configured CFRP strengthened steel CHS beams.

INTRODUCTION

Tubular members are widely applied as structural and nonstructural elements because of having equal strength in both axes and aesthetic appearance. These structures are sometime found structurally deficient due to various reasons as mentioned byKabir *et al*. (2015).Therefore, it is required to retrofit or strengthen these structures to restore their structural integrity. The new carbon fibre reinforced polymer (CFRP) composites have emerged as a smart solution to retrofit or strengthen these deficit structures due to numerous of advantages (Alsayed *et al*. 2000; Teng *et al*. 2002; Cromwell *et al*. 2011). The strength increment for strengthened circular hollow section (CHS) member depends mainly on number and orientation of CFRP layers (Shaat and Fam 2006; 2009; Jiao and Zhao 2004; 2007; Haedir *et al*. 2009; Seica and Packer 2007; Alam and Fawzia 2015).The studies conducted so far were involved of HHL, LLH and HHLLlayers configuration of CFRP strengthened CHS compact beams tested in bending (Seica and Packer 2007; Haedir *et al*. 2009). However, the effects of other CFRP layer combinations such as LHLH, HLHL and LHHL have not been revealed yet. Moreover, the cost effective study with respect to strength increment between three and four layer CFRP configured strengthened steel CHS beams has not yet been done for compact section. To address these gaps in knowledge, this paper presents a numerical study to see the effects of layer variations on CFRP strengthened steel circular hollow members under bending.

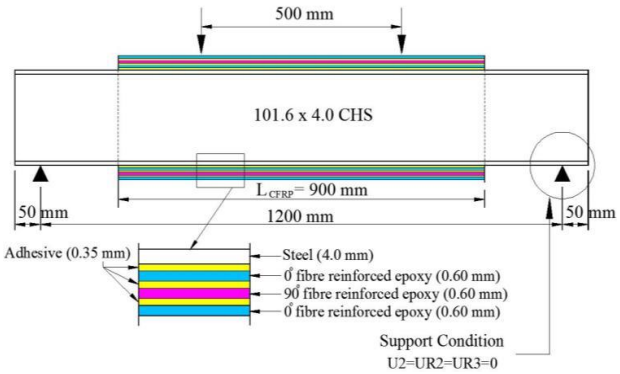

Figure 1Geometry for the composite beam for FE model

FINITE ELEMENT INVESTIGATION

To investigate the effects oflayer variations numerically, finite element (FE) models were developed using the finite element package ABAQUS version 6.12-2 for the tested beams having LHL layer combination of CFRP, with the same geometrics, strengthening parameters and support conditions used in the experiment as given in Figure 1, where *U* is the linear displacement, and *UR* denotes the rotation. Firstly, the FE models were validated by experimental results and later the effects of parameters such as number of layers and layers orientations including LHLH, HLHL and LHHL were studied.

ELEMENT TYPES AND MODEL

Three materials including steel, adhesive and CFRP are modelled as three different types of elements. The steel tube component is modelled using 8-node 3-D solid element (C3D8H) as a classical elastic-plastic metal with isotropic hardening. Adhesive layers between the fibre layers were modelled using the eight-node three-dimensional cohesive elements COHD8. Cohesive elements are generally capable of simulating damage and delamination in composites (Naghipour *et al*. 2009; Shi *et al*. 2012; Al-Zubaidy *et al*. 2013). A triangular traction-separation cohesive law with linear softening is used to characterize the material behaviour of the adhesive.The CFRP patches are meshed with an 8-node quadrilateral in-plane general-purpose continuum shell, reduced integration with hourglass control, finite membrane strains (SC8R). This type of element is capable of predicting CFRP failure (Al-Zubaidy *et al*. 2013; Faggiani and Falzon 2010). Hashin damage criteria in ABAQUS(2011) is used to describe the in-ply damage in each lamina.

MATERIAL PROPERTIES IN FE ANALYSIS

The tensile strength, strain and modulus of elasticity for steel, CFRP and adhesive are taken form experimental data. The steel tubes had an average yield stress of 327 MPa, an ultimate strength of 383 MPa and the modulus of elasticity was about 214 GPa confirmed by coupon test. The properties for all the other elements used in FE model are listed in Table 1.

Table 1Material properties for FE analysis

Adhesive		CFRP	
Parameters	Value	Parameters	Value
Elastic modulus, E_a (Pa)	2.86 x 10^9	Elastic modulus, E1 (Pa)	205 x 10^9
Normal traction stress, t_n (Pa)	46 x 10^6	Poisson's ratio, Nu12	0.33
Shear traction stresses, t_s (Pa)	46 x 10^6	Ultimate in-plane strength in fibre direction, X^T (Pa)	2760 x 10^6
Shear traction stresses, t_t (Pa)	46 x 10^6		

VALIDATION OF THE NUMERICAL MODEL

The first numerical model proposed in this study is standardized against the corresponding experimental data. The ultimate load, load-deflection curve of the unstrengthened and strengthened beams executed by FE models are compared with the experimental results. The failure mode of the unstrengthened and control strengthened beams is also compared.

Table 2 Validation of ultimate load

Beam ID	Beam type	Wrapping scheme	Ultimate load: Experiment P_{ult} (kN)	Ultimate load: Finite element analysis P_{FE} (kN)	P_{FE}/P_{ult}
B1	Unstrengthened	NA	78.40	79.20	1.01
B2	Unstrengthened	NA	76.75	79.20	1.03
S5B-1	Strengthened	LHL	101.70	102.00	1.00
S5B-1R	Strengthened	LHL	102.00	102.00	1.00

NA for not applicable

Ultimate Load

A clear comparison of the experimentally measured ultimate load and those executed from FE analyses for unstrengthened and CFRP strengthened LHL layer oriented beams is shown in Table 2. The ultimate loads determined numerically are validated closely with experimental results by showing ratios of ultimate loads (P_{FE}/P_{ult}) close to unity.

Mid-span Deflection

The comparison between load vs deflection measured experimentally and numerically for the unstrengthened and strengthened beams is show in Figure 2. It can be seen that the numerical results and experimental data match very well until failure of the both beams.

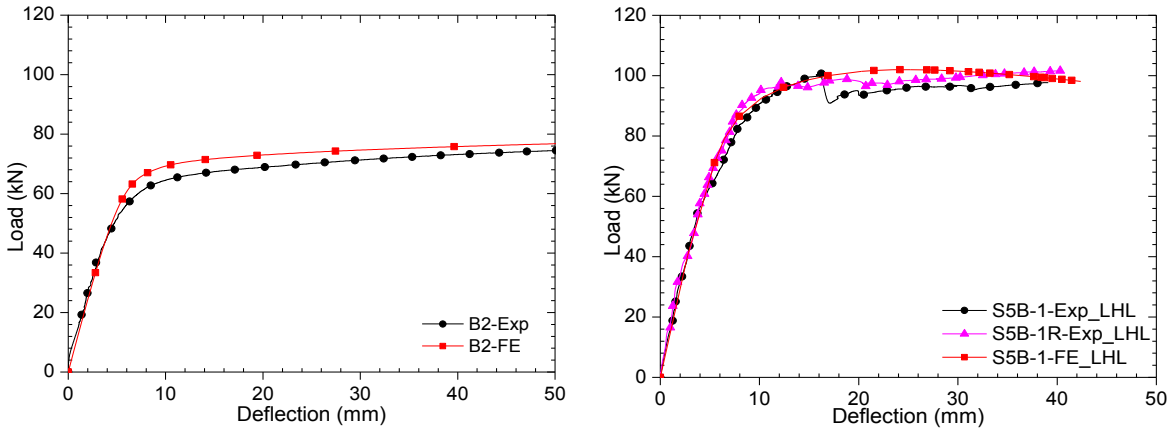

Figure 2Numerical and experimental load-displacement response of (a) unstrengthened, (b) LHL layer CFRP strengthened beams

Failure Modes

Furthermore failure modes of FE analyses are found similar with the tested unstrengthened and strengthened beams as shown in Figure 3.

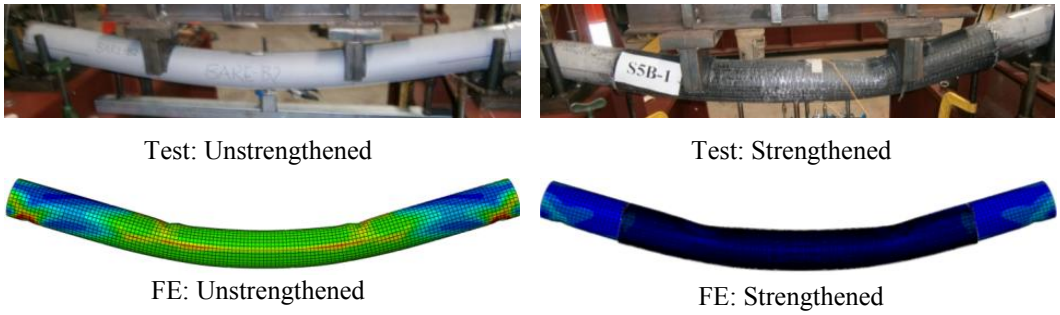

Figure 3 Comparison of failure modes between test and FE analysis

PARAMETRIC STUDY

It is obvious that some strengthening parameters such as number of wrapping layer and layer orientation affect the strength and stiffness particularly CFRP strengthened circular hollow section members under bending. To understand the effects of these parameters, parametric studies have been conducted using corresponding validated models.

RESULTS AND DISCUSSIONS

In this study, the comparison of ultimate loads and stiffness are presented for three and four layers configured CFRP strengthened beams by varying layer orientations to find suitable layers orientation under bending.

Effects of Number of Layer and Layer Orientations on Ultimate Load

The effects of layer numbers (three and four layer) and layer orientations on ultimate strength of strengthened beams are clearly depicted in Figure 4. It can be seen that the ultimate load increases with the increase of number of layers. It is also found that the strength increases 11.90% for four layer configured beams compared to three layer configured beams while the amount of CFRP increases about 33.34% for four layer configured beams. Therefore, by considering cost of CFRP with respect to strength increment, the three layers are considered economical. For three layer configured beams, the strength deference between LHL and LLH layer oriented beams is found marginal. While for four layer configured beams, LHLH performs slightly better by gaining 2.40% and 3.48% more strength than HLHL and LHHL layers configured beams. And the performance difference between HLHL and LHHL layers oriented beams are negligible.

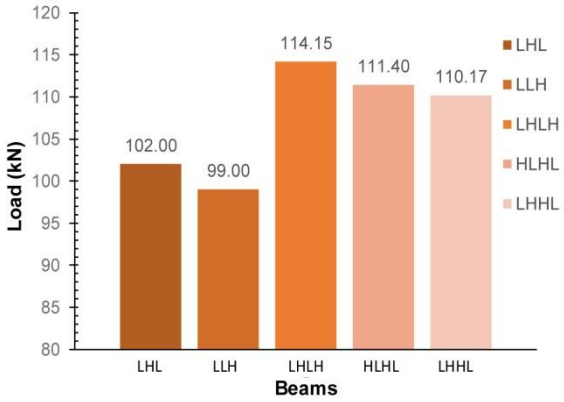

Figure 4 Ultimate loads for beams

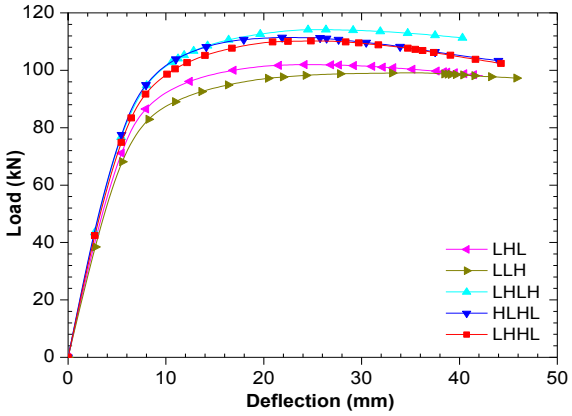

Figure 5 Load-midspan deflection curves for beams

Effects of Number of Layer and Layer Orientations on Stiffness

Figure 5 has clearly presented the effects of layer numbers and orientations on stiffness of CFRP strengthened steel circular hollow section beams under bending. It can be seen that all the strengthened beams with various layer combinations show similar deflection trend and linear-elastic behaviour until around the 68 kN load, and then the deflection trend changes to inelastic behaviour. In the plastic zone, the four layer configured beams show significant increase in stiffness than three layer configured beams. The LHL layer oriented beam performs slightly better in plastic zone. While all the beams with four layer CFRP show negligible difference of stiffness in plastic zone. The stiffness difference in the plastic zone may have appeared due to debonding of CFRP composites or yielding of steel.

CONCLUSIONS

In this work, the FE models are developed by considering CFRP as continuum shell and adhesive as cohesive elements which are capable to predict real behaviour of CFRP strengthened steel structures and validated by experiment conducted by authors in laboratory. The three dimensional unstrengthened and CFRP strengthened CHS beams are developed to investigate the effects of layer variations under bending. The fundamental findings from this current study are as follows:

- The higher number of CFRP layers increase the strength and stiffness under bending.

- By considering cost of CFRP with respect to strength increment, the three layer are considered economical than four layer configured beams.
- The stiffness differences are found evident in plastic zone.

ABSTRACT

In 2010, New Zealand introduced High Productivity Motor Vehicles onto the road network. To date, the movement of these heavier vehicles has been limited by the capacity of infrastructure, particularly bridges on the State Highway and local road networks. To limit the extent of costly bridge strengthening and replacement, the New Zealand Transport Agency is currently undertaking Structural Response Monitoring of three key bridges in the South Island. The Structural Response Monitoring systems employed to date include a range of conventional bridge monitoring and testing techniques, such as visual inspections, material testing, and survey levelling; as well as more advanced monitoring systems using accelerometers, displacement transducers, vehicle weigh-in-motion testing, advanced bridge model calibration, and concrete condition assessment. Whilst the monitoring is still its initial stages, significant conclusions around the structural performance of the bridges have already been made. These include the low likelihood of first degree resonance of the beams, calculation of a bridge specific impact factor, information on the continuity of the joints and interactions of the split piers. To minimise the cost of response monitoring, a five step methodology was developed. This included preliminary diagnostics, detailed bridge analysis and model calibration, assessment of critical failure mechanisms and focussed response monitoring on key regions under high stress. This paper outlines the findings of this testing and provides a cost effective solution for the monitoring of bridge structures.

BACKGROUND

In May 2010, the New Zealand Ministry of Transport amended the Vehicle Dimension and Mass (VDM) Rule. This amendment allowed vehicle operators with divisible loads to apply for 'High Productivity Motor Vehicle' (HPMV) permits to operate on approved routes at greater dimension and mass limits than those that would otherwise be allowed under the Rule. However, HPMV movements have been restricted by the capacity of key infrastructure, particularly weaker bridges on the State Highway (SH) and Territorial Local Authority (TLA) road networks.

There are approximately 15,500 road bridges in New Zealand, with 4,500 bridges and large culverts on the New Zealand Transport Agency (NZ Transport Agency) State Highway Network and around 11,000 on TLA roads. Whilst most bridges constructed since 1943 have the capacity to support HPMV loading; design standards prior to the 1940's had considerably lower live load demands, meaning that many bridges constructed prior to this period cannot support HPMVs without some form of strengthening. A significant percentage (around 18%) of New Zealand's road bridges were constructed prior to 1943, as is the case for much of the developed world. Therefore, there is a significant cost in upgrading infrastructure to support these heavier vehicles.

Between 2010 and 2012, significant investigations were undertaken to identify the restrictive bridges on key freight networks, re-analyse and test bridges to provide more accurate structural data, quantify the freight demand on these networks, and determine which routes could economically be strengthened. In 2013, the NZ Transport Agency embarked on the first significant phase (Tranche 1) of strengthening of bridges on key investment routes to allow them to support HPMV loading. The key South Island route over SH1 between Christchurch and Oamaru was identified as a Tranche 1 investment route due to the considerable amount of freight transported over this highway. Three significant impediments to the upgrade of this route were the Rakaia and two Rangitata River Bridges.

INTRODUCTION

The Rakaia River and Rangitata River No.1 and No.2 Bridges are located on State Highway 1S (SH1S) within the South Island of New Zealand, just north of Rakaia township, and approximately 35km south of Ashburton township respectively. All three bridges were constructed between 1939 and 1940, and comprise of conventional two lane reinforced concrete bridges, with essentially identical superstructures. The superstructures consist of four reinforced concrete T-beams, supported on reinforced concrete columns and pile caps, founded on driven reinforced concrete piles, as illustrated in Figure 1 below.

At 1.76km long, the Rakaia River Bridge is the longest bridge in New Zealand, and consists of 144, 40 foot (12.2m) spans. The Rangitata River No.1 and No.2 Bridges are 650m and 320m long and consist of 53 and 26, 12.2m spans respectively. All three bridges have expansion joints in the form of split piers generally every 5 spans. The bridges are currently managed by Opus International Consultants Ltd (Opus) as part of the Region 11 and 12 (Canterbury and West Coast) Bridge Management Contract. Previous assessments of the bridges undertaken by Opus indicated that they are all under-capacity for supporting Full HPMV loading.

Figure 1 View of SH1S Rakaia River Bridge beams, superstructure and piers

Given the length of the Rakaia and Rangitata River Bridges; the cost of strengthening these bridges to support HPMV loading was estimated at over $10M (NZD). Therefore, the NZ Transport Agency and Opus have proposed allowing these bridges to operate at slightly higher stresses, as allowed for within Section 7.4.3 of NZ Transport Agency Bridge Manual (the Bridge Manual). However, this constitutes as a departure from the Bridge Manual, as clause 7.4.3 (i) requires the bridges to be one of a small number of bridges restricting vehicles on an important route, and clause 7.4.3 (vi) requires early replacement or strengthening to be feasible. Given the number of bridges, the high cost and time required for strengthening and the lack of feasible alternative routes, these criteria are not considered to be met.

As such, Opus have developed a Structural Response Monitoring (SRM) system. This includes a range of conventional bridge monitoring and testing techniques, such as visual inspections, material testing, crack monitoring and survey levelling; as well as more advanced monitoring systems using accelerometers, displacement transducers, vehicle weigh-in-motion testing, advanced bridge model calibration, and concrete condition assessment. The objectives of SRM are:

1. To provide confidence in the HPMV load capacity and safety of the bridges; and
2. To provide confidence that the bridges will not require unexpected, early replacement or extensive refurbishment due to serviceability problems.

This paper provides a cost effective solution to monitoring bridge structures and outlines the findings from the monitoring undertaken to date.

STRUCTURAL RESPONSE MONITORING (SRM) METHODOLOGY

Historically, Structural Health Monitoring (SHM) of bridges has typically been limited to larger more complex structures. Detailed monitoring of more simple, low value structures is often cost-prohibitive, due to the cost of

electronic equipment, access for installation, maintenance and ongoing storage, processing and interpretation of data.

To mitigate risk and minimise costs, a five step SRM methodology has been developed for the monitoring of the Rakaia and Rangitata River Bridges, as shown in Figure 2 below. This methodology has the potential to provide significant whole life cost improvements to older bridge structures by avoiding, reducing or delaying costly strengthening or bridge replacement. This is particularly the case where observed deterioration is less than would be expected from analysis, or where significant unknowns exist in the assessment and modelling of the structure. The monitoring also provides valuable data on the strength and performance of the most common type of weaker bridge in New Zealand, thereby assisting the management of other typical bridges.

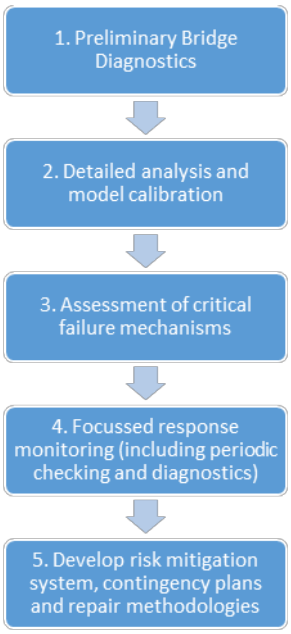

Figure 2 Proposed Structural Response Monitoring (SRM) Methodology

STRUCTURAL RESPONSE MONITORING (SRM) – CASE STUDY

Case Study of the Rakaia and Rangitata River Bridges

The five step SRM methodology outlined in Figure 2 has been employed on the Rakaia and Rangitata River Bridges between June 2014 and July 2015. Details of the monitoring systems utilised are described in the sections below. Although the monitoring system has only been in place for a short period of time, the preliminary findings have already provided some significant conclusions for these bridges.

Preliminary Bridge Diagnostics

The purpose of preliminary bridge diagnostics is to better understand the condition and behaviour of a bridge to help refine the assessment models. Various techniques were utilised on the Rakaia and Rangitata River Bridges, as described below. Many of these also provided long term response monitoring systems on the bridge.

Concrete condition assessment

An extensive concrete condition assessment of was undertaken on the Rakaia River Bridge in October 2014. This included a comprehensive visual inspection, sounding of the concrete to identify areas of spalling, a reinforcement cover meter survey, x-ray fluorescence spectroscopy (XRF) testing to measure chloride ion ingress, pH testing to assess the depletion of $Ca(OH)_2$ and estimate the carbonation depth, and isolated concrete breakout to identify the extent of corrosion and condition of reinforcing bars. The extent of carbonation and chloride ion ingress was compared with the depth of reinforcement measured, to assess the overall risk of corrosion to the bars. This information was then be used to assess the likely maintenance demand on the bridge, and expected remaining life.

The concrete investigations confirmed that the bridge was generally in good condition for its 76 year age. Concrete testing results showed that the environment was very benign, with very low corrosion rates observed. The carbonation front was not generally at the level of the outer reinforcing bars, and chloride ingress was found to be minimal, with only very low risk of initiating corrosion at average cover depths. Based on the test results, minor increases in crack widths from heavier loading are unlikely to significantly reduce the life of the bridge.

The worst concrete deterioration was observed in the upper sections of the split pier columns, beneath the partially split deck joints, and in the soffit of the deck cantilevers. This damage was attributed to poor compaction of the concrete within these zones, combined with significant bending moments in the split piers. Similar conclusions would be expected for the Rangitata River Bridges, which from visual inspections appear in comparable (slightly better) condition to the Rakaia River Bridge.

Material testing

Opus Research undertook non-destructive steel leeb hardness testing on 35 samples taken from all three bridges to derive the yield strength of the reinforcing steel. Given the close proximity of the bridges, the similar construction dates and similarities in the sample sets, these results can be considered as a larger combined sample set. The average yield stress of the reinforcement was calculated as 288MPa, compared with a previously assumed value of 205MPa from the NZ Transport Agency Bridge Manual. Statistical assessment indicated that the lower 5th percentile yield strength for the whole sample set was 254MPa for a single bar, 265MPa for a group of two bars, and 279MPa for a group of 12 reinforcing bars at the mid-span of the beams.

Concrete core samples were also taken and crushed to determine the material properties of the concrete. Concrete compressive strength results for the Rakaia River Bridge were highly variable, ranging from 17.0 – 62.0MPa with an average of 35.7MPa. This was likely due to the variability the quality of materials and the quality of construction and compaction of the concrete. Samples with rounded greywacke aggregate were identified in three of the sample spans, and exhibited lower strengths. Samples with crushed greywacke aggregate were identified in the other two sample spans, and exhibited considerably higher strengths.

Survey levelling

Conventional survey was undertaken on the bridges using total stations to calculate the level of the mid-span of each of the beams. This provided an indication of typical beam sagging along the length of the bridge, and acted as a benchmark for future monitoring. The survey indicated that the largest variation in levels occurs in spans adjacent to split piers, indicating that some of the split piers may have undergone minor plastic rotation. More sophisticated three-dimensional survey from beneath the bridges is proposed in the future to reduce the need for lane closures during survey, and provide a more holistic survey profile of the bridges.

Accelerometer instrumentation

Three 'Reftek' uni-axial accelerometers and one tri-axial accelerometer were installed at the mid-span of all four beams on the 6th span from the northern abutment of the Rakaia River Bridge in October 2014. All accelerometer outputs are sampled at 200Hz, and the data acquisition system connected to mains power adjacent to the bridge. These acceleration outputs were then double integrated to calculate real-time deflection of the beams at mid-span. This was undertaken to allow the bridge model to be more accurately calibrated, and to provide ongoing monitoring of the response of the beams to increased live loading. A further benefit of having a tri-axial accelerometer installed is the ability to analyse the bridge's performance during seismic events, which still occur on a regular basis within the Canterbury Region.

Accelerometers also have the benefit of providing the fundamental frequency of the bridge span based on the residual vibrations of the beams following impact loading. This can be used to back-calculate a number of structural parameters, including beam stiffness and end fixity conditions. The fundamental frequency of vibration on the Rakaia River Bridge was found to be in the order of 9Hz, compared with a theoretical fundamental frequency of 3-4Hz as a simply supported span or 7-9Hz with fixed supports. This confirmed that the spans have considerable continuity/fixity at their ends. Based on the measured fundamental frequency and typical truck axle spacings, heavy vehicle speeds in excess of 130km/hr would be required to initiate resonance in the spans, and this is considered highly unlikely on these narrow bridges. This therefore reduces the likelihood of impact factors reaching the level of 1.3 specified in the Bridge Manual.

Test loading

A number of cycles of test loading were undertaken on all three bridges using truck combinations that loaded the bridge spans to their maximum legal (Class 1) limits. This testing measured mid-span beam deflection and allowed the accelerometers to be calibrated to enable beam deflection to be derived from acceleration.

The results from one of the more critical cycles of test loading are summarised in Table 1 below. The maximum beam displacements under two lanes of Class 1 loading at 10km/hr were around 3.7mm. This compares with theoretical simply supported displacements in excess of 10mm, indicating that considerable continuity existed over the pier supports. The difference in displacement between adjacent beams allow the beam and deck stiffness values to be more accurately calculated.

A span specific impact factor was calculated based on the sum of the beam displacements compared with the base displacement at crawl speed (<10km/hr). The sum of the displacements has been used, as individual beam displacements are highly dependent on transverse vehicle position. The results show that the Rakaia River Bridge span has a maximum impact factor of around 1.18 under this particular vehicle load scenario. Obviously, considerably more vehicle runs would be required to give this result more statistical accuracy. However, initial results indicate that the Bridge Manual impact factor of 1.3 may be conservative for the Rakaia River Bridge. Moving forward, a system is being developed to calculate impact by correlating results from an adjacent Weigh-in-Motion (WiM) site with the response of the bridge span.

Table 1: Mid-span beam displacement from the live load testing of the Rakaia River Bridge

Vehicle Run	Displacement (dial gauge)					
	Beam 1	Beam 2	Beam 3	Beam 4	Total	Impact Factor
	mm	mm	mm	mm		
10kph nose-tail	2.551524	2.399312	1.378563	0.387255	6.716654	1.000

Figure 3 below shows the typical mid-span displacement response of each of the Rakaia River Bridge beams under the test load travelling north. This further proves the continuity between spans, with loads in adjacent spans resulting in uplift at mid-span. The test loads also show interaction between full depth split piers. The horizontal load and bending in one split pier causes bending in the adjacent pier, resulting in minor uplift in the adjacent span (approximately 0.25mm uplift shown after the downwards deflection in figure ~~10~~ 3 below). This interaction has now been incorporated in our calibrated bridge model, and has an effect on the overall capacity and performance of the bridge.

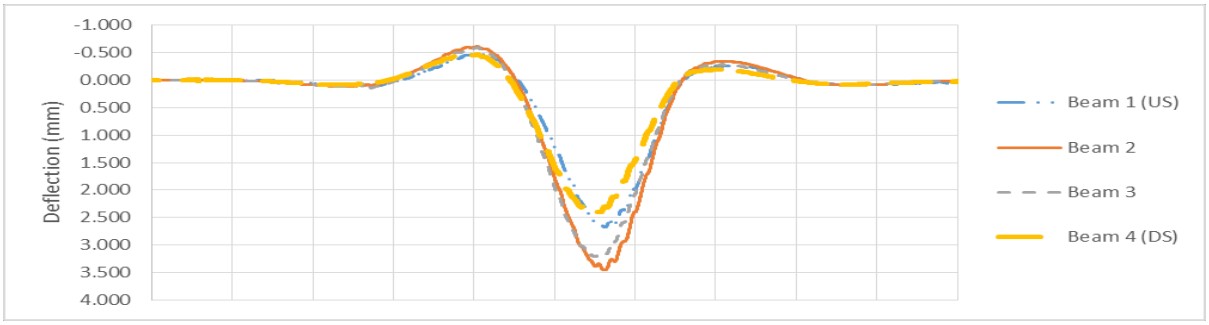

Figure 3: Typical vertical displacement vs time response at mid-span under side-by-side test load runs. This is for span 6 from the northern end, which has a split pier at one end.

Detailed Analysis and Model Calibration

One significant benefit of the SRM and test loading of the bridge was the ability to refine the analysis model of the bridge. The following calibration was undertaken:

- Material testing was used to calculate more accurate properties for the concrete and reinforcing steel.
- The true level of fixity at the ends of the beams under serviceability loads was modelled, based on the fundamental frequency of the bridge span and the measured mid-span displacements under test loads.
- The variation in beam stiffness could be calculated, based on the distribution of mid-span deflection under test loading of one and both lanes. This allowed the contribution of the kerbs and handrails to beam stiffness to be determined.
- The true stiffness of the deck under serviceability loads was calculated, based on the deflection of the beams under the unloaded lanes during test loading.
- The level of continuity through the partially split piers was calculated, based on the known vertical uplift in beams during the test loading.
- The level of continuity between split pier columns was calculated, based on the known vertical uplift in beams during the test loading.
- The range of expected thermal movement at the joints was calculated by applying a thermal profile to the microstran grillage model.

This information was used to calibrate and refine a three-dimensional grillage model of the bridge, as shown in Figure 4, to allow it to accurately predict the true deflection and stresses in critical elements.

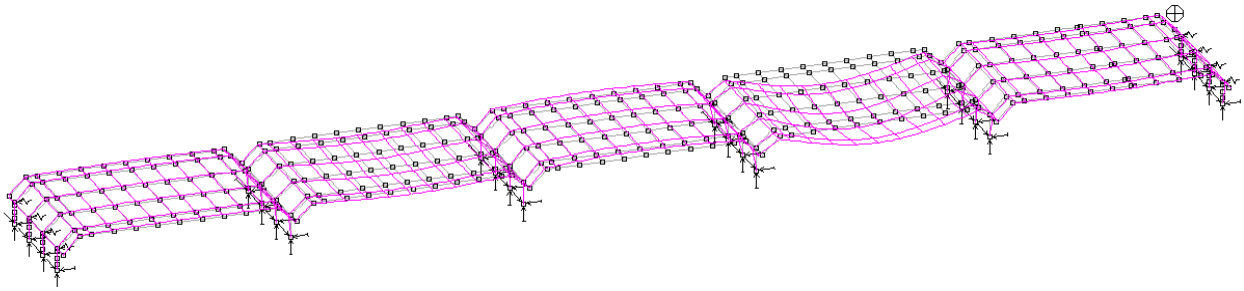

Figure 4 Three-Dimensional Grillage Model of Rakaia and Rangitata River Bridges. Typical deflection profile from vehicle movement is shown.

Assessment of Critical Failure Mechanisms

Previous analysis of the Rakaia and Rangitata River Bridges indicated that they had live load capacities of only 87% HPMV, limited by the mid-span bending capacity of the beams. All previous bridge assessments assumed that the beams act as simply supported at the Ultimate Limit State. This assumption was based on the detailing of the steel in the ends of the beams, and curtailment of all longitudinal beam reinforcement, as shown in Figure 5. However, with a small amount of fixity at the pier supports, the mid-span bending moments decrease significantly, resulting in increases in the overall capacity of the bridge. Conversely, fixity though the pier joints has the potential to cause significant stresses within reinforcing steel in these zones. This increases the risk of damage to the joints, and yielding and/or fatigue failure in reinforcing bars that were not designed to resist these high loads. Given these joints were found to exhibit considerable fixity; further detailed assessment of the loads within the joints was undertaken.

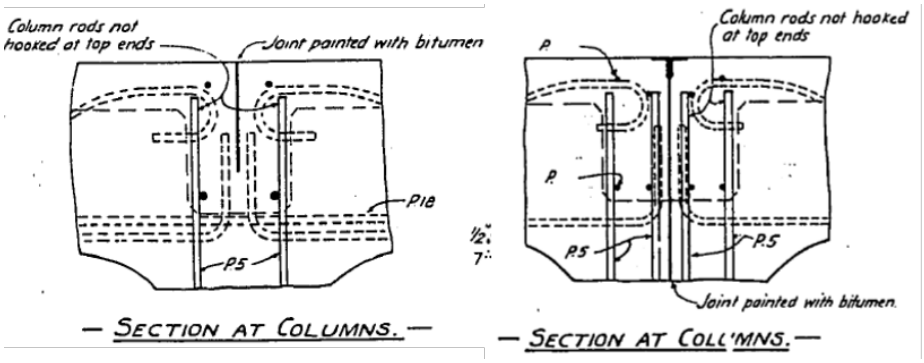

Figure 5: Typical beam reinforcement at pier and split pier joints of Rakaia and Rangitata River Bridges.

Outputs from the grillage model were inputted into Computer-Aided Strut-and-Tie (CAST) software, to assess critical components of the beam-column joint, as shown in Figure 6. Given the complexity of the reinforced concrete joint; a simple finite element model was developed within the software programme LUSAS to confirm that the strut-and-tie geometry accurately represented the elastic concrete stress geometry in the joint, as shown in Figure 7.

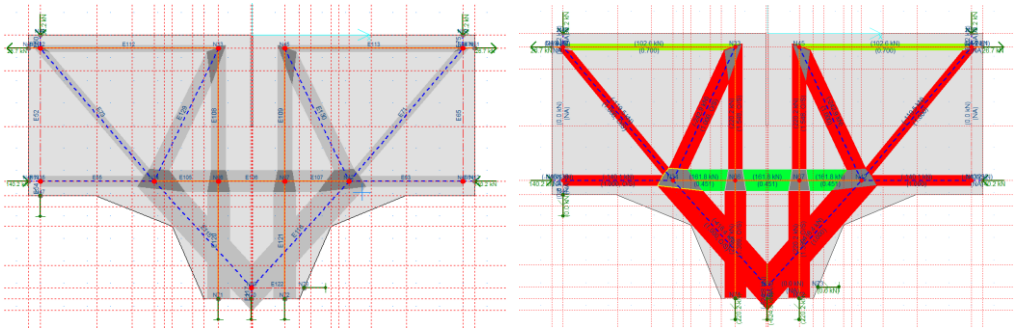

Figure 6: Model of partially split pier joint, modelled using Computer Aided Strut-and-Tie (CAST) software.

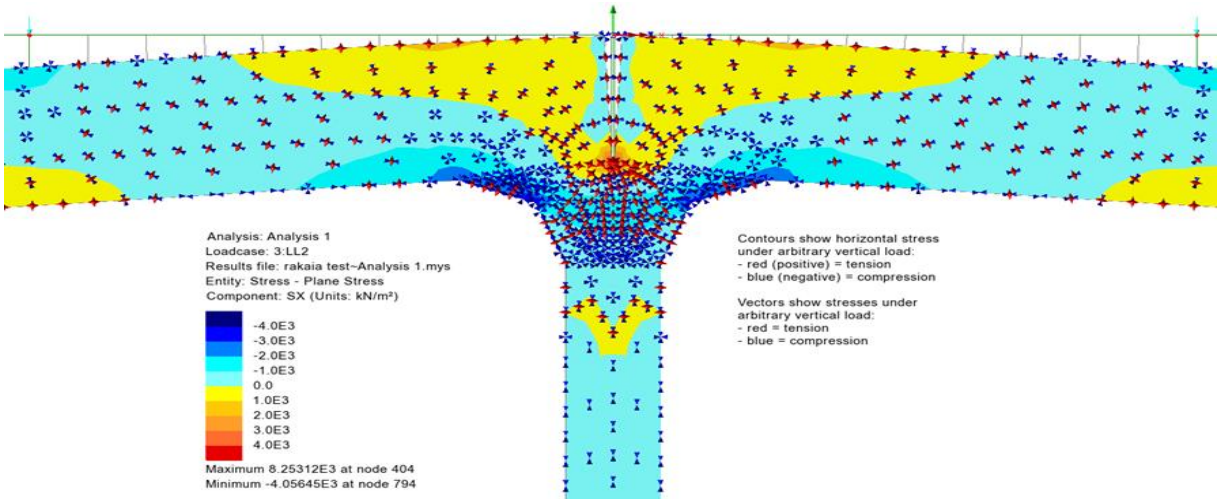

Figure 7: LUSAS model illustrating magnitude of stress vectors. Shading indicates the magnitude of the horizontal stress component.

Following test loading, SRM, and detailed inspections, the following hierarchy of failure of the bridges were able to be determined:

1. Increased cracking of the beam-column joints, and yielding of linkage bars and diaphragm reinforcement. Typical crack patterns are shown visually in Figure 8. The size of these cracks are expected to be minimal (typically <0.8mm) due to stiffness of the beams.
2. Cracking and spalling of the upper sections of pier columns.
3. Pull out of the vertical bars within the pier-columns, causing increased beam rotation and deflection.
4. Increased cracking in the soffit of the beams and yielding of the beams at midspan.
5. Continued deflection of the superstructure until the concrete kerbs and handrails rupture, transferring the entire compression force into the deck slab.
6. Considerable further deflection of the ductile reinforced concrete beams, prior to ultimate collapse. The beams are expected to gain around 25% additional capacity due to strain hardening of the reinforcement, with further additional strength due to the contribution of the concrete handrails and upper reinforcing steel in the deck

Partial continuity of reinforcement through the bridge joint provided a capacity improvement from 87% to around 100% HPMV capacity, allowing a significant increase in the gross mass of vehicles over these bridges. However, the beam/column joints were identified as highly stressed, with some reinforcement being at or near yield under service loads. In particular, the horizontal linkage bars were identified as being vulnerable to fatigue cracking. This could occur at any stage in the hierarchy above, although is more likely earlier on, while the

beam column joints are relatively stiff. Failure of these bars is not necessarily critical to vehicle loading, but would significantly reduce the bridges seismic resilience.

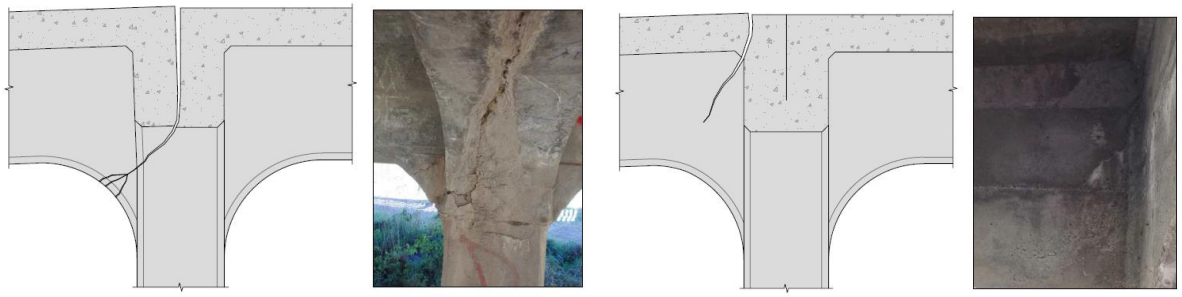

Figure 8: Critical joint failure mechanisms and examples of similar cracking on site

Focussed Response Monitoring

Ongoing monitoring systems

Based on the calibrated bridge analysis and identification of critical failure mechanisms, the following Structural Response Monitoring (SRM) systems were selected for ongoing monitoring of the bridges.

Weigh-in-Motion monitoring and enforcement

A Weigh in Motion (WiM) site was installed on the north approach of the Rakaia River Bridge in December 2014. The purpose of the WiM site is to provide real time information on the current loading profile of the bridge, to allow comparison with the increase once the route is opened to Full HPMVs. The WiM site also acts as a deterrent to vehicles overloading (by identifying vehicles for weight compliance checking), and provides considerable vehicle loading information to the NZ Transport Agency

Continuous accelerometers

Accelerometer outputs from the Rakaia River Bridge were monitored monthly by summarising the beam deflections into ‘bands’, and comparing these to vehicle weight ‘bands’ from the WiM site. This monitoring will specifically identify whether the proportion of larger beam deflections is increasing out of proportion with the heavy vehicle movements. The fundamental frequency of the beams is also being monitored to confirm this is not decreasing (as would be expected with damage to the joints or beams).

While the continuous accelerometer outputs have been valuable, the equipment and installation costs prohibit their installation on a larger proportion of the spans of these three bridges. More beneficial long term information may be obtained through alternative cost effective joint monitoring, as discussed below.

Continuous joint monitoring

Given the vulnerability of the beam-column joints on all three bridges; ongoing continuous monitoring systems are focussed on these critical zones to confirm whether any unrecoverable deformation is occurring. This monitoring will help protect against other damage mechanisms, which can only occur once significant damage to the joints has occurred. Joint monitoring can also be undertaken more readily and at lower cost than mid-span beam deflection using accelerometers, or other similar devices.

Permanent joint monitoring using displacement transducers has now been installed on both of the Rangitata River Bridges (as shown in Figure 9), with data transmitted via solar powered data loggers to the Opus network. If this monitoring is successful, this can be cost effectively extended to incorporate additional vulnerable spans. Joint damage will be monitored by separating peak joint displacements into ‘bands’. Site inspections will be triggered if the frequency of peak joint displacements increases out of proportion with the heavy vehicle movements. Trigger levels will also be set if the joint displacement is above critical thresholds, or if the frequency of joint displacement decreases, as this would be a sign that damage has occurred in the beam away from the joint. Overall thermal variations are being filtered out of the overall data when assessing vehicle displacements.

Figure 9: Permanent displacement transducer installed to monitor beam/column joint opening

Periodic test loading

Given the difficulty in tracing the response of a vehicle from the WiM to the accelerometer and displacement transducer outputs, and the complexity of effects from multiple vehicles; periodic annual test loading of the monitored spans is to be undertaken. This will ensure the accelerometers are calibrated, and will provide an independent confirmation that the overall fundamental frequency and stiffness are not altering, and deflection behaviour is remaining elastic. Moving forward, this requirement may be eliminated by comparing the WiM results from isolated heavy vehicles with the corresponding beam and joint displacements.

Periodic survey

Periodic six-monthly beam survey of all three bridges is being undertaken. This ensures the majority of the bridge spans have some form of coarse monitoring, given real-time monitoring will only occur on a very small proportion of the spans. The overall change in survey will be compared to that expected from thermal variation, and further investigations will occur if beam sagging increases beyond a specified threshold.

Concrete repairs

Concrete repair are currently being undertaken to critical areas of spalling on the Rakaia River Bridge. As part of the concrete repair contract, concrete is being removed within the diaphragms to identify the extent of corrosion of the lower bars. This will give an indication of the condition of the critical linkage bars across the piers, given the extent of leakage of water through the partially split joints. Installation of temporary strain gauges is also being considered, to confirm the actual stress in the linkage bars.

Develop Risk Mitigation System, Contingency Plans and Repair Methodologies

Given the existing risk and vulnerabilities identified on the Rakaia and Rangitata River Bridges, a risk assessment was undertaken following the general principles of the NZ Transport Agencies Risk Management standard (Z/44). This indicates that the overall residual risk to the bridges following the recommended mitigation measures was not significantly worse than in their previous state. However, significant risks were identified through the SRM process, particularly a vulnerability to corrosion and fatigue damage to the linkage bars over the non-split piers, and damage to the tops of the split piers. These risks are being partially mitigated through the current programme of concrete investigations and repairs. Linkage retrofit designs are likely to be prepared in the future to provide a retrofit solution that can be progressively installed along the bridge to further mitigate the risk of damage to these joints.

CONCLUSIONS

Whilst the SRM on the Rakaia and Rangitata River Bridges is still its initial stages, significant conclusions around the structural performance of the bridge have already been made. These include the following:

- The vehicle speeds required to cause resonance in the beams are around 130km/hr, and therefore increased impact loading through resonance is highly unlikely.
- The maximum span specific impact factor for these bridges is likely to be less than specified in the NZ Transport Agency Bridge Manual.
- Impact on these common T-Beam bridges increases with increased speed, as assumed by the NZTA Bridge Manual.

- The bridge spans are not acting as simply supported, and have considerable continuity across the partially split joints.
- Some continuity exists between superstructures even across the split piers, due to the interaction between the split pier columns.
- The inner beams displace significantly more than the outer beams. This is due to the additional stiffness from the kerbs and handrails, and the position that vehicles travel within their lane.
- Given the continuity through the spans and the reduced impact factor; the HPMV Evaluation capacity of the beams is > 100%.
- The beam/column joints are under significant stress under Class 1 and HPMV loading.
- This common form of beam/column joint is vulnerable to cracking and fatigue. This vulnerability is exacerbated for longer span bridges.
- The linkage bars in the beam column joints are under significant stress, and are at risk of fatigue cracking. This may result in a significant reduction in the seismic capacity and resilience of the bridge.
- The WiM data indicates that the level of overloading over the Rakaia River Bridge is relatively low. However, there is a risk that the level of overloading will increase once Full HPMVs are permitted over these bridges.

The five step SRM methodology has provide a cost effective framework for monitoring, which can be employed to other bridge structures in the future. This process is particularly beneficial where programmed strengthening or replacement is expensive, observed deterioration is less than would be expected from analysis, or where significant unknowns exist in the assessment and modelling of the structure.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the financial support provided by the NZ Transport Agency in the investment in this project, and the preparation of this report. John Reynolds and Barry Wright from the NZ Transport Agency have also provided technical inputs, advice and review throughout the project.

Significant technical inputs have been provided by various members of Opus Research, including Sheldon Bruce, Paul Carpenter, and Anthony Paterson. Initial review and inputs into the preliminary design statement were also provided by Giovanna Zanardon of Main Roads, Western Australia.

MEASURING DYNAMIC IMPACTON AGED TIMBER BRIDGES; SOME EXPERIMENTAL OPTIONS

John Moore[1,*], Saeed Mahini[1]

*Email: jmoore30@une.edu.au

ABSTRACT

There are thousands of aged timber beam bridges on local roads in New South Wales (NSW) and because of deterioration their safety levels are unknown. To identify a bridge safety level requires structural performance measurement, preferably with a Structural Health Monitoring (SHM) system, so that any significant temporal change can be quickly identified. There is a need, however, to identify sensors and systems that can be used to monitor the dynamic impact of loads moving at highway speeds that are of adequate performance and of a cost that is a small fraction of the structures' value. Three measurement systems are considered: a high speed camera system to enable the establishment of base-line performance; a laser sensor system to enable accurate validation of other measurement systems on in-service structures; and a system comprising accelerometers to provide a relative motion record of components compared to the motion of a main girder.

KEYWORDS

Aged timber beam bridge, dynamic impact, mid-span deflection, laser, high speed camera, accelerometer.

INTRODUCTION

In the 19th and 20th centuries thousands of timber beam bridges were built on local roads in New South Wales (NSW) Australia; hundreds of thousands worldwide. Over two thousand are extant on local roads in NSW (Roorda, 2006); one example is Horton's Creek bridge on the Armidale Grafton road in NSW as shown in Figure 1, and another is Munsies Bridge as shown in Figure 2. Both of these structures carry some heavy loads and numerous light loads daily. Many have an unknown level of deterioration and their safety levels are unknown (Howard, 2009). Economic maintenance of these bridges is, therefore, an ongoing concern for the owners of regional bridges.

Figure 1: Hortons Creek Bridge, Armidale Road, NSW

Figure 2: Munsies Bridge, Gostwyck, NSW

In most of these bridges the components are bolted and spiked together with the elasticity of the joints being rarely well defined and often temporally changeable. Girders will sometimes twist and sometimes not depending on the position of the vehicle loading. Loose bolts will sometimes bind and freeze and other times move freely. To accurately determine the level of nodal coupling of such joints under load requires a method that includes the continuous measurement of every joint. A further measurement complication is that the level of nodal coupling will vary dependent on the traverse speed of any vehicle loading those joints. There is thus a deflection that is caused by a static load and an increased deflection that is caused by a moving dynamic load. Such an increased deflection is termed the 'impact factor' and Bakht & Pinjarkar(1989) identified that "impact factor is not a tangible entity susceptible of deterministic evaluation"; a reference more recently cited by Mufti (2001). While it may be straightforward to create a repeatable deterministic solution or even a Finite Element Model (FEM) solution for a new tightly constrained Timber Bridge it is more difficult to do so for a structure that can vary unpredictably in performance week by week. The effect of impact by an individual vehicle on a specific bridge can, therefore, only be determined by direct measurement of aged timber beam bridge girders with poorly constrained decks and to ensure the probability of failure is updated daily, continuous measurement with a Structural Health Monitoring (SHM) system is required.

In order to implement an SHM system on an aged timber bridge of unknown performance a baseline performance must be established and to achieve this the bridge must be measured under differing loading conditions. This baseline performance can then be compared with subsequent measurements to determine if temporal changes have occurred. Such temporal changes can then be used, particularly in the case of aged timber structures, to provide a Structural Safety Evaluation (SSE) as discussed by (Chan *et al*., 2011). To sense such temporal changes there are several possible systems that can be used but the ones considered here are:the measurement of the absolute mid-span deflection using both a high speed camera(Moore, 2013) and laboratory quality laser distance sensors; and the use of accelerometers to determine the relative movement of bridge girders and components.

THE MEASUREMENT OF MID-SPAN DEFLECTION

Deflection Recording With a High Speed Camera, Staff and Vernier

Deflections caused by traversing vehicles of known mass over a test bridge (Munsies Bridge, Gostwyck NSW)were recorded using a high speed high quality camera (Casio EX-FH25)(Moore, 2013). The camera was capable of recording at 120 frames per second (fps), 240 fps and 480 fps, with an upper speed of 1000 fps; 120 fps were used in this test. The camera and software were calibrated by comparing the recorded images with the moving sweep-hand of a standard clock. The software used to interpret the images was AVS Video Editor 5.2 sourced from Online Media Technologies Ltd, UK. The recordings from the video camera were used to identify the instantaneous mid-span deflectionsfrom a test vehicle moving across the bridge as measured with a graduated scale and vernier (refer Figures 3 and 4) .

Figure 3: Graduated scale, staff and vernier

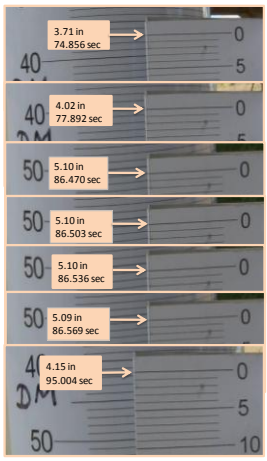

Figure 4: Close up view of some graduated scale and vernier measurement examples

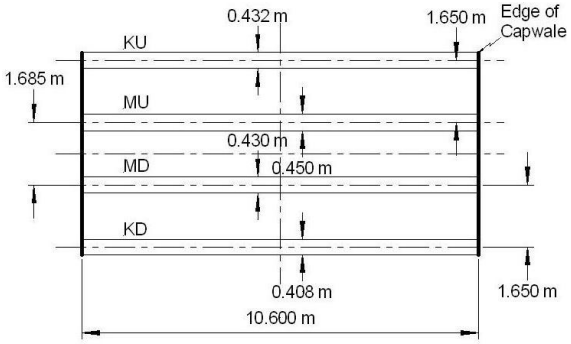
The plan of Munsies Bridge, Gostwyck, NSW,is shown in Figure 5 and the cross-section in Figure 6. The span was 10.6 m and the four girders of various diameters in the range 400-450 mm. The bridge was originally constructed in 1938 and is still in operation. It is currently recommended by the Roads and Maritime Services (RMS), NSW, that a replacement bridge girder should be of F27 hardwood, Group S2, Durability class 2 to AS1720 with a minimum diameter of 450 mm (RTA, 2008: Section 1.9.1.2), but manyin-service girders do not comply with this recommendation. To determine the in-service girder Modulus of Elasticity (MoE), the mid-span deflection was measured under a known load. This was achieved by placing graduated scales under the mid-spans and attaching staffs with vernier scales to the mid-spans. A test vehicle of known axle load (refer Table 1 and Figure 7) was then driven across the span and the mid-span deflections recorded. Two models, one a finite element model (CSI, 2010) and the other a spread sheet model, were used to determine the effective values of girder MoE.



Girder nomenclature: K ~ kerb;
U ~ upstream; M ~ main; D ~ downstream

Parameter	Value
Front axle load	41 kN
Rear axle load	124 kN
Axle spacing	4.3 m

To validate that the deflection data was a reasonable reflection of the applied load, a continuous record was made of the test vehicle traversing Span 4. The combined influence line was computed for both axles of the test vehicle (refer Table 2) and is shown in Figure 7 (smooth light grey line) The impact factor (Mufti, 2001: Equation 2.4) as determined in Table 5 and Figure 8 was 0.14.

Deflection Recording With Laser Distance Sensors

To validate other in-service measurements a high quality measurement system is required and to test such a system a Tokyo Sokki Kenkyujo TMR 200 Multi-recorder was tested in a laboratory situation. The first requirement is that samples can be recorded at sufficient speed to determine the peak mid-span deflection of a timber bridge girder. If a point load is one half a metre either side of the mid-span then the mid-span deflection will be within 5% of the peak value (Moore, 2009, Appendix C). At a traverse speed of 100 km.h^{-1} the time for such a point load to move half a metre is 18 millisecond. A logging system capable of recording at 200 samples per second or higher (5 milliseconds between samples) is thus an appropriate system to use to record dynamic deflection in sufficient detail to accurately identify the peak deflection. The test system that was setup in the laboratory comprised: a simply supported 5 metre aluminium beam (plank); a TMR 200 Multi-recorder together with a TMR-231 Voltage/Thermocouple unit and a computer interface sampling at five millisecond intervals; and a Micro-Epsilon optoNCDT 1402 laser sensor to measure the deflection near mid-span when deflected by an impulse load (refer Figure 10). The beam was loaded by stepping onto it and causing it to vibrate at its natural frequency. The resultant transient was as shown in Figure 11 and a cycle of the transient shown in Figure 12. The measured period was 1.9 Hz with about 100 samples per cycle.

Figure 10: Beam used to test vibration logging system

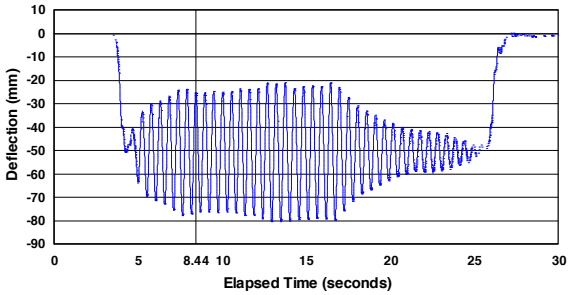

Figure 11: Transient deflection of beam

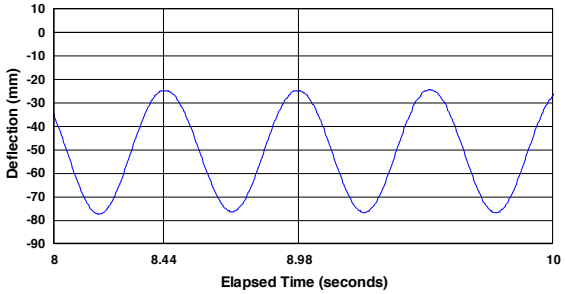

Figure 12: One cycle, between 8.44 and 8.98 seconds

RECORDING RELATIVE MOTION WITH ACCELEROMETERS

To enable the choice of which accelerometers can be used in-service on timber beam bridges it is required that the sensor sensitivity must be first be established. This was achieved by examining the case of a simply supported beam as shown in Figure 13, of length l, with a concentrated load, P, applied at a distance x from the support. The deflection of the beam, δ, at a distance d from the support, providing $d > a$is then given (Benham & Crawford, 1987, p. 181: Equation 7.31)as shown by Equation 1. If the deflection is doubly differentiated then the vertical mid-span acceleration, a_{vp}, is obtained as shown by Equation 5.

$$\delta = \frac{P}{6\,E\,I} \times \frac{d(L-x)}{L} \times (2xL - x^2 - d^2) \tag{1}$$

where:

P	Load (N)
d	Distance from support to measured deflection
L	Beam span (m)
x	Distance from support to Load
E	MoE (GPa)
I	Second moment of area (m^4)

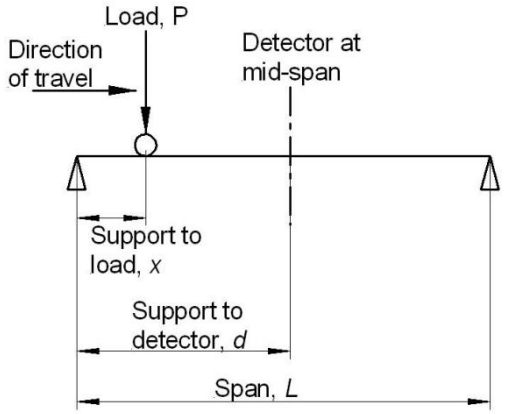

Figure 13:

Then if $d = \frac{L}{2}$:

$$\delta = \frac{P}{48\,E\,I}(4x^3 - 12x^2L + 9bL^2 - L^3) \tag{2}$$

If the load traverses the beam at a speed v and takes the time t to traverse the distance x then:

$x = vt$, and

$$\delta = \frac{P}{48\,E\,I} \times (4v^3t^3 - 12Lv^2t^2 + 9L^2vt - L^3) \tag{3}$$

The vertical velocity of the beam at mid-span is given by:

$$\frac{\partial\delta}{\partial t} = \frac{P}{48\,EI} \times (12v^3t^2 - 24Lv^2t + 9L^2v) \tag{4}$$

Now the peak vertical acceleration, a_{vp}, will occur when the vehicle is at the mid-span, hence:

$$a_{vp} = \frac{\partial^2\delta}{\partial t^2} = \frac{Pv^2L}{4\,EI} \tag{5}$$

The peak mid-span vertical acceleration of the beam is thus proportional to the load and the square of the traverse speed of the load across the beam. A typical timber beam bridge with four girders will support 32% of the load on one main central girder (Moore *et al*., 2012, Table 1)and a typical set of acceleration values is given in Table 3. The first two cases (I & II) evaluated are for a light load, 3 tonne, traversing at medium and high speed (40 $km.hr^{-1}$ and 100 $km.hr^{-1}$). The typical maximum axle load in NSW is about 20 tonne and this is

evaluated at a speed of 60 km.hr^{-1}(Case III) and to compare the data reported by Feltrin, Steiger, Gsell, Gulzow, & Wilson(2010) Case IV is evaluated for a point load of 40 tonne.

A sensor is, therefore, required that can be used to detect accelerations in the range 0.005G to 0.5G. A practical example of measurements of this type has been reported by Feltrin et al.(2010). They reported that a newly constructed wooden trough bridge loaded with a 40 tonne vehicle created beam mid-span vertical accelerations in the range 0.1 ms^{-2} rising to 1 ms^{-2} for vehicle traverse speeds of about 10 kmh^{-1} to 60 kmh^{-1}. While the structure they report is different to a four girder timber beam bridge the measured accelerations are indicative of a timber structure designed to carry similar loads on local roads and, therefore, expected to undergo comparable accelerations to those that might be expected on a timber beam bridge structure.

Table 3: Calculation of vertical acceleration of beam at mid-span for a 3 tonne point load at 40 km.hr^{-1} and 100 km.hr^{-1} (Case I & 2), and also fora 20 tonne and a 40 tonne point load at 60 km.hr^{-1}(Case III&IV)

Case	I	II	III	IV	Parameter (units)
P	3	3	20	40	Total load (tonne)
P	29	29	196	392	Total load (kN)
0.35P	9418	9 418	62784	125568	Load per central girder (N)
l	10	10	10	10	Beam span (m)
v	40	100	60	60	Vehicle traverse speed (km.hr^{-1})
v	11.1	27.8	16.7	16.7	Vehicle traverse speed (m.s^{-1})
E	20	20	20	20	MoE (GPa)
I	0.002	0.002	0.002	0.002	Second moment of area (m^4)
a_{vp}	0.07	0.45	1.1	2.2	Vertical beam acceleration (m.s^{-2})
a_{vp}	0.007 G	0.046 G	0.1 G	0.2 G	Vertical acceleration as a fraction of G (9,8 m.s^{-1})

DISCUSSION

While it has been reported (Moore, 2013; Moore *et al*., 2013) that continuous monitoring of timber beam bridges is viable the possibility of lower cost systems has not been reported. While a monitoring system to record the mid-span deflection of a single girder might cost less than five thousand dollars this cost rises significantly if all the girders on a multi-span bridge need to be monitored. A single girder monitoring system such as the camera based system discussed above can be economically used to determine base line performance and a camera and laser based system (Moore *et al*., 2013) can be used to continuously monitor several girders. These systems can be validated when used in-service by using laboratory laser distance sensors as also indicated above. However, the cost of these laboratory sensors is prohibitive, for local councils, when twenty to thirty sensors are required to monitor one bridge.

An alternative approach is to monitor the mid-span deflection of a few girders with a device such as the Bridge Deflection Meter (BDM) described by Moore(2013) and to monitor the remainder with accelerometers. While laboratory style accelerometers can be high cost at several thousand dollars lower cost proprietary devices can be constructed for about one hundred dollars (Citation: personal experience). Accelerometer integrated circuits are available for less than one dollar, they just need to be packaged appropriately with suitable data interfaces for in-service use on timber bridges. Twenty devices at $100 is thus more economical than 20 at $5000. To attempt to utilise such accelerometers to monitor girder deflection is not straightforward as discussed by (Arraigada & Partl, 2006). Identifying the required constants of integration can require excessive repetitive calibration experiments. However, the relative component motions can be compared by comparing their accelerations. The motions can firstly be compared amongst all the girders and then with the base line measurements. Since these types of comparisons can be done in real time a structural health monitoring system

can be constructed that could be used to identify significant temporal change at costs that are a small fraction of the structural value.

CONCLUSIONS

Because of the ongoing need to economically determine the health of aged timber beam bridges, viable sensing systems need to be identified that can be effectively used on such structures. Three different types of sensing systems have been presented that are suitable for use to evaluate timber bridge structural health. The use of these types of systems should enable Local Government Engineers to effectively establish baseline performance and the occurrence of any ongoing temporal change. It is also anticipated that these sensors will be used in further research to establish the validity of determining the baseline and ongoing temporal structural health of aged timber beam bridges. It was not possible, in this paper, to compare the results, using the three methods from one in-service bridge but such a comparison will be made in a future paper as soon as data is available. To achieve this we are interacting with Local Government in our area to establish suitable measurement opportunities.

ABSTRACT

The fundamentals of the seismic resilience and evaluation method are presented. The evaluation is based on a non-dimensional analytical function for loss variation and a linear recovery function for a community in an average state of preparedness within a specified 'recovery period'. The loss function is a normalized function where the drop of functionality right after the extreme event. The formulated framework, applied for a complex system of six hospitals (considering direct and indirect losses), is employed for low and medium-rise retrofitted reinforced concrete buildings in which the seismic performance has been evaluated by the displacement-based design method. Although this type of design prevents loss of people life it cannot maintain functionality or limit damages. A newly developed Resilience-Based Earthquake Design is promising to address these demands. This research shows that the FRP retrofit is more effective than steel bracing in terms of improving performance and ductility in low-rise RC buildings and the measuring seismic resilience shows an enhanced value as opposed to the un-retrofitted structure.

KEYWORDS

Performance-based design, resilience, seismic, buildings, assessment.

INTRODUCTION

The main objective of Resilience-Based Design (RBD) is to make communities 'resilient'. It aims to develop actions and technologies that allow structure and/or community to recover its function as promptly as possible whenever a disaster occurs (Cimellaro, 2013). The MCEER terminology defines seismic 'Resilience' as a decision variable (DV) that compares the seismic performance recovery with a given loss required in order to maintain the functionality of the system with minimal disruption. The seismic resilience framework can compare losses and different pre- and post- event measures in order to verify if strategies and actions can reduce or eliminate disruptions during seismic events (Cimellaro, 2008). In this regard, Chang et al. (2004) proposed a series of quantitative measures of resilience and applied them to a case study of an actual community (seismic mitigation of a water system). Biondini et al. (2015) developed a probabilistic approach to the lifetime assessment of seismic resilience of deteriorating concrete structures. Cimellaro et al. (2010) presented a quantitative evaluation of the concepts of disaster resilience and a unified terminology for a common reference framework for the evaluation of health care facilities subjected to earthquakes.

To date, earthquake is considered as part of the general loading requirements applicable to all regions of Australia practically Melbourne and Sydney (Standards Australia 2007 and Wilson et al. 2008). In conventional seismic assessment of structures, the trade-off strength demand is compared with the ductility (displacement) demand on the structure (Lumantarna, et al., 2010). In recent years, performance-based design (PBD) method is implemented in many of the seismic design codes. In this method, performance objective can be the target displacement as the response parameter of a substitute single- degree-of-freedom (SDOF) system which is so-called displacement-based design method (DBDM). It can be also related to strain-based limit state, and the level of damage (Ghobarah, 2001) on a capacity spectrum curve (Hadigeh et al., 2015). ATC-40 (1996) is recommended Capacity Spectrum Method (CSM) for performance assessment of concrete structures. Although, DBDM prevents loss of life, the damages cannot be limited or functionality cannot be maintained.

A number of studies have focused on the influence of retrofitted joints using fibre-reinforced polymers (FRPs) on the overall behaviour of an RC frame. Zou et al. (2007) investigated a 3-storey frame that was strengthened with FRP around its columns. They observed that this could increase the strength of the columns while marginally increasing their stiffness. Reducing stiffness is, however, more desirable for the overall stability of a frame, as stiffer columns are more vulnerable to higher seismic forces. Niroomandi et al. (2010) and many recently Hadigeh et al. (2015) studied the seismic performance of RC ordinary moment resisting frames (OMRFs) retrofitted by FRPs or steel braces using DBDM. Hadigeh et al. (2015) showed that while using X-braces will decrease the ductility of the frames, FRP retrofitting increases the behaviour factor and maintain the ductility within a reasonable margin.

In this paper a formulated framework for a hospital complex system is employed in order to assess the seismic resilience of low-to-medium-rise RC Buildings retrofitted with steel braces and FRP composites (Mahini, 2015, Mahini and Ronagh, 2010, 2011) previously evaluated by DBDM (Niroomandi et al., 2010 and Hadigeh et al., 2015).

PBD OF THE SELECTED RETROFITTED FRAMES

An eight storey four bay Ordinary Moment Resisting Frame (OMRF) was selected frame. The frame was designed according to the Australian Concrete Code AS3600 (2001) as an OMRF. A 1/2.2 scale model of the frame (see Figure 2a) was then formed by the application of the similitude requirements of the Buckingham's theorem (Mahini, 2005). Based on the scale factors, the scale down frame was loaded, analysed and designed according to AS3600. Four N12 (ϕ 12mm) rebars were used for both the column vertical reinforcement and the beam longitudinal reinforcement. R6.5 bars (ϕ 6.5mm) were used for stirrups at a spacing of 150mm in both beam and column. A 30mm concrete cover was considered for the beam and column reinforcements which is about half of the corresponding covers in prototype. The tensile properties of various deformed N12 reinforcing steel bars and plain R6.5 (ϕ 6.5mm) stirrups and ties are obtained by testing them under monotonic loading in a Universal Testing Machine (UTM) using a mechanical extensometer of 20mm gage length. The average yield strengths of deformed N12 reinforcing steel bars and plain R6.5mm stirrups and ties, were 507 MPa and 382 MPa respectively and the modulus of elasticity of both reinforcements was 200GPa. Four N12 rebars were used for both the column vertical reinforcement and the beam longitudinal reinforcement. R6.5 bars were used for stirrups with a spacing of 150mm in both column and beam.

To study the seismic behaviour of low-rise frames, a 2-storey and a 4-storey frame, retrofitted by FRP materials and by steel braces, two OMRFs were investigated (Figure 2c). The column and beam dimensions are presented in Table 1. The vertical gravity loads were calculated as D.L. = 21.6kN/m and L.L. = 13.7kN/m, and equivalent static earthquake lateral loads on the frames were derived by using the design response spectrum of Standard No. 2800 (2005).

In the case of steel brace retrofitting, braces were placed in the middle bay of the frames. For the FRP retrofitting technique, all of the joints (except the joints of the last floor) were retrofitted on their web by FRP sheets with overall 2mm thickness and a length of 350mm (Figure 2b). Further details of the FRP-retrofitting design can be found in Mahini (2005). For simplicity, the FRP retrofitting scheme is designed based on the critical joint at the first floor and is then kept identical for other levels in order to guarantee that the plastic hinge relocations are formed in the upper levels and prove the practicality of the proposed retrofitting system in a real-world application.

A nonlinear static procedure (NSP) represents the response of a structure undergoing dynamic loads. A pushover analysis, as a nonlinear static procedure, is employed as an alternative for static and nonlinear dynamic analysis because of its accuracy and simplicity. To study the influence of the retrofitting technique, a nonlinear pushover analysis was performed for both the original and the retrofitted frames. The moment-rotation relationship of the joints (obtained from ABAQUS) was then incorporated into the FE models of the frames and pushover analyses were carried out. The lateral load distribution is proportional to the product of the storey mass and the first mode shape of the structure. The mass source of frame is assumed to be the dead load plus 20% of the live load, according to Standard No. 2800 (2005).

To evaluate the seismic load, it was assumed that the frames are located in a zone with a high seismic hazard (DBA = 0.35 g). The seismic reduction factor was initially assumed to be R=4 and 75% of the lateral load (0.75 V) was applied to the design of each RC frame. However after adding the X-steel brace to the RC frames 100% of the lateral load was applied (V). Therefore, the steel braces were designed to withstand a 25% share of the

lateral load. In case of FRP retrofitting, frames were designed with 75% V and retrofitted with FRP sheets. Details of the bracing system are presented in Hadigeh et al. (2015). The compressive strength of the concrete and the yield stress of the steel reinforcements were assumed to be 40N/mm^2 and 340N/mm^2, respectively. For all sections, the minimum and maximum values of the steel reinforcements were checked against the ABA concrete code (2005).

According to FEMA 356 (2000), the state of building damage under earthquake excitation defines the performance level of a building by considering the vertical and horizontal lateral-force-resisting elements. These performance levels consist of three main objectives; immediate occupancy (IO), life safety (LS) and collapse prevention (CP). Life safety is defined as the post-earthquake state that includes damage to the elements but retains a margin against the onset of a partial or total collapse in the structure (FEMA 2000). For instance, Figure 3 represents the plastic hinge distributions at the specific performance levels of the original and retrofitted 4- and 8-storey structures.

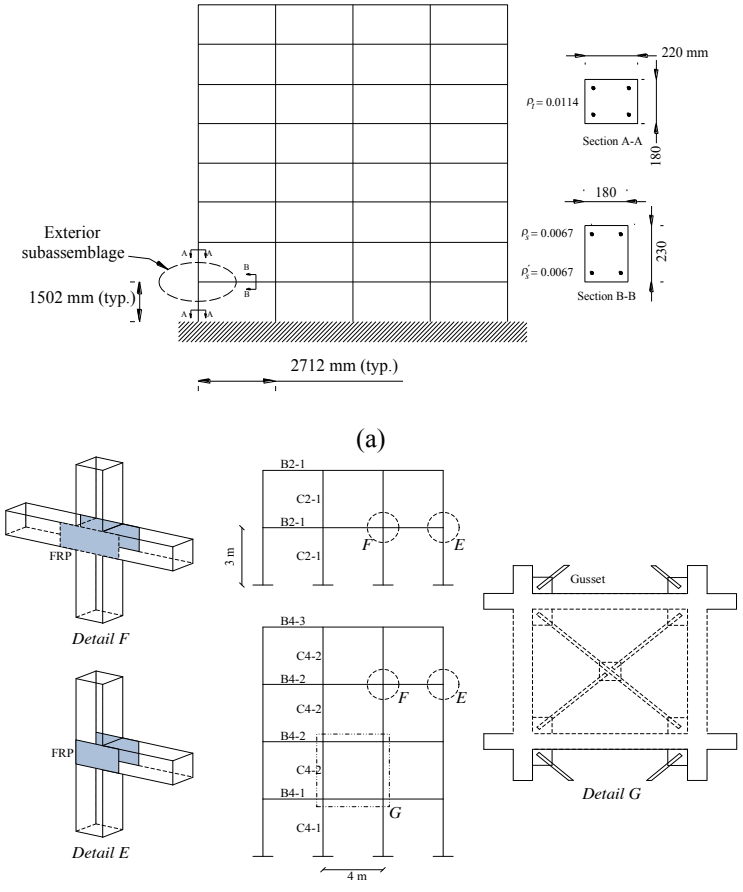

Figure 2. Studied frames, (a) geometry of eight-storey frames (b) FRP strengthening details, (c) geometry of two and four-storey frames, and (d) steel bracing system (Hadigeh et al., 2015).

Table 1 Column and beam dimensions of 2- and 4-storey frames

Section	Height (mm)	Width (mm)	Longitudinal Reinforcement (%)
C2-1, 2	300	300	2.053
B2-1, 2	400	300	1.166 (Top) 0.528 (Bottom)
C4-1	450	450	1.007
C4-2, 3, 4	350	350	1.312
B4-1	450	450	0.638 (Top) 0.503 (Bottom)
B4-2, 3	350	350	1.396 (Top) 0.684 (Bottom)
B4-4	300	300	1.286 (Top) 0.986 (Bottom)

In the 8-storey frames, no plastic hinges are formed on the 6th floor after retrofitting. In the plain eight-storey frame, approximately 74 per cent of plastic hinging occurs on the beams, whereas the FRP retrofitted frames exhibit a 5 per cent improvement in beam hinging. This trend was observed in previous research (Niroomandi et al. 2010) for plain frames but not for FRP retrofitted frames (in which plastic hinging in the beams was similar). This can be explained from the difference between the additional moment-rotation stiffness of the retrofitted joints; in (Niroomandi et al. 2010), only the peak strengths were captured and implemented in the pushover analysis. The steel braces are not promising in this regard, as only 62 to 66 per cent of hinges formed on beams. Although no beam hinging occurred in the low-rise building frames after FRP retrofitting, the plastic hinging improved in the 4-storey building, which was reclassified from Collapse (C) to the acceptance criteria of Immediate Occupancy (IO). This trend was also observed for a 2-story frame. However, the plastic hinge numbers increased after FRP retrofitting. Again, the steel braced systems exhibit lower plastic hinge formation, and a lower ductility demand is therefore expected for this system.

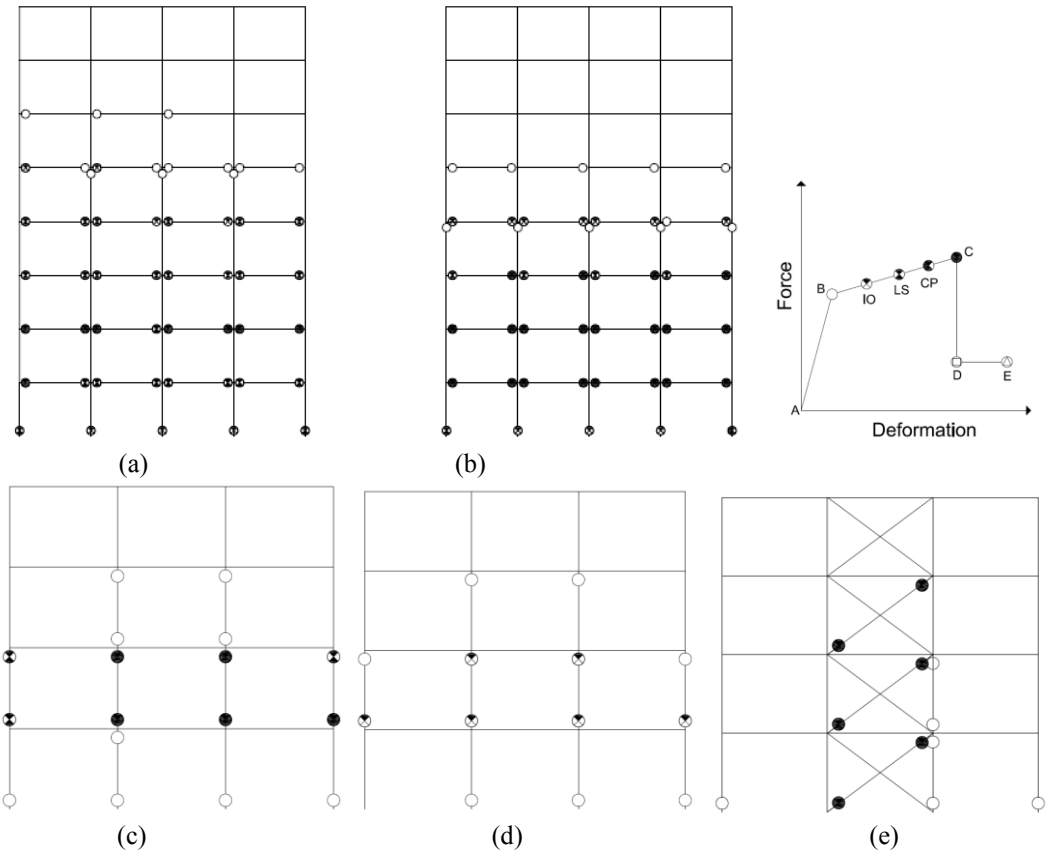

Fig. 3. Plastic hinge formation for (a) original 8-storey, (b) FRP retrofitted 8-storey, (c) original 4-storey, (d) FRP retrofitted 4-storey and (e) steel-braced 4-storey frames.

Therefore, the retrofitted frames meet the performance objectives of life safety. According to these results, this retrofitting technique can improve the behaviour of the frame under earthquake motions to the desired level. It should be noted that response spectrum of Standard 2800 is much higher than the response spectrum of the Australian Standard AS1170.4 (1993) because earthquake hazards in Australia are lower than in Iran. As the original frame was designed according to the Australian seismic code the shortfall of the frame is explained by the differences between the Iranian and the Australian response spectra. However, the FRP retrofitting of the joints upgraded the frame to satisfy the LS performance level of Standard 2800.

Table 2 presents the performance points of the frames. According to this table, the FRP-retrofitting of the 4-storey frame failed to upgrade the frame to satisfy the life-safety performance demand of the selected Standard 2800 earthquake, indicating insufficient thickness for the FRP laminates. However the steel bracing of the frames considerably enhanced the performance to meet the required LS demands by substantially increasing capacities of the frames at the expense of highly reduced ductility.

Table 2. Performance points of the original and retrofitted frames

Type of frame	Performance point (S_d, S_a)		
	2-storey	4-storey	8-storey
Plain	(4.00, 0.36 g)	(2.66, 0.27 g)	N.A.
Retrofitted with FRP laminates	(3.79, 0.38 g)	N.A.	(12.27,0.126 g)
Retrofitted with X-braced steel	(1.00, 0.70 g)	(0.92, 0.66 g)	---

DEFINITION OF RESILIENCE

Resilience is the capability of the system to sustain the effects ΔQ of the extreme event at time t_{oE} and to recover efficiently a target level of functionality Q(t) at time t_{oE} plus T_{LC} . For a single event, it can be defined by the following equation.

$$R = \int_{t_{OE}}^{t_{OE}+T_{LC}} Q(t)/T_{LC}\,dt \tag{1}$$

where

$$Q(t) = [1 - L(I, T_{RE})][H(t - t_{OE}) - H(t_{OE} + T_{RE}))]\{f_{\text{Rec}}(t, t_{OE}, T_{RE})\} \tag{2}$$

where t_{OE} is the time of occurrence of event, T_{LC} is the control time of the system E , $L(I, T_{RE})$ is the loss function; $H()$ is the Heaviside step function, f_{Rec} (t , t_{0E} , T_{RE}) is the recovery function and T_{RE} is the recovery time from event E necessary to go back to pre-disaster condition evaluated starting from t_{0E}.

The Resilience can be illustrated graphically as the normalized shaded area underneath the functionality function of a system, Q (t). Q (t) is a non-stationary stochastic process and each ensemble is a piecewise continuous function as the one shown in Figure 1, where the functionality Q (t) is measured as a percentage function of time.

In this figure, L is the loss, or the drop of functionality, right after the extreme event, and R is the Robustness which is strength, or the ability of elements, systems and other measures of analysis to withstand a given level of stress or demand without suffering degradation or loss of function. It is therefore the residual functionality right after the extreme event and can be represented by:

$$\text{Robustness (\%)} = 1\text{-}L\ (m_L, \sigma_L) \tag{3}$$

where L is a random variable expressed as a function of the mean m_L and the standard deviation σL.

Normally, three different types of recovery functions which are (i) linear, (ii) exponential and (iii) trigonometric can be selected depending on the system (resources and societal response) and societal preparedness.

The simplest form; linear recovery function, is used herein as there is no information available regarding the preparedness, resources and societal response as follows.

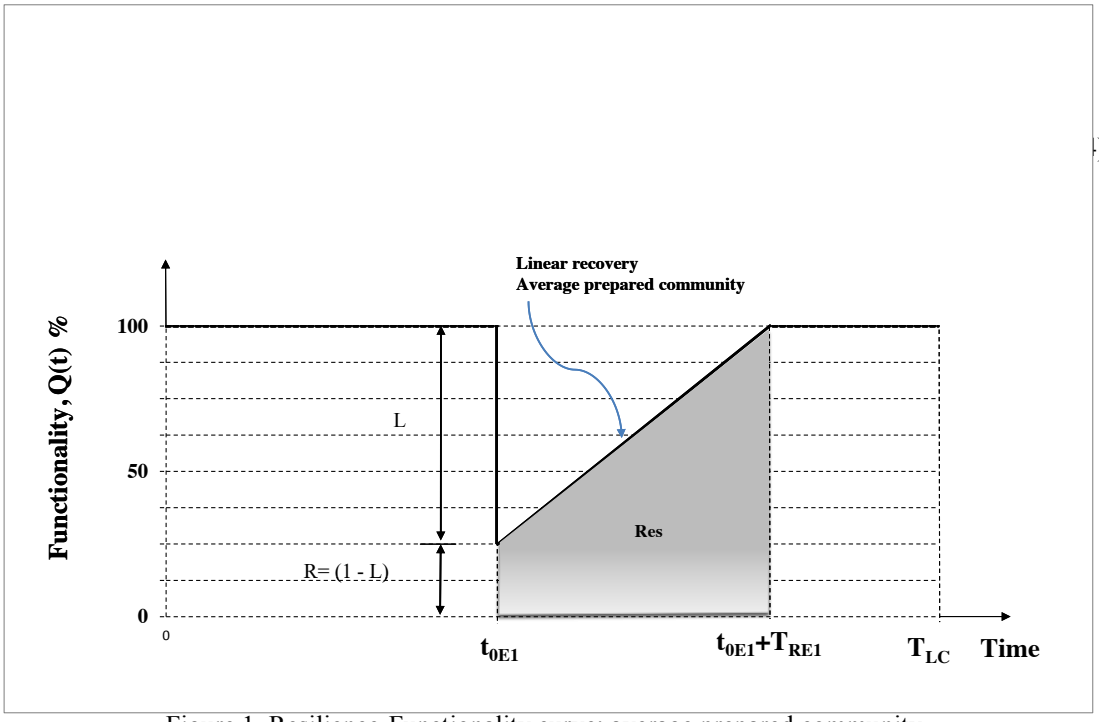

Figure 1. Resilience-Functionality curve: average prepared community

REFERENCE CASE STUDY: Hospital building (Cimerallo et al., 2010)

To illustrate the proposed framework equation (Eq. 1) a complex of six hospitals located in Memphis, Tennessee has been selected (Figure 4). It consists of a regional loss estimation study aimed at the estimation of economic losses of several buildings within a geographical region like a city. Figure 4 shows the locations by Zip codes that were used to define the seismic Hazard and the structural type of the hospitals used to define the structural vulnerability.

Four seismic rehabilitation alternative schemes are considered for each structural type as per FEMA 276: 1) no action; 2) rehabilitation to LS level; 3) rehabilitation to IO level; 4) construction of a new building which are the target performance levels for rehabilitation against an earthquake.

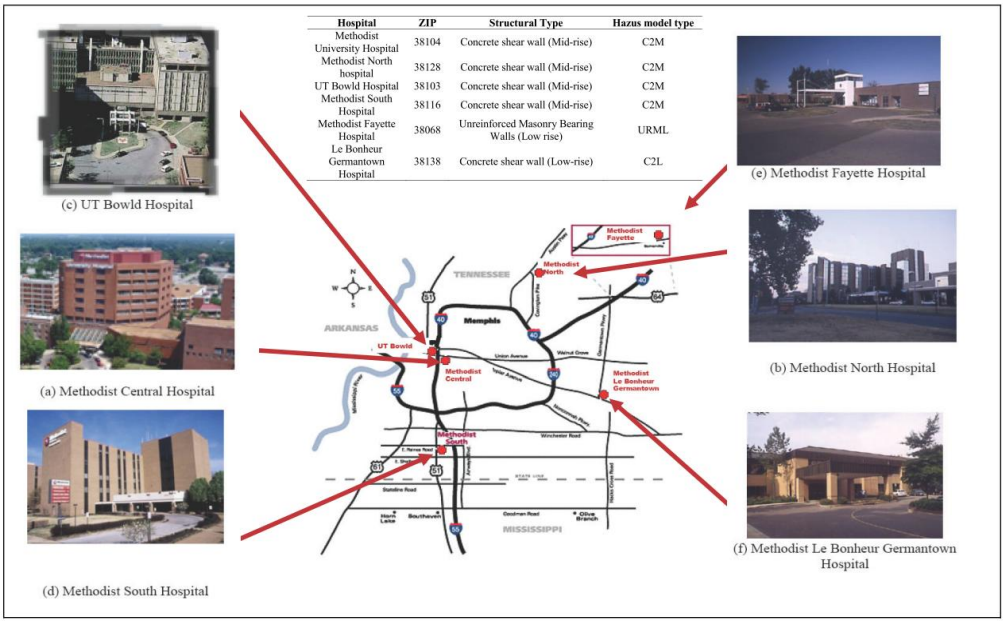

Figure 4. System definition (Cimerallo et al., 2010)

In order to avoid the seismic record the input value was normalized using the four different hazard levels. After normalization the value were determined for different rehabilitation strategies (Figure 5). In order to improve the disaster resilience of the hospital system, four different seismic retrofit schemes were considered for this

reference case study: (a) Moment resisting frames (MRF); (b) Buckling restrained braces (UB); (c) Shear walls (SW) and (d) Weakening and Damping (Cimerallo et al., 2010).
The disaster resilience value is calculated according to Eq. (1). The expected equivalent earthquake losses for each rehabilitation scheme were obtained considering the probability of each level of the earthquake, along with the initial rehabilitation costs, followed by the total expected losses considering an observation period T_{LC} of 30 years.

The recovery time and resilience values of this case study are shown in Figure 5. It is shown that the Rebuild option has the largest disaster resilience of 96.5%, when compared with the other three strategies, but it is also the most expensive solution. When No Action is taken, however, the disaster resilience is still reasonably high (81.9%). Based on Cimellaro (2008), the initial investments and resilience are not linearly related.

When the functionality Q (t) is very high for it to be improved by a small amount it is required to invest a very large amount compared with the case when the function Q (t) of the system is low. Although this is obvious the procedure presented herein can be used by decision makers.

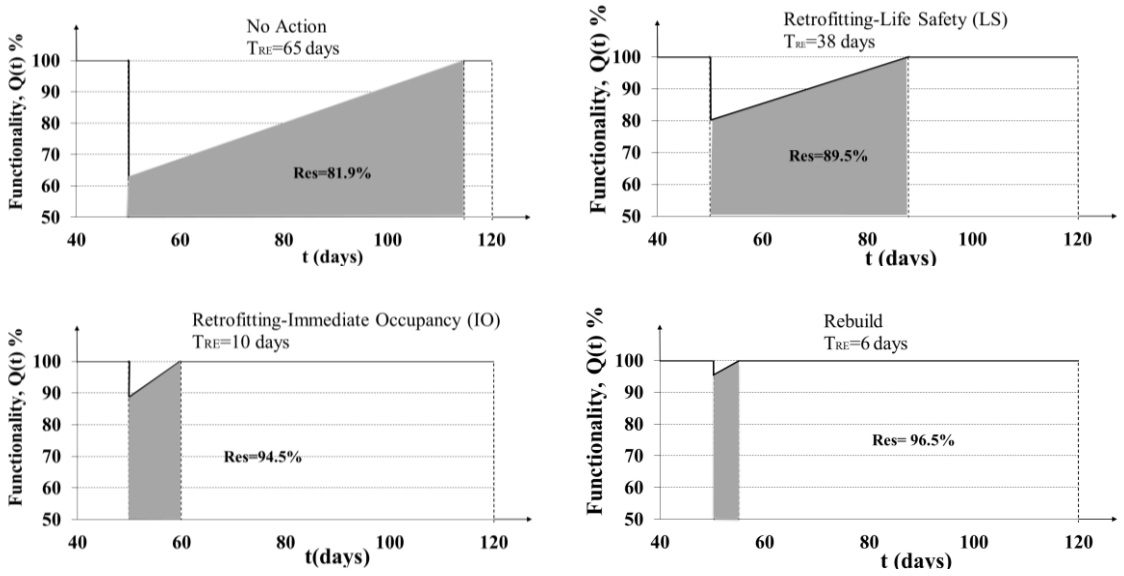

Figure 5. Resilience for different retrofitting strategies, adapted from Cimellaro (2008).

SEISMIC RESILIENCE OF RETROFITTED OMRFs (this study)

Table 3 shows the values of resilience for the two different retrofit techniques (FRP and X-braces) and for different low-to-medium-rise RC frames (see Figure 2).

This shows that the best improvement in terms of resilience is obtained using a FRP retrofit strategy for 2 and 4 storey frames. However with the 8-storey building both retrofitting strategies led to the same improvement in shifting the building performance to the LS level.

Although in term of resilience the difference seems small, the loss term of ductility (complementary to resilience) clearly shows the advantage of the FRP scheme. This retrofit technique produces a reduction of displacements and maintains the ductility, regardless of the number of stories. The maintenance of ductility is important for RC OMRFs as it is not desirable in the seismic performance of existing frames with OMRFs.

The steel bracing considerably enhanced the performance of the frames to meet the required life-safety demands by substantially increasing strength capacity of the frames at the expense of highly reduced ductility and lower seismic resilience.

Table 3 Recovery time and resilience of RC frames for rehabilitation strategies (T_{LC} = 65 days).

Rehabilitation Alternatives	Type of frame / Performance level	2-storey	4-storey	8-storey	Recovery Time T_{RE}, [days]	Resilience Res [%]
Plain	No Action	●	●	●	65	81.9
	Life Safety (LS)	NA	NA	NA	-	-
	Immediate Occupancy (IO)	NA	NA	NA	-	-
	Rebuild	●	●	●	6	96.5
Retrofitted with FRP sheets	Life Safety (LS)	-	-	●	38	89.5
	Immediate Occupancy (IO)	●	●	-	10	94.5
Retrofitted with X-braced steel	Life Safety (LS)	●	●	●	38	89.5
	Immediate Occupancy (IO)	-	-	-	-	-

CONCLUSIONS

Resilience-based design integrates information from these different fields such as earthquake engineering, social science and economics into a unique function leading to results that are unbiased by uninformed intuitions or preconceived notions of risk. This paper aims to provide a quantitative definition of seismic resilience versus the more conventional DBDM method in OMRFs retrofitted with FRPs or X-braced steel techniques. In this rational way an analytical function is used that may fit both technical and organizational issues. A regional complex of six hospitals built in low to medium-rise concrete frames has been used as a reference to illustrate the applicability of the framework and to assess the seismic resilience of the selected retrofitted OMRFS versus the DBDM assessment technique. It is shown that FRP retrofitting improves resilience up to 15% from 89.5% to 94.5%.

It is concluded that FRP retrofit is more effective in terms of improving both performance and ductility in low-rise RC buildings as well as an enhanced value of seismic resilience compared to the un-retrofitted structure. However, the assumptions made herein are only representative for the cases presented.

ABSTRACT

Applications of fibre-reinforced polymer (FRP) composites for retrofitting, strengthening and repairing concrete structures have been growing dramatically. FRPs have high specific strength and stiffness compared to conventional construction materials, e.g. steel. Ease of preparation and installation, resistance to corrosion, versatile fabrication and adjustable mechanical properties are other advantages of FRP composites. However, there are serious concerns about long-term performance, serviceability and durability of FRP applications on concrete structures. Therefore, structural health monitoring (SHM) in FRP-retrofitted concrete structures must be given special consideration. Proper defect detection methods are a crucial part for SHM. This paper presents a study on investigating the application of guided waves for detecting debonding between FRP and concrete structures. A three-dimensional finite element (FE) model has been developed to simulate generation and propagation of guided waves in FRP-bonded concrete elements, and scattering at debonding. Absorbing layers have been developed to provide a computationally efficient tool for investigating guided wave propagation and scattering characteristics in FRP-retrofitted concrete structures. Phase and group velocities arecalculated from FE simulations and then compared with results obtained from analytical solutions. To examine the wave scattering features at the defect, debonding between FRP and concrete issimulatedin the FE model. The FE model isthen used to investigate the feasibilityof guided waves on debonding detection.

FRP-retrofitted concrete structures, SHM, defect detection, debonding, guided waves, finite element simulation.

INTRODUCTION

Structural heath monitoring (SHM) is the implementation of a damage identification scheme to civil engineering infrastructures(Wenzel 2009; Worden *et al*. 2007). SHM is aimed at providing reliable data on the real conditions of structure or structural components,assessing structural integrity and ensuring serviceability and safety. Thus, the overwhelming importance of SHM is beyond question(Ng *et al*. 2012).Among different damage identification methods, guided wave-based approach has emerged as a promising technique(Ng 2015). Guided waves propagate in solid media, interacting with the boundaries in such a way that boundary conditions could be satisfied. Different types of guided waves can occur depending on geometrical properties and boundary conditions of the structure. For instance, Rayleigh waves propagate on the surface of a semi-infinite solid medium. Lamb waves propagate in plate-like structures and their propagation is guided by the free upper and lower surfaces of the plate. Compared to conventional bulk wave methods, guided wave–based damage identification approaches offer some advantages includingability of guided waves to travel over long distances, the active nature of guided waves, sensitivity of guided waves to small damages and capability of guided waves to inspect inaccessible, embedded and encapsulated structural components(Ng and Veidt 2012; Rose2014).

Meanwhile, the use of fibre-reinforced polymer (FRP) compositesin concrete structures has been extensively expanding(Choi *et al*.2013; Taillade *et al*. 2011).FRPs are used to increase flexural or shear strength, improve ductility and repair damaged concrete elements(Teng *et al*. 2001; Hollaway 2010). The need for retrofitting may arise from errors in design and/or construction, changes in codes and standards or new requirements of client. Application of FRP is economical because they can be readily available and easily installed on construction site using minimum labour and equipment and with no need to temporary support. FRPs, also, offer very high specific strength and specific stiffness and they show good resistance to fatigue and corrosion(GangaRao *et al*. 2007). However,FRPs are susceptible to different types of defects,which can be initiated in constituent raw materials, during preparation and installation of FRP on concrete substrate and also in service life of retrofitted

structures(Akuthota *et al*. 2004). If defects go undetected and untreated, effectiveness of retrofitting and performance of FRP/RC elements can be adversely affected. Thus, SHM needs to be implemented in FRP-retrofitted concrete structures using proper damage identification methods. Currently, a number of non-destructive evaluation (NDE) techniques are used for detecting defects in hybrid FRP/RC structures including visual testing, impact testing, infrared thermography and acoustic emission (Telang *et al*. 2006). This paper seeks to explore application of guided wave method for inspecting FRP-retrofitted concrete structures and detecting debonding at the interface of FRP and concrete.

METHODOLOGY

In this study, three-dimensional finite element (FE) simulations have been performed using Dynamic/Explicit module of ABAQUS version 6.12. FE analyses involved modelling of FRP-retrofitted concrete, excitation of guided waves signals and investigation of wave propagation in structural components. It is clear that for any FE simulation to yield precise results; appropriate element size must be adopted. Based on material properties of the structure, central excitation frequency and excited guided wave modes, the size of element used in this FE model is 1 mm; i.e. 1mm×1mm shell elements and 1mm×1mm×1mm solid elements. However, modelling concrete elements with real dimensions will result in a huge number of elements in the model, i.e. expensive computational cost, as the element size is usually very small compared to the size of the structure being modelled. To overcome this issue, only a section of FRP-retrofitted concrete element has been modelled in ABAQUS. That is a 40cm×5cm×8cm (L×W×H) concrete beam with 40cm×5cm CFRP attached on the top surface of the beam as shown in Figure 1. In order to avoid boundary reflections and maintain computational efficiency, absorbing regions have been applied on the extremities of the modelled slice.

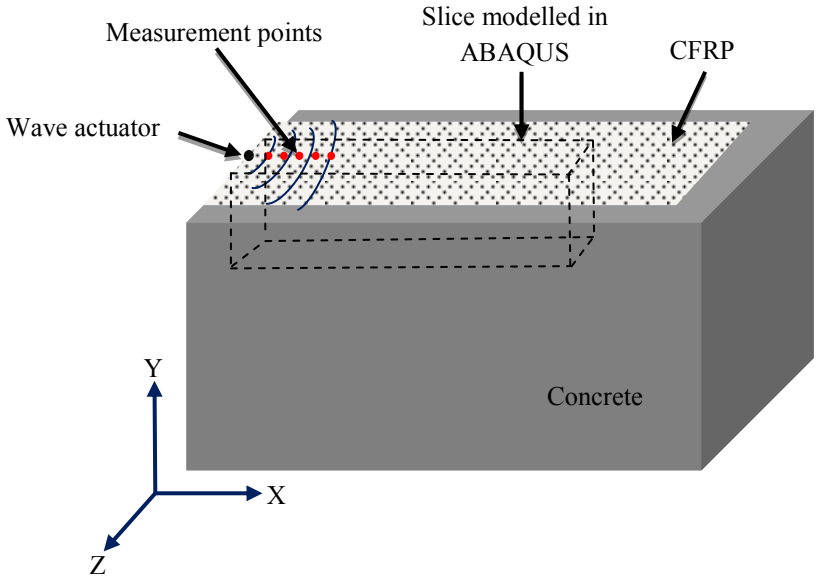

Figure 1 Schematic of FRP/RC model

Accuracy and efficiency of finite element simulations are highly dependent on the successful implementation of absorbing regions. Absorbing Layers by Increasing Damping (ALID) is one of commonly used methods in guided wave problems(Pettit *et al*. 2014). It involves adding successive layers to the main structure with gradual increase in damping values while other elastic properties are the same as main structure. To keep explicit analyses computationally efficient, only mass-proportional damping has been applied as it has small effect on stable time increment. Mass-proportional damping across absorbing regions can be formulated as(Rajagopal *et al*.2012):

$$C_M(x) = C_{Mmax} X(x)^P \tag{1}$$

where *X(x)* ranges from 0 at the beginning of absorbing layer and 1 at the end of absorbing layer, and C_{Mmax} has a real positive value.

Analytical verification of FE simulation has been carried out by DISPERSE computer program. DISPERSE has been designed to obtain dispersion curves, helping study of guided wave propagation in multi-layered media. DISPERSEapplies global matrix method to create dispersion curves. In this method, the propagation of waves in a bulk material should be described and related to displacements and stresses in the material. Then, individual layers would be assembled to create the global matrix representing a complete system(Pavlakovic and Lowe 2003).

RESULTS AND DISCUSSIONS

To study guided waves scattering characteristics due to debonding at FRP/RC interface, wave propagation modelin FRP-retrofitted concrete structure needs to be verified the in different media.To do so, absorbing regions have been applied to FRP, RC and FRP/RC models. For this study, absorbing layer has been considered acceptable if the ratio of amplitude of reflected wave to incident wave is smaller than -46 dB. Considering Eq. 1, a value of P equal to 3 has been used based on the practice of Rajagopal *et al*. (2012). Also, the width of absorbing region for all models is 40 mmand $C_{Mmax} = 2.5\times10^{+06}$.Guided waves were simulated using a Hanning windowed tone burst pulse as:

$$u(t) = \frac{a}{2}\left(1 - cos\frac{2\pi f_c t}{N}\right) cos2\pi f_c t \tag{2}$$

where$a$, N, $f_c$denote the wave amplitude, number of cycles and central frequency respectively. It has been assumed that a=10^{-7} m, N=5 and f_c=150 kHz as shown in Figure 2:

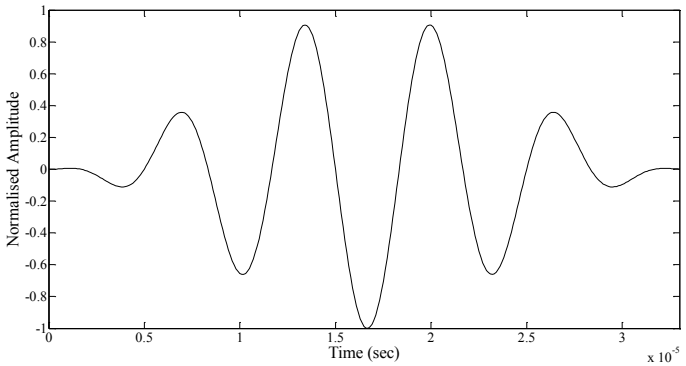

Figure 2 Excitation signal

Mechanical properties of reinforced concrete are assumedas:

E_c=25 GPa, ρ_c=2400 kg/m^3, ν_c= 0.16

CFRP composite is comprised of 4 plies with reference orientation angle of 0^o, 90^o, 90^o and 0^o. It is assumed that each FRP ply is made up of carbon fibre and epoxy matrix with a fibre weight fraction (W_f) of 80%. Table 1 displays mechanical properties of carbon fibre and epoxy matrix:

Table 1 Properties of CFRP constituent materials

Elastic properties of fibre					
E_{f11} (GPa)	E_{f22} (GPa)	G_{f12} (GPa)	G_{f23} (GPa)	ρ_f (kg/m^3)	ν_{f12}
231	14.48	22.75	4.83	1760	0.27

Elastic properties of matrix			
E_m (GPa)	G_m (GPa)	ρ_m (kg/m^3)	ν_m
3.77	1.35	1220	0.40

Chamis (1984) formulated mechanical properties of a composite ply based on the properties of fibre and matrix:

$$\rho = V_f\rho_f + V_m\rho_m = \frac{1}{\frac{W_f}{\rho_f} + \frac{W_m}{\rho_m}} \tag{3}$$

$$E_{11} = V_f E_{f11} + V_m E_m \tag{4}$$

$$E_{22} = E_{33} = \frac{E_m}{1 - \sqrt{V_f}(1 - \frac{E_m}{E_{f22}})} \tag{5}$$

$$G_{12} = G_{13} = \frac{G_m}{1 - \sqrt{V_f}(1 - \frac{G_m}{G_{f12}})} \tag{6}$$

$$G_{23} = \frac{G_m}{1 - \sqrt{V_f}(1 - \frac{G_m}{G_{f23}})} \tag{7}$$

$$\nu_{12} = \nu_{13} = V_f\nu_{f12} + V_m\nu_m \tag{8}$$

$$\nu_{23} = \frac{E_{22}}{2G_{23}} - 1 \tag{9}$$

where V, W, E, G, ρ and ν represent the volume fraction, weight fraction, modulus of elasticity, shear modulus, density and Poisson's ratio of constituent materials respectively. Also, subscripts f and m denote properties of fibre and matrix respectively. Based on the elastic properties of carbon fibre and epoxy matrix and also carbon fibre weight fraction, elastic properties of CFRP composite can be calculated as shown in Table 2.

Table 2 Elastic properties of CFRP lamina

E_{11} (GPa)	E_{22} (GPa)	E_{33} (GPa)	G_{12} (GPa)	G_{13} (GPa)	G_{23} (GPa)
169.6	10.24	10.24	6.88	6.88	3.51
	ν_{12}	ν_{13}	ν_{23}	ρ (kg/m^3)	
	0.31	0.31	0.46	1616	

Generation and propagation of guided waves were simulated in ABAQUS and results were then used to calculate group velocity and phase velocity denoted by C_g and C_p respectively:

$$C_g = \frac{\Delta x}{\Delta t} \tag{10}$$

$$C_p = \frac{2\pi f_c \Delta x}{\Delta \varphi} \tag{11}$$

whereΔx is distance between measurement points, $\Delta t$is difference of wave arrival time, f_c is the excitation frequency, and $\Delta\varphi$ indicates phase difference between measurement points. Next, group and phase velocities for all FRP, RC and FRP/RC models were obtained from FE simulations and then compared with DISPERSE results.

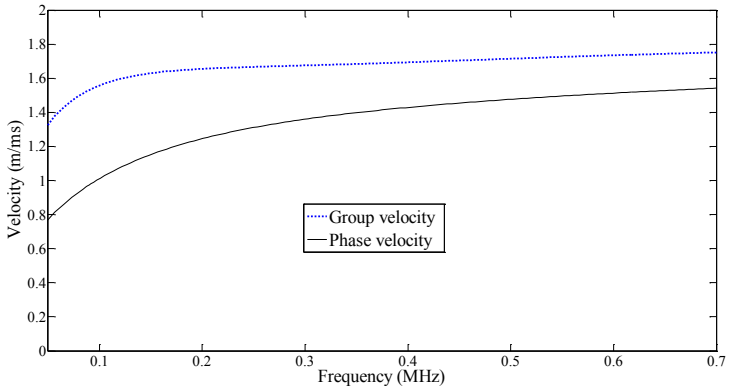

Figure 3Dispersion curves obtained from DISPERSE of a 4-ply CFRP for fundamental asymmetric mode of guided waves

Table 3 displays values of phase and group velocities for fundamental asymmetric and symmetric modes (denoted by *A*and S respectively) for FRP, RC and FRP/RC models.It can be seen that FE simulation results have been verified by DISPERSE.

Table 3 Comparison between FE and DISPERSE results

	FE				DISPERSE			
	A		*S*		*A*		*S*	
	C_g(m/s)	C_p(m/s)	C_g(m/s)	C_p(m/s)	C_g(m/s)	C_p(m/s)	C_g(m/s)	C_p(m/s)
FRP	1517	1138	7478	7553	1630	1152	7439	7467
RC	1892	1898	1882	1904	1896	1896	1896	1896
FRP/RC	2020	2047	2021	2047	2038	2038	2038	2038

To localize the damage, time-of-flight (ToF) method has been used. ToF-based damage localization has been widely used in guided Lamb wave damage detection schemes(Harri *et al*. 2008; Diamantia *et al*. 2005).Basically, ToFcan be defined as the time difference between the incident wave and damage-scattered wave captured by the same sensor. A simple example is when damage is located exactly on the projection of actuator and sensor. As shown in Figure 4, the sensor captures the incident wave first and then the wave reflected back from the damage. Difference of ToF between thescattered wave from the damage and incident wave (Δt) can be obtained from the measured data. Since the material properties of the structures are known in advance, and hence, the group velocity of the wave (C_g) is known, damage location can be determined as:

$$L\_d = \frac{1}{2}\left(C_g.\Delta t\right) \tag{12}$$

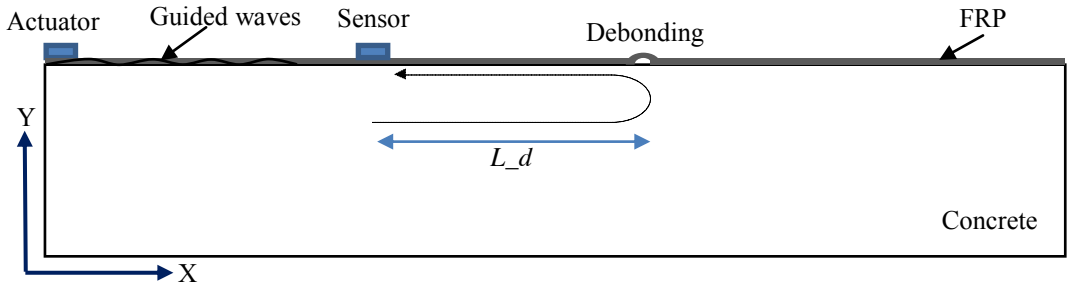

Figure 4 Schematic of one-dimensional damage localization in FRP/RC using ToF

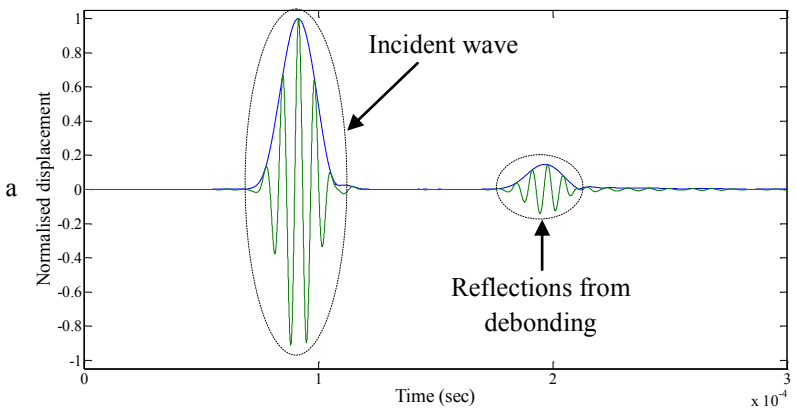
To deploy ToF method in FE model, debonding at FRP/RC interface was added to the model. Two cases were studied with debonding located between *x*=0.250–0.255m and *x*=0.280–0.285 m. Guided waves were generated at *x*=0 and then incident waves and scattered waves were sensed at *x*=0.150 m.In order to obtain signal envelopes, Hilbert transform (Ng 2014)wasthen applied to process the measured wave signals. Figure 5 displays normalised out-of-plane displacements at the measurement point and signal envelope for two cases of debonding:



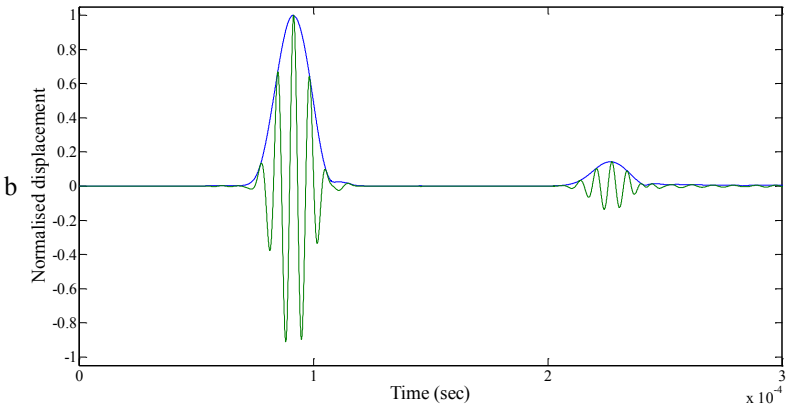


Figure 5Normalised out-of-plane displacements at measurement point in model with debonding at a)x=0.250–0.255 m; and b)x=0.280–0.285 m

Considering Eq. 12 and the group velocity value from Table 3 for FRP/RC model (2020 m/s), we can estimate the damage location using ToF information of the scattered wave. For example, the debonding area in second case begins at x=0.280 m and debonding location is estimated at x=0.285 m.

As seen above, the estimated debonding location using the ToF information hasa good agreement with the real debonding location.

CONCLUSIONS

A three-dimensional computationally efficient FE model was developed to simulate propagation and scattering of guided waves at debondings in FRP-retrofitted concrete elements. Absorbing regions were successfully implemented in FE model to avoid unwanted wave reflections from boundaries, and hence, to improve the computational efficiency of the FE simulation. FE results were verified by analytical methods. The study shows that guided wave is sensitive to debonding and ToF information can be used to determine the debonding location in FRP/RC structures.

PROBABILISTIC EVALUATION OF THE SEISMIC PERFORMANCE OF A CONCRETE HIGHWAY BRIDGE IN QUEENSLAND

ABSTRACT

Being intraplate, the Australian continent has shown low seismicity in its recorded history. However, Australia has been acknowledged as not completely free from seismic hazard. Performance-based earthquake engineering (PBEE) methodology has been widely developed during the past two decades, and has become a key approach for seismic analysis and design. Yet such an approach has not been implemented in Australian structural codes. Therefore, further research is required to develop a domestic approach for Australian applications. In this study, the seismic capacity of a concrete highway bridge is evaluated through a probabilistic method. For this purpose, an analytical model of a typical highway bridge in Queensland was built in OpenSees. The important seismic responses to be considered include the curvature ductility of columns, and the deformations in bearings and abutments. The main uncertainties are related to the source and ground motion models for potential Australian earthquakes. A set of synthetic intraplate ground motions, which was provided by the GeoscienceAustralian, is anticipated to be used in the generation of future probabilistic ground motion maps for Australia, and is presently used for nonlinear incremental dynamic analyses (IDA). The results of this study in the form of seismic capacity limit-states can be further employed for developing performance-based seismic design and/or seismic risk and fragility analyses of Queensland highway bridges.

Performance-based earthquake engineering (PBEE), analytical modelling, intraplate ground motion model, synthetic accelerograms, incremental dynamic analyses (IDA), seismic capacity.

INTRODUCTION

Earthquakes have always had undesirable influences on infrastructure, human life, economy and communities. Considering the high randomness of return period and shaking intensity of earthquakes, they remain one of the most unpredictable natural hazards. In response to this, the extensive research on performance-based approaches in structural engineering during the last two decades has brought about the invention of performance-based earthquake engineering (PBEE) methods. However, as discussed by Cornell and Krawinkler (2000), it should not be forgotten that PBEE methods are not essentially developed for predicting structural performance or estimating seismic losses; they are established to ultimately contribute to the effective reduction of seismic losses and improvement of structural safety.

A key, and the preliminary, step in PBEE is identification and assessment of the seismic hazard at the site of interest as well as the selection of appropriate suits of ground motion records which are relevant to the geological region. The Australian continent is generally identified as intraplate with very low seismic activities. Despite the wide and large area, the Atlas of Seismic Hazard Maps of Australia (Leonard *et al*.2013) shows a uniform hazard level across the continent. Large-magnitude earthquakes are very rare and only a few strong ground motions have been recorded in Australia. The most destructive earthquake which has raised the public attention toward seismic hazards in the short recorded seismic history of Australia was the 1989 Newcastle Earthquake with only 5.6 magnitudes on the Richter scale (Geoscience Australian.d.). However, there is no clear record of the response spectra and ground motion time-histories of this earthquake and preceding strong ground motions due to the prohibitive logistics and cost of taking measurements over such a large area. Under these circumstances, estimation of the consequences of probable seismic events to structures and infrastructures in Australia is unclear and would be beneficial for adoption of state or federal seismic risk mitigation plans.

Seismic performance assessment is particularly important for bridge infrastructure management and maintenance in order for transportation networks to continue functioning during post-earthquake operations. Highway bridges, such as the one shown in Figure 1, are usually constructed by using a number of typical bridge components. It has been shown that all major contributing bridge components should be accounted in the adequate evaluation of seismic performance, in which neglecting to account for some of these components can result in a misestimation of the bridges' overall seismic performance (Nielson andDesRoches 2007). In view of this, the multi-span simply supported (MSSS) concrete girder bridge is a common class in Australia. A detailed review of the concrete bridges in the Queensland bridge inventory shows that the "concrete box girder bridges have been used extensively on or over freeways in Queensland" (Bridge InspectionManual 2004, p. 2.23).

Figure 1 Picture of typical highway bridge

In this paper the seismic performance of a typical MSSS concrete box girder highway bridge was studied. For this purpose, a three-dimensional analytical model of the bridge system was created, which encompasses all the bridge major components. It is noteworthy to mention that this analytical model was developed for generalised MSSS concrete box girder bridges and not for a specific bridge. Nonlinear dynamic analysis was applied to simulate the earthquake loads over the analytical model. As described above, it is difficult to find appropriate strong ground motion records in Australia to be used for dynamic analysis. Therefore, a ground motion prediction (GMP) model, which was developed for the generation of probabilistic ground motion maps for Australia (Somerville *et al*. 2009), was employed as the source of probable Australian earthquakes. By using this GMP model, a suit of synthetic seismic accelerograms were generated and applied for performing nonlinear transient dynamic analyses over the analytical model. The seismic performance and overall seismic capacity of the bridge were then investigated through incremental dynamic analyses (IDA), (Vamvatsikos and Cornell 2002),by developing IDA curves.

METHODOLOGY

Analytical Modelling of MSSS Highway Bridges

The highway bridge model, which was used in this study, has a high degree of accuracy by modelling the various bridge components. These components are classified into three major categories as the superstructure, substructure and linking elements. The first category which is known as superstructure consists of bridge girders, deck slabs and parapets. The substructure consisting of abutments, piers, headstocks, footings and piles provides support to the superstructure. Finally, there are the bearings as the linking elements which are installed to tie the superstructure to the substructure.

In addition to representing a lower degree of accuracy, a common question which arises in deterministic two-dimensional bridge modellings is which dimension is dominant under seismic loads i.e. longitudinal or latitudinal.Relying on two-dimensional bridge modelling is highly probable, as movements one direction will dominatea deterministic setting, while responses to movements in the other direction may still make a significant contribution in a probabilistic setting (Nielson2005).Therefore, three-dimensional bridge modellingisperformedin this study. The bridge model which is used for numerical simulation could be developed through a complex finite element modelling containing a very large number of degrees-of-freedom. However, such a model would be computationally very expensive when a full-scale three-dimensional model is considered. Therefore, a simplified analytical modelling is utilised which allows for more economical analysis time when a large number of simulations are required.The analytical bridge model was established in the OpenSees analysis software developed by the Pacific Earthquake Engineering Research (PEER) Centre

(McKenna and Feneves2005). The modelling was performed consistent with Nielson's (2005) findings on typical bridge properties and modelling assumptions. An example of the modelling method is shown in Figure 2.

The bridge superstructure consists of four symmetric spans where the mid-spans are 22m long and end-spans are shorter by half. The superstructure is supported by two seat-type pile abutments at its two ends and three multi-column piersin the middle which are supported by footings and pile capsat the columns bases. The bearing system is provided by an elastomeric rubber pad and two steel dowels under box girders endover the headstocks. Normally, the superstructure does not dominate the overall seismic response of a concrete highway bridge system because composite deck sections are much stiffer than other bridge components.This means that the concrete box girders and slab behave like rigid elements and are expected to remain linearly elastic under seismic loads. Therefore, the superstructureis modelled using elastic beam-column elements by calculating the section properties of each span. The columns and headstock of the piers are however modelled by displacement-beam-column elements to reflect the nonlinearities in steel and concrete materials and P-Δ effects. The translational and rotational deformations of the foundations at columns bases, including the footing and pile caps, are also modelled by linear force-displacement and moment-curvature materials, respectively. The analytical model of the bridge bearings consists of an elastic material with no hardening ratio as of the elastomeric rubber pad, in parallel with a hysteretic material which represents the behaviour of the two steel dowels (Choi 2002). The difference between fixed and expansion bearings, due to expansion washers, is reflected by adding an initial gap to the hysteretic steel dowel material.

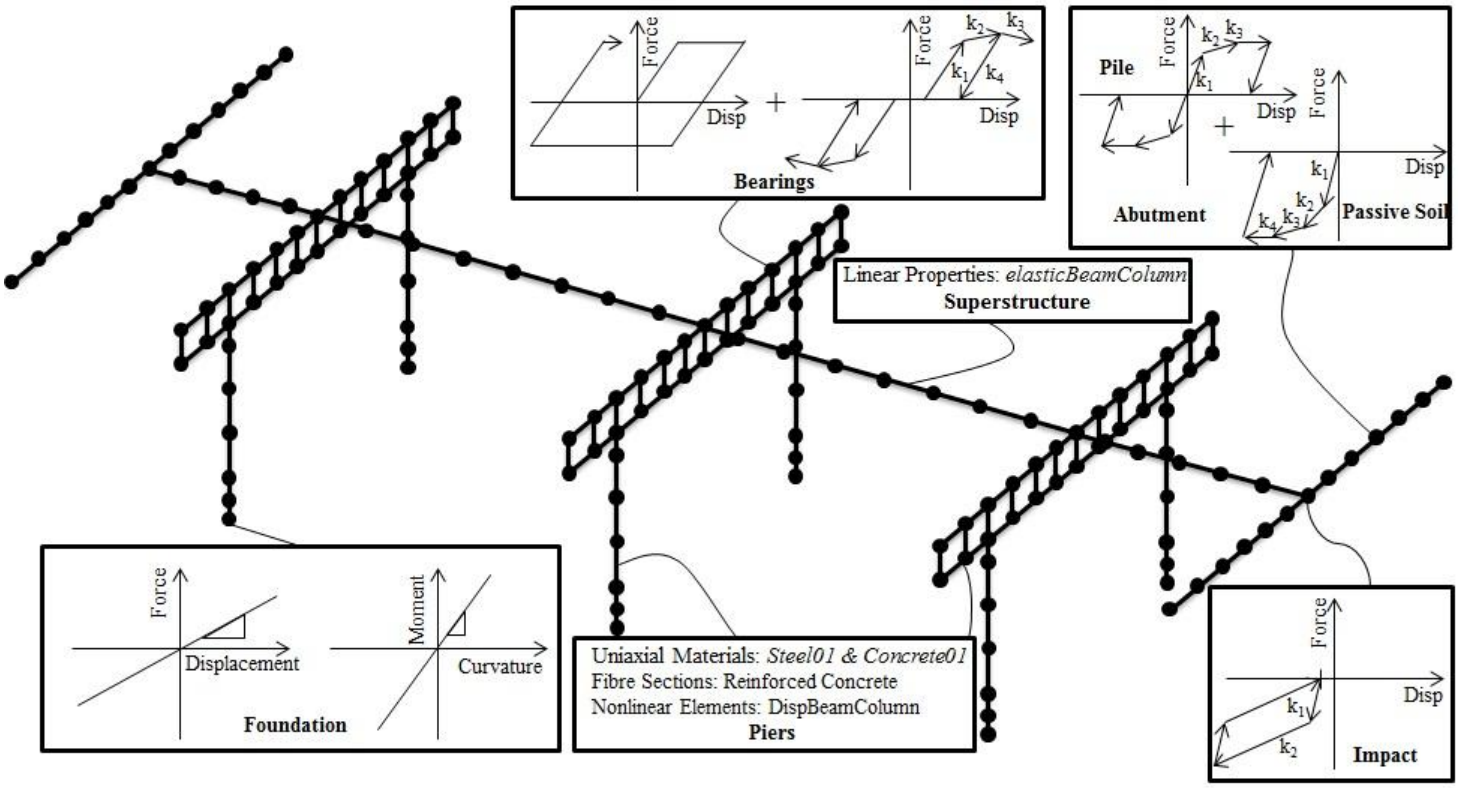

Figure 2 Three-dimensional analytical model of a MSSS concrete box girder highway bridge

There are three types of seismic resistancesin the abutments (Nielson 2005). In the longitudinal passive direction, this resistance is partially provided by the piles and partially by the soil and is modelled by hysteretic pile and soil materials in parallel.While in the transverse and longitudinal active directions the soil contribution is neglected. Poundings of deck spans under seismic loads, either together or to abutments, may lead to debonding of the bridge superstructure from its substructure. Therefore, an impact element is used in the form of an initial gap, which represents the expansion joints between the deck spans, followed by a bilinear spring working in compression (Muthukumarand DesRoches2006).

Seismic Hazard Source Model and Ground Motion Records

For seismic performance assessment of civil structures and infrastructure in a specific area, it is particularly important to have a representative suit of ground motion time-histories recorded from earthquake sources at the

area. Since strong ground motions records for Australia do not exist, GMP models can be used instead. The GMP model which is used in this study was developed by Somerville *et al*. (2009) and was considered by Geoscience Australian for generation of future probabilistic ground motion maps for. Figure 3 shows calculated response spectrum of an artificial earthquake with magnitude 6 M_W on Richter scale and hypocentral distance of 7.8 km using this GMP model. Seismic response spectra calculated from GMP models often represent geometric mean of two horizontal orthogonal components. However, considering three-dimensional modelling of the bridge, the issue of three-dimensional analysis needs to be addressed. Therefore, using the method outlined in Baker and Cornell (2005), two orthogonal components response spectra were simulated for the calculated geometric mean response spectrum.

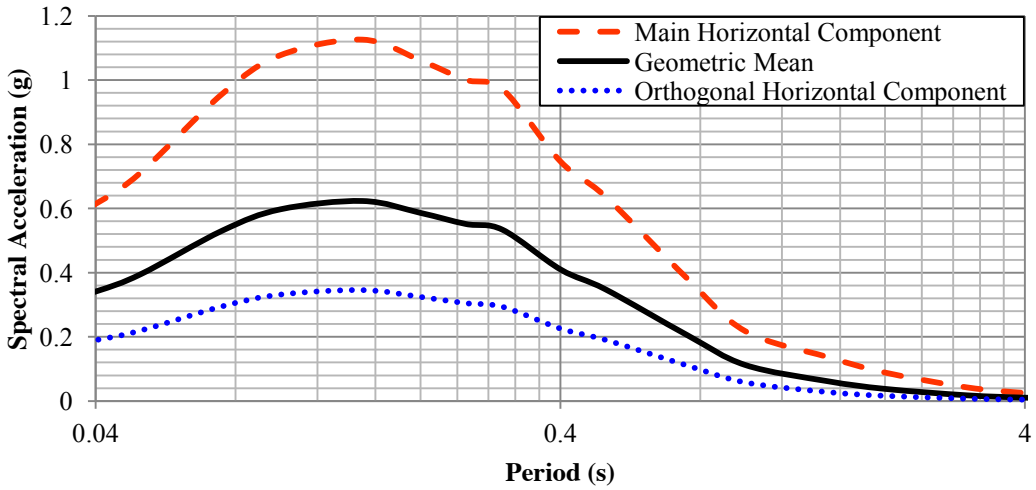

Figure 3 Seismic Response Spectrum based on GMP Model for Non-Cratonic Australia (Somerville *et al*. 2009)

The seismic hazard level at the area of interest could be evaluated from the Atlas of Seismic Hazard Maps of Australia (Leonard *et al*.2013). Nevertheless, for the sake of this study, the Worldwide Seismic Design Tool (Seismic Design Maps & Tools 2011) was utilised which is an online GIS-based application for approximation of Maximum Considered Earthquake (MCE) at a geographical region. Using this tool, the mapped values of MCE for the city of Brisbanewere estimated as S_S= 0.32g and S_1= 0.15g,where S_S and S_1 are 5% damp spectral accelerations(Sa)at the first mode periods (T_1) of 0.2 and 1.0 seconds, respectively. These values were estimated for rock site classes, with the shear wave velocity (Vs) ranging from 750 to 1,500 (m/s), and they increase in soft soil. Since no earthquake by moment magnitude higher than 6 M_W has yet been recorded in Queensland (Geoscience Australia n.d.), this value was kept constant (equal to 6) for the generation of synthetic ground motions. Instead, for ground motion generation,Near-Field andFar-Field approacheswereadoptedto account for the issue of an unknown earthquake source. The synthetic accelerograms were then created using appropriate software (Seismosoft, 2002).

Nonlinear Transient Analysis

This research adopts nonlinear transient (time-history) analysis to simulate the earthquake loads acting on the analytical bridge model. As said before, the sources of nonlinearity were the nonlinear materials and bridge components behaviors. The ground motions were applied at the nodes representing the pile caps and abutments, in which the main horizontal component was acting along the longitudinal direction and the orthogonal component was applied along the transverse direction. The time-history analyses were performed by a time step of 0.05s which was half of the synthetic accelerograms' time step. Nevertheless, where required the analysis time step was decreased until numerical convergence was achieved. Moreover, the dynamic analyses were conducted using 5% Rayleigh damping. The damping coefficient was calculated deterministically such that the 5% damping occurs in the first two modes of vibration for the bridge analytical model, as calculated by the eigenvalueanalysis.

Incremental dynamic analysis (IDA), (Vamvatsikos and Cornell 2002), was performed to investigate the seismic performance and loading capacity of the highway bridge. For this purpose each single ground motion record should be scaled up and down to form different ground shaking levels. Therefore, the Near-Field synthetic accelerograms were scaled by factors of 0.2, 0.4, 0.6, 0.8, 1.0, 1.5 and 2.0. This resulted in seven component responses, at different levels of spectral acceleration, by each Near-Field ground motion. Consequently, an IDA

curve was constructed using each Near-Field ground motion which demonstrates the bridge's decaying under increasing ground shaking level. However, no scale factor was considered for the far-field records since they are in scale based upon the epicentral distance, and therefore only a single IDA curve was constructed by using the Far-Field ground motions. According to Vamvatsikos and Cornell (2002), the seismic capacity performance level is reached on the IDA curve where the local tangent reaches 20% of the elastic slope.

RESULTS AND DISCUSSIONS

Synthetic Accelerograms

The source of ground shaking was assumed to be an artificial shallow earthquake at the focal depth of 6 km by a moment magnitude 6 M_W on Richter scale. Two sets of synthetic ground motions were created: a set of synthetic accelerograms generated at sites located 5 km from the surface projection of the rupture surface (Joyner-Boore distance), referred to as the "Near-Field" record set; and a set of synthetic accelerograms generated at sites with equal to or greater than 10 km Joyner-Boore distance. Figure 4(a) shows the response spectra of the Near-field set in a semi-logarithmic space. Note that the bold continuous line represents the response spectrum calculated based upon an intra-plate regime by using the GMP model proposed by Somerville *et al*. (2009) and the non-continuous lines represent the response spectra of the accelerograms generated in this study.

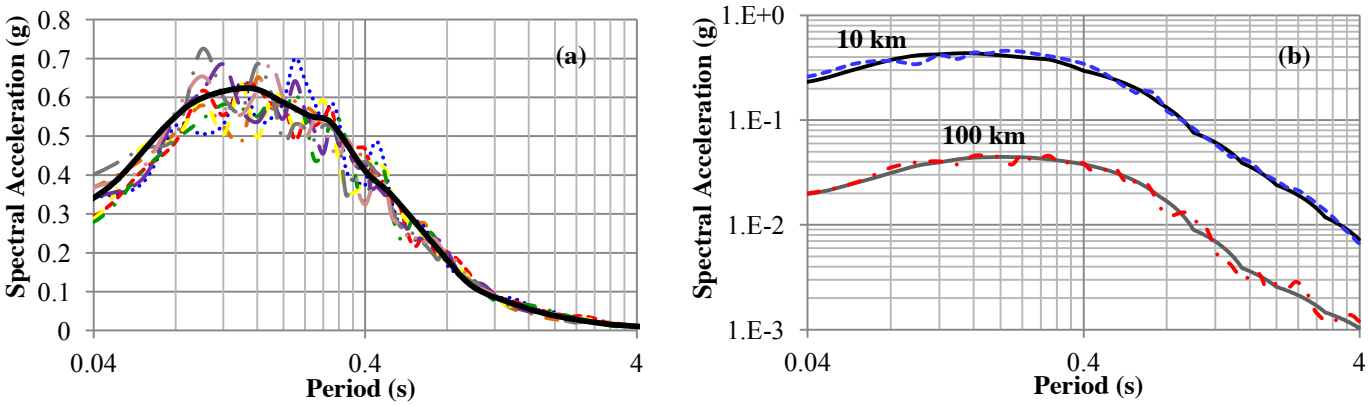

Figure 4Seismic response spectra; a) Near-Field ground motions; b) Far-Field ground motions

There were 8 synthetic accelerograms in the Near-field set. These accelerograms were generated for generic rock with Vs = 760 (m/s). Figure 5 shows the time-history of the main horizontal component of the generated Near-Field accelerograms. The Near-Field set encompasses ground motions with both strong pulses, referred to as the "NF-Pulse", as well as ground motions without such pulses, referred to as the "NF-No Pulse". The peak ground acceleration (PGA) in this set was 0.57g and duration of all of these records was constant by 4.36 seconds. Further information about the synthetic accelerograms is illustrated in Table 1.

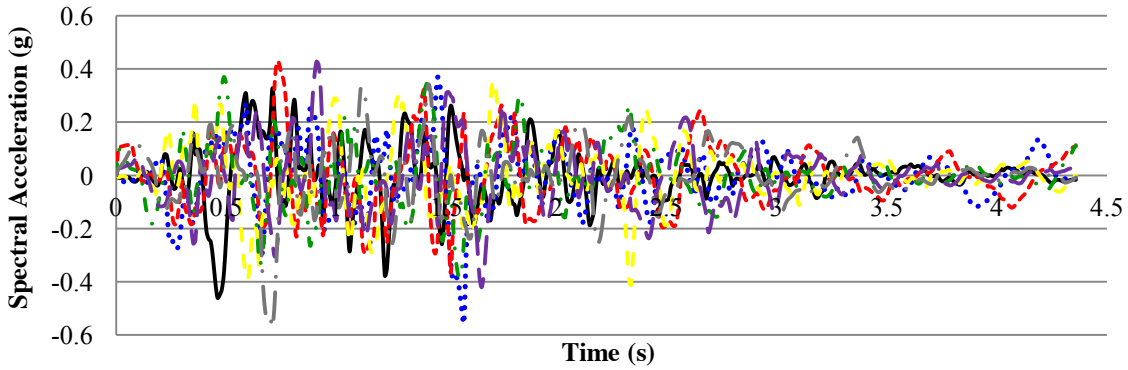

Figure 5Synthetic Near-Field accelerograms.

As of the Far-Field ground motions, 10 synthetic accelerograms were generated at the Joyner-Boore distances of 10, 20, 30, 40, 50, 60, 70, 80, 90 and 100 km. The seismic response spectra of these ground motions at the distances of 10 and 100 km are shown in Figure 4 (b). Again the continuous line outlines the response spectra calculated by the GMP model and the dash-lines represent those of created artificial earthquakes. This time both

axes are in logarithmic scale to illustrate the differences of spectral acceleration values between the response spectra clearly. Further information about the Far-Field synthetic accelerograms, as well as the Near-Field accelerograms, was summarised in Table 1. As can be seen, while the Joyner-Boore distance is increased for the Far-Field accelerograms, the PGA is decreased and the time- history duration is also increased.

Table 1Summary of synthetic accelerograms information

Seismic Responses

Seismic responses of the overall bridge system were recorded for its different components. These included the nodal and element responses as well as the responses of analytical models of the components described before.Figure 6 to 8 illustrate theses seismic responses which were recorded during dynamic transient analysis by using the ground motion #1 of the Near-Field set. As can be found by the decks' displacement responses, presented in Figure 6, the longitudinal responses are predominant and the effects of transverse responses are negligible. This significant difference would not be difficult to understand as it is revealed that the first mode structural period was T_1=0.28s by a predominant longitudinal mode shape while the dominant transverse mode was mode five by period of T_5=0.13s.

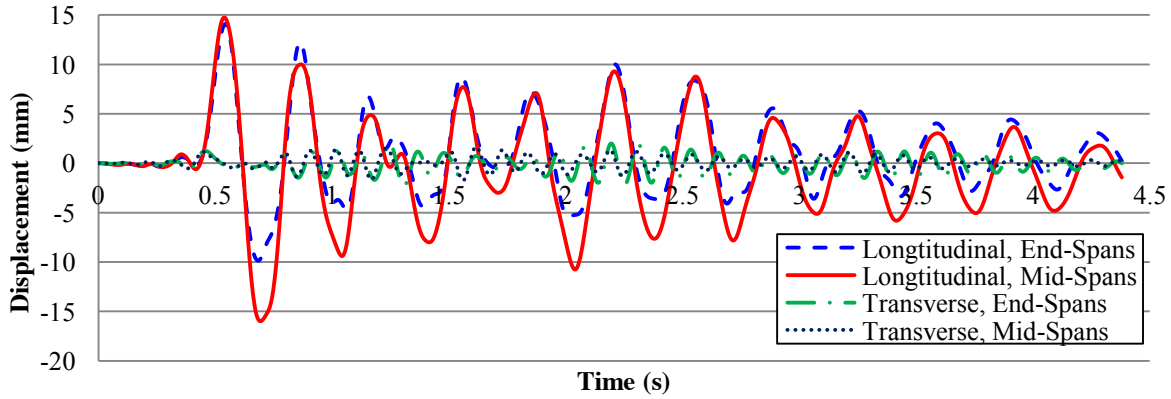

Figure 6 Decks time-history seismic responses

Figure 7 (a) shows the lateral drift responses of the bridge columns at substructural supports. The column drift deformation was recorded at the tip of columns,in both directions, for investigation of the columns displacement demands. Nevertheless, another way of investigating the seismic responses in columns is through a curvature ductility ratio defined by $\mu_c=C_{max}/C_{yield}$, where C_{max} and C_{yield} are the maximum curvature demanded by seismic loads and the curvature in the column which causes first yield of the outer most reinforcing bar, respectively

(Nielson 2005). Therefore, in addition to the columns drift, the columns' seismic responses were recorded in terms of Moment-Curvatureat the columns' base, as shown in Figure 7 (b).The seismic responses of the analytical models of the bridge components are shown in Figure 8. As it is understood, the portion of pile resistance in transverse direction is minor while it is quite significant in the longitudinal active direction.Comparing the seismic responses of the four elements presented in this figure with the decks' deformation responses in Figure 6, it is evident that most of thedisplacement in longitudinal directionisdemanded by deformation in the abutment piles.This happened while the passive soil resistance still showed linear responses.The response of the impact element, presented in Figure 8 (b), indicates that the initial gap in impact elements (expansion gap between adjacent decks) was not closed under seismic loads. A similar trend is observed both in the fixed and expansion bearings' responses, as illustrated by Figures 8 (a) and (b) as not many hysteric loops were recorded by these elements. This would be due to the large stiffness of elastomeric pads which have been assigned to the bearing elements.

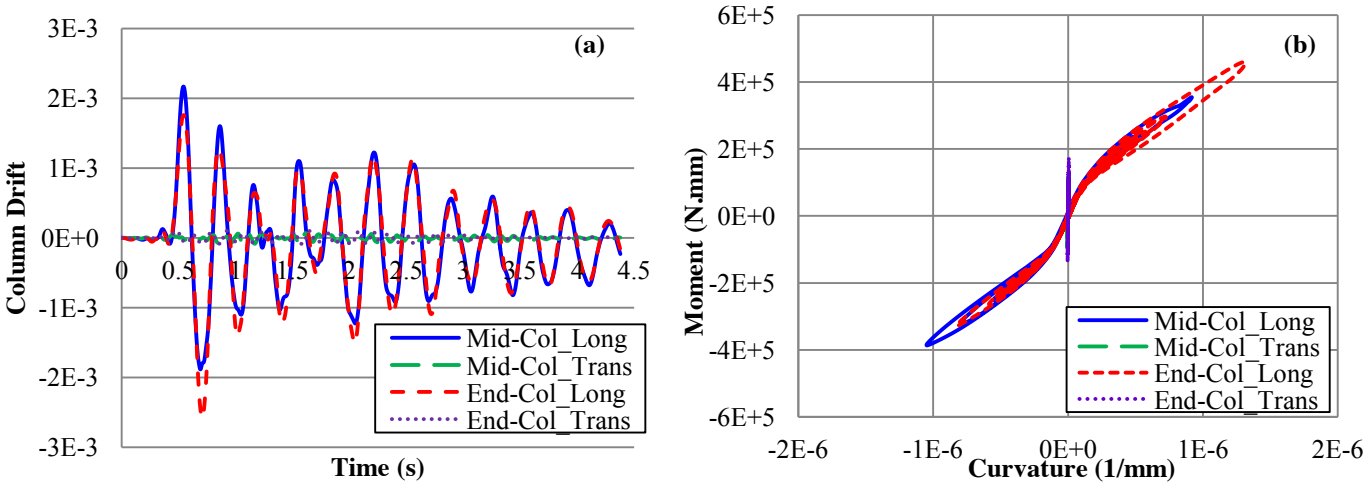

Figure 7 Columns seismic responses: a) drift deformation and b) moment-curvature hysteretic loops

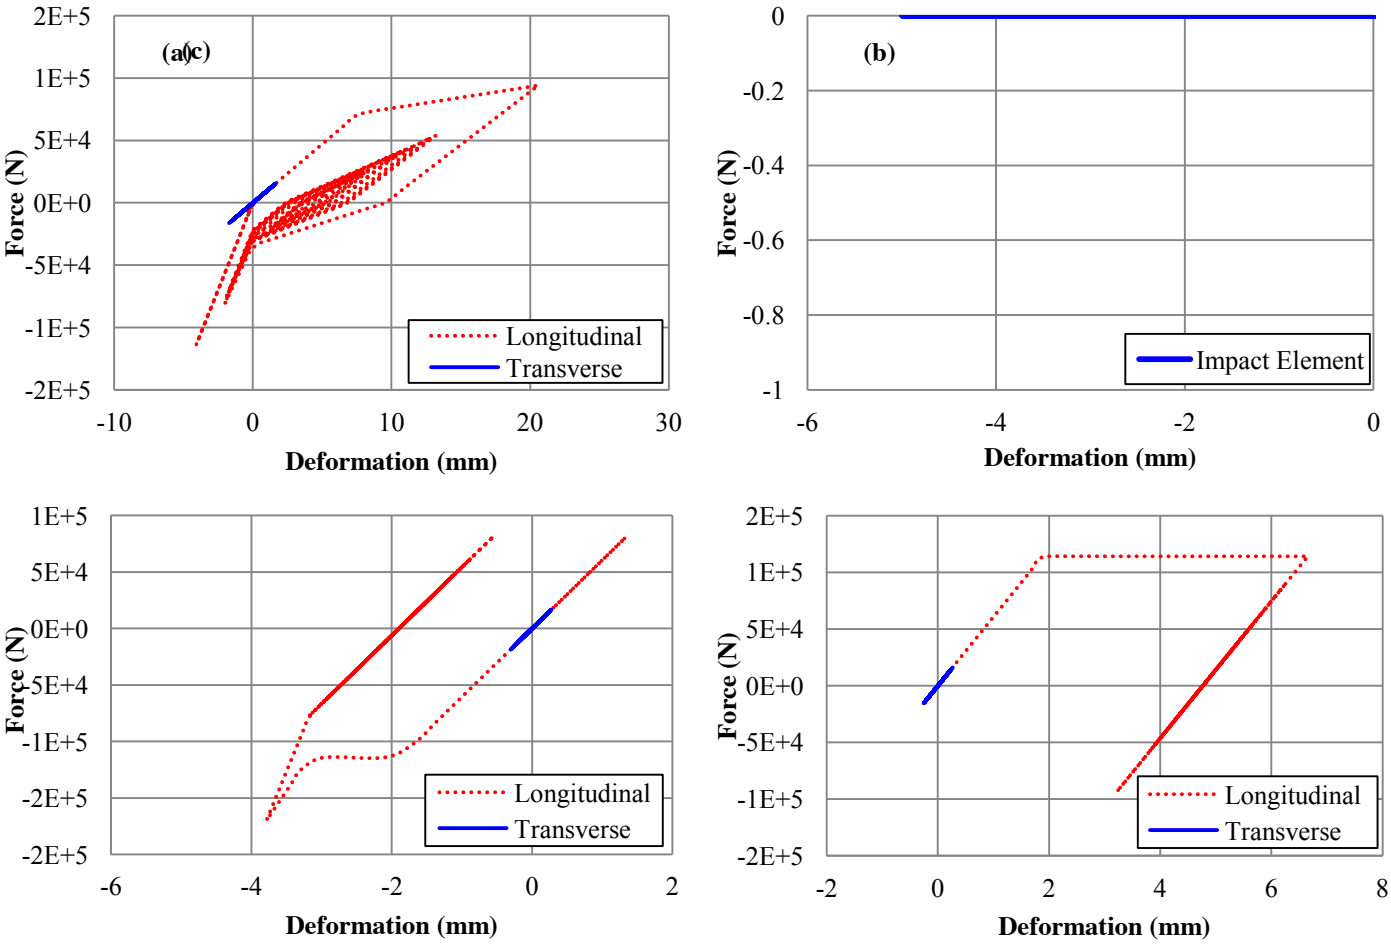

Figure 8 Nonlinear seismic responses of the analytical model: a) abutment, b) impact, c) fixed bearing and d) expansion bearing elements.

Probabilistic Seismic Demand Analysis

Among the recorded seismic responses, the columns'curvature ductility (μc), longitudinal deformations in the fixed and expansion bearings, and active and passive deformations in the abutments were nominated as the seismic demand parameters for performance assessment of the bridge system, since they have been reported to be determinant in evaluating the seismic capacity of highway bridges (Nielson andDesRoches 2007). Figures 9 (a) to9 (e) show the developed IDA curves for these bridge components.

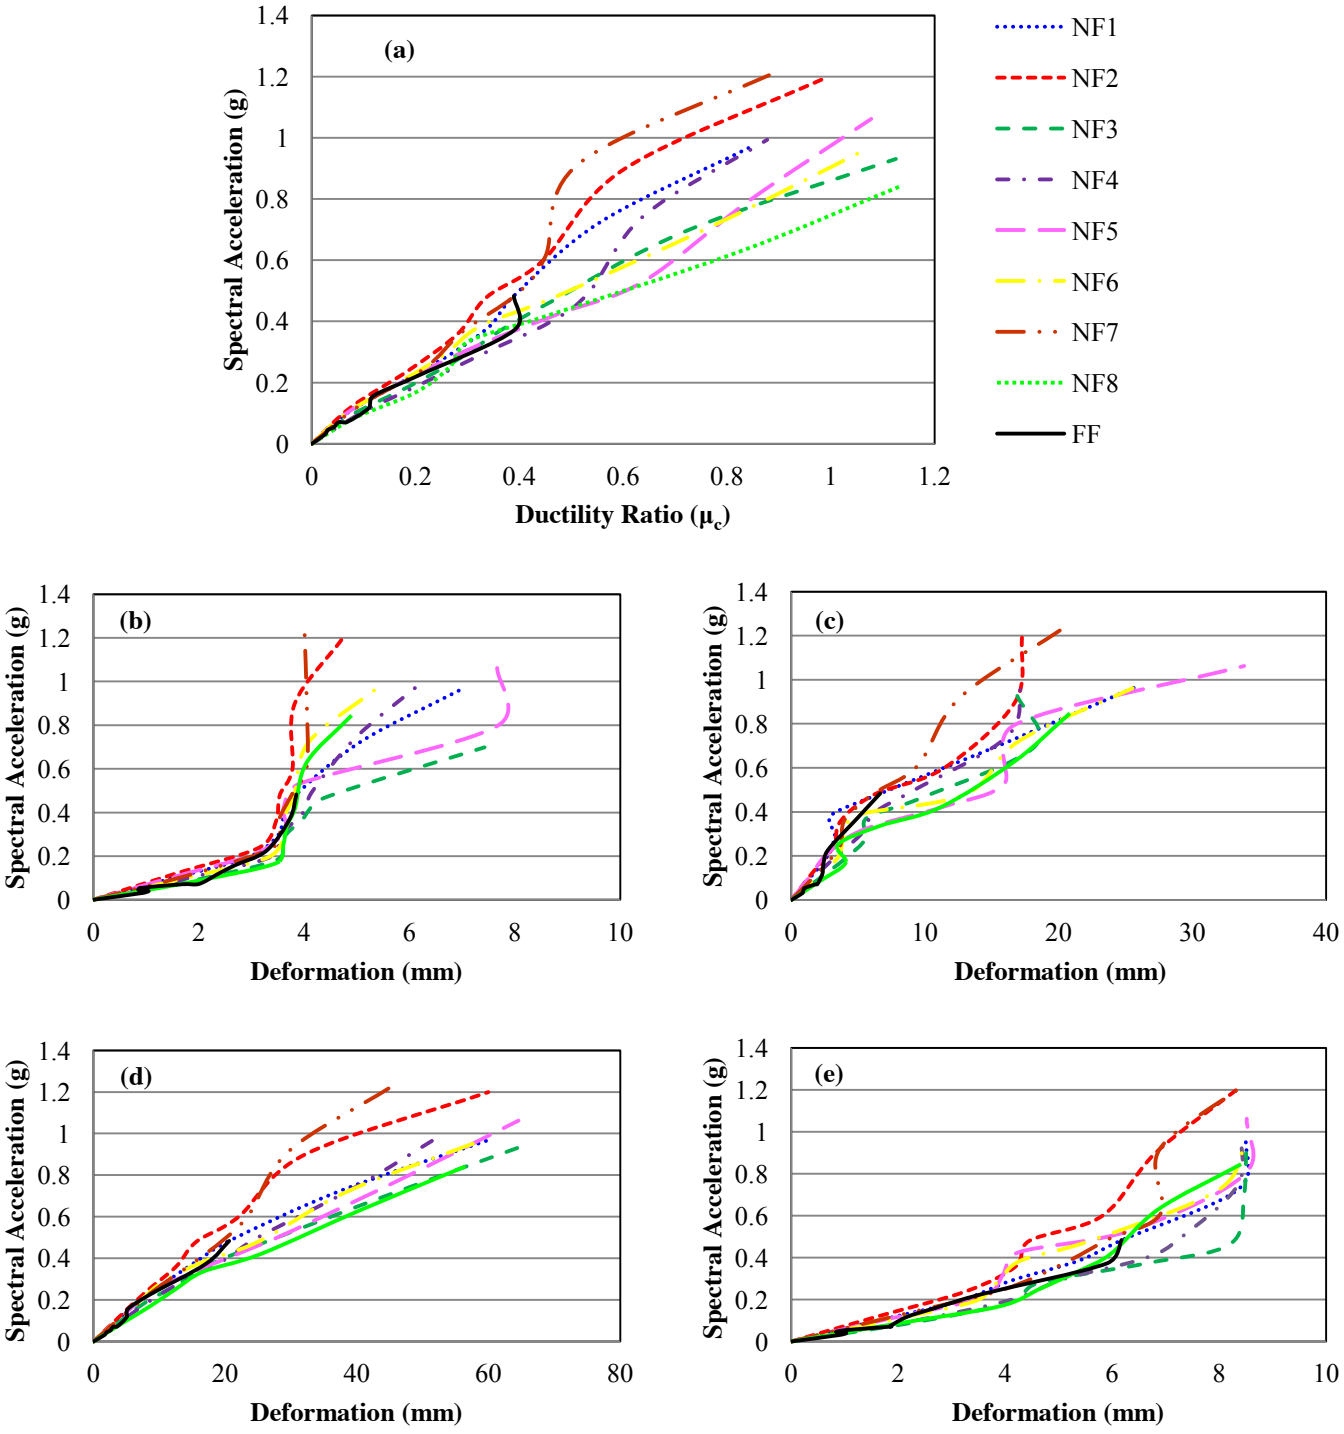

Figure 9 Developed IDA forsignificant bridge components; a) column, b) fixed bearing, c) expansion bearing, d) abutment in active direction and e) abutment in passive active direction

Except the fixed bearing, which demonstrates a severe hardening, the other components show a softening or a slight hardening behaviour. This happened while the deformations demanded in the fixed bearing were much smaller than the deformations demanded in the expansion bearings. The reason for this behaviour could be the large initial gap, due to expansion washers, assigned to the expansion bearings which permitted larger deformations while the absence of such a gap in the fixed bearings resulted in the yielding of steel dowels. As understood from Figure 9 (d), the abutment piles had the main contribution in the bridge's deflections under seismic forces. This was mainly due to the quantities which were assigned to the element properties of different bridge components. As mention previously, the bridge analytical model developed for this study represented a generalised highway bridge. Therefore, this contribution may be different in other cases or other concrete

bridges. In addition, for further investigation of the bridge seismic performance, a stripe analysis (Jalayer2003) was performed over the IDA column ductility responses, as shown in Figure 10.Then, the well-accepted power model distribution suggested by Cornel *et al*. (2002) was used to establish a relation between the spectral accelerations (analyses inputs) and the columns' ductility (seismic demands). This was performed using the median seismic demand values of the Near-Field results and original Far-Field seismic responses.

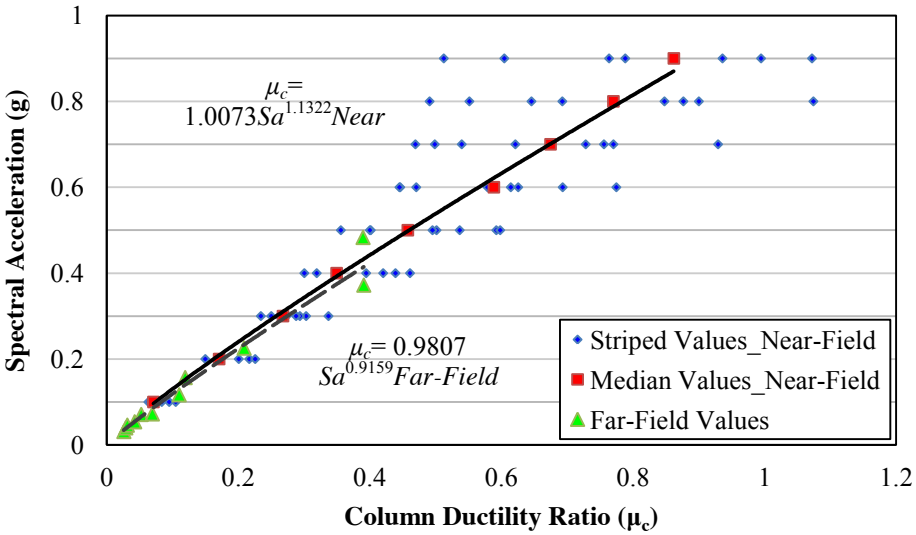

Figure 10 Stripe analysis of the IDA analysis results by using the column ductility responses

The obtained equations, shown in Figure 10, can be used to predict the columnductility seismic responses of a highway bridge demanded by arbitrary shaking intensities. Note that these power models are valid for Near-Field and Far-Field earthquakes with maximum PGA of 0.9g and 0.48g, respectively. Using these equations, it is possible to evaluate the seismic performance of bridge components under different design earthquake levels. For example, taking the evaluated MCE for short-period structures in the city of Brisbane (S_S=0.32g) into consideration, the demanded column ductility by the Near-Field and Far-Field seismic events are estimated as 27.72% and 34.54%, respectively. In addition, these power model distributions can be used to predict highway bridge column performancein various seismic hazard levels, as suggested by the probabilistic earthquake maps. Nevertheless, the most significant use of such distributions is in finding closed-form solutionsfor seismic fragility analysis of bridge components or an overall bridge system.This would provide an appropriate insightfor seismic vulnerability and risk assessment of Australian bridges through developing bridge fragility curves. Development of such curves for selected bridges would profit the bridge asset managers and stakeholders and the regulatory authorities in the adoption of state or national plans for mitigating future seismic hazards. This last pointis the ultimateobjective of performance-based earthquake and structural engineering.

CONCLUSION

A studyhas been presented herein for the seismic performance assessment of a MSSS concrete box-girder highway bridge by creating an analytical model in OpenSees software. A suit of synthetic ground motions was created, based on a GMP model, to properly simulate the circumstances of Australian earthquakes. It is noteworthy to mention that these strong ground motions will bevery beneficial for further seismic studies relevant to Australia.IDA analyses were also performed over the analytical model to investigate the bridge seismic responses. The probabilistic seismic performance of the bridge columns was obtained through a stripe analysis over the IDA responses and by fitting the well-accepted power model to the median values. This model can be used further to develop the seismic fragility curve of bridge columns.

ABSTRACT

This paper investigates the possibility and effectiveness of using a recently developed relative displacement sensor for the damage detection of gusset plate conditions in steel truss bridges. The developed sensor is an innovative design offering some advantages and unique features, and is a much easier and cheaper method of structural health monitoring due to the simplicity of its direct measurement of relative displacement without the need for a stable reference point. To investigate the potential applications of the developed sensor to the damage detection of joint conditions, a steel truss bridge model is fabricated in the laboratory and installed with the developed sensors to detect the loosen bolt damage in the gusset plates by using measured relative displacements. Those measured relative displacement measurements from the free vibration tests of both the undamaged and damaged truss models are analyzed, and a damage index based on the wavelet packet energy percentage change is used to detect the existence of the loosen bolt damage in steel truss bridges. Experimental studies demonstrate that the developed relative displacement sensor has a sensitive performance to indicate the joint conditions in steel truss bridges.

Damage detection, steel truss bridge, gusset plate, loosen bolt damage, wavelet packet energy percentage, relative displacement sensor.

INTRODUCTION

Steel truss bridge is a main engineering structure type, which plays an important role in the transportation network. It is considered as an economical and reliable long span bridge solution. In such bridges, the joint connection conditions are essentially significant to guarantee the rigidity and load-carrying capacity of bridges. The overstress or distortion in the joint connection would result in the condition degradation and damage accumulation, which might eventually cause a catastrophic failure of the bridge if not carefully inspected or detected. The collapse of the I-35W Bridge in Minnesota is a recent disaster that exposes the weaknesses in current visual inspection practices and structural health monitoring of steel structures (Gastineau *et al*. 2009). I-35W was a highway bridge over the Mississippi river that collapsed on August 1, 2007. The national transportation safety board identified the gusset plate U10W was the likely point of the initial failure (Liao and Okazaki 2009). The collapse of this bridge draws attention to steel structures failing under the strain of ageing and the increasing loading demands placed upon them. Holt and Hartman (2008) suggested that the strength of the gusset plate was insufficient to develop the shear forces expected at this panel point. Investigations into the failure showed that the gusset plates were giving warning signs in the form of out-of-plane displacements in the months leading up to the disaster. Ocel and Wright (2008) investigated and found out that those out-of-plane displacements in the gusset were a contributing factor to the collapse and caused the direction of movement that matched the physical evidence. The fact that these warning signs went undetected indicates that a more sophisticated structural condition monitoring strategy is required.

In this paper, a newly developed relative displacement sensor, which is used to directly measure the relative displacement between two points, is briefly reviewed. To investigate the potential applications of this sensor to structural joint condition monitoring, an experimental steel truss bridge model is fabricated and installed with the developed sensors to measure relative displacements at joint connections. Experimental studies with free vibration testing measurements are conducted to demonstrate if the relative displacement sensor is capable of identifying the minor changes in the bolt connection of joints in truss bridges. Wavelet packet decomposition is performed with the measured responses. A damage index based on the change in the energy percentage of some specifically selected wavelet packet component energy to the total wavelet packet energy is calculated to identify the damage in the gusset plate of steel truss bridges.

METHODOLOGY

Relative Displacement Sensor

A relative displacement sensor, which is able to measure relative displacements between two points based on the principles of the Wheatstone bridge circuit, has been developed and its accuracy has been validated. This sensor is developed to be an efficient and cost-effective approach to measure relative displacement whilst offering its own unique advantages. It is very sensitive to the relative movement between two points on the structure, and is also easy to be directly mounted on the structure without the need for a stable reference point. The investigations on the sensor's accuracy and ability in monitoring the relative displacements due to the shear connection damage of composite bridges have been conducted (Li *et al*. 2015). Comparing with traditional measurements from laser displacement sensors and accelerometers, experimental studies demonstrated the advantages of using this new sensor, which offers an innovative tool to be utilized in a structural health monitoring system, to detect the shear connection conditions for composite bridges under moving load excitations (Li and Hao (2015)). Taking the advantages of the decent performance of the developed relative displacement sensor in detecting the shear displacement, this paper will study if this sensor could be successfully applied for monitoring other structural systems, in particular the joint conditions in steel truss bridges.

The sensitive component of the sensor is a square metallic block around 20mm with two ends installed on the testing structure. The square metal block in the center is as thin as 1mm to prevent the installed sensor affecting the structural local stiffness. Four strain gauges are placed on the square metal component as four diagonal members to construct a Wheatstone bridge circuit. The four arms of the Wheatstone bridge circuit are formed by the resistors R_1 to R_4. The output voltage of the full bridge is calculated based on the principle of Wheatstone bridge circuit (Wheatstone 1843) as follows

$$\frac{v}{U} = \frac{1}{4}\left(\frac{\Delta R_1}{R_1} - \frac{\Delta R_2}{R_2} + \frac{\Delta R_3}{R_3} - \frac{\Delta R_4}{R_4}\right) \tag{1}$$

where v and U are output and input voltages, respectively. ΔR_1, ΔR_2, ΔR_3 and ΔR_4 are the resistance variations of the four resistors R_1 to R_4, respectively.

The relationship between the input and output voltages is

$$v = \frac{1}{4} \cdot k \cdot U \cdot (\varepsilon_1 - \varepsilon_2 + \varepsilon_3 - \varepsilon_4) \tag{2}$$

where $\varepsilon_1, \varepsilon_2, \varepsilon_3$ and ε_4 are strains of the four resistors R_1, R_2, R_3 and R_4, respectively. k is the gauge factor, which is about 2 for metal strain gauges. Equation (2) indicates that the base values those four resistors are not important as long as the gauge factors are equal.

A relative displacement d along the horizontal direction of the sensor, will deform the four strain gauges differentially due to the diagonal orientation, so that the relative displacement appears as shear distortion of the sensor. With four strain gauges deformed in diagonal orientations, we have the following relationship

$$\varepsilon = \varepsilon_1 = -\varepsilon_2 = \varepsilon_3 = -\varepsilon_4 \tag{3}$$

Substituting Equation (3) into Equation (2), the output voltage due to the shear distortion is

$$v = \frac{1}{4} \cdot k \cdot U \cdot (\varepsilon_1 - \varepsilon_2 + \varepsilon_3 - \varepsilon_4) = k \cdot U \cdot \varepsilon \tag{4}$$

From Equation (4), the output voltage is linearly proportional to the strain ε and hence d for a given input voltage with a constant strain gauge factor. The supplying input voltage for the developed sensor is 2.5V. A calibration test is necessary to find out the constant K in the following equation between measured strain and relative displacement

$$d = K \cdot \varepsilon \tag{5}$$

The sensor may actually suffer not only shear distortion, but also tension, compression, bending and torsion effects in real applications. In order to highlight the signal-to-noise ratio of the relative displacement measurements, it is desirable to minimize the sensor output due to tension, compression, bending and torsion effects. This is achieved by taking advantages of the symmetry of the used Wheatstone bridge circuit. More details about the sensor's design idea and features can be referred (Li et al. 2015).

Damage Index Based on Wavelet Packet Energy Percentage Change

Damage detection is conducted based on the change in the wavelet packet energy percentage, which is the change in the energy of the selected wavelet packet components with respect to the total energy of all the wavelet packet components. The damage index has been defined as follows (Li *et al*. 2014)

$$DI = \frac{|P_d - P_{ud}|}{P_{ud}} \tag{6}$$

where DI is the damage index, P_d and P_{ud} are the percentages of selected wavelet packet components energy to the total energy of all the wavelet components under the damaged and undamaged states, respectively. It should be noted that this is a non-model based damage detection since the finite element model of the structure is not required and only the vibration measurements are processed for the wavelet packet decomposition and damage index calculation. However, it should be noticed that this damage index requires the measurement information from the baseline structure for the comparison of structural vibration properties and the identification of structural condition change.

EXPERIMENTAL INVESTIGATIONS

Experimental studies on a steel truss bridge model in the laboratory are conducted to investigate the possibility and effectiveness of using the developed relative displacement sensor for the damage detection of gusset plate conditions in truss bridges. A steel truss model is constructed with four 50mm×50mm×5mm equal angles for the beams and 50mm×5mm flat bars for the chord members as shown in Figure 1. M6 bolts are used to connect all the chord members and gusset plates to the equal angles. More than 300 bolts are used in the whole bridge model. The truss model has a length of 2m, width 0.35m and height 0.5m. The truss bridge model is placed on two steel frames which are fixed to the ground. A static loading is applied on the bridge model by using a hydraulic loading frame.

Three relative displacement sensors are installed on a joint connection in the central bottom of the truss to monitor the relative displacements that could occur under different loadings and damage scenarios. One end of the sensor is fixed on the gusset plate and the other end on the chord member so that the relative displacement between the gusset plate and the chord member surfaces will be detected and measured. A National Instruments dynamic data acquisition system was used for data recording. The setup of those relative displacement sensors provides an easy installation than vision-based approaches, which need to setup a number of cameras or other optical devices. The laser displacement sensors or cameras also require a fixed reference point for the setup, and may not be able to target the interface between the gusset plate and chord members to measure the relative displacement. This is a highlighted superiority of the developed relative displacement sensor, which enables the direct installation on the bridge for uniquely measuring the relative displacement for structural health monitoring purposes.

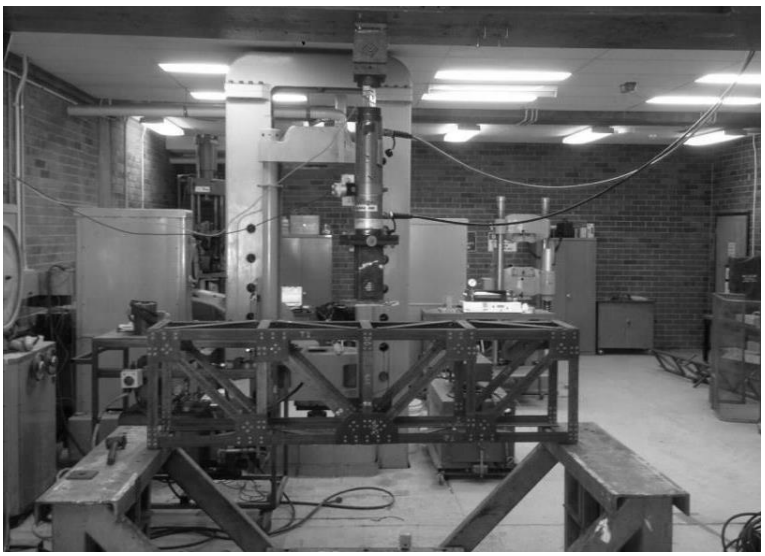

Figure 1 Steel truss bridge model in the laboratory

Figure 2 shows the sensor locations on the truss bridge model. Sensors 1 and 3 are orientated diagonally so as to detect both the vertical and horizontal relative displacements while sensor 2 will only detect the horizontal relative displacement. Damage can be introduced by loosening the specific bolts in different joint connections. The sensor will output a time-history strain, which can be converted to a time domain relative displacement record using a calibrated sensitivity. The aim is to investigate the feasibility of using the relative displacement in detecting structural local bolt damage in the joints of truss bridges. If all bolts are engaged in the nuts and tightened, the structure condition corresponds to the undamaged state. It may be noted that the bolt is fully unscrewed to simulate the local damage in the joint condition. It is interesting to note the detection with partial damage in a single bolt is not covered in this study because of no available equipment in the laboratory to introduce partial damage to an individual bolt. However, in this study, only a single bolt is removed in a single joint connection to introduce the partial damage in the joint connection of truss bridges.

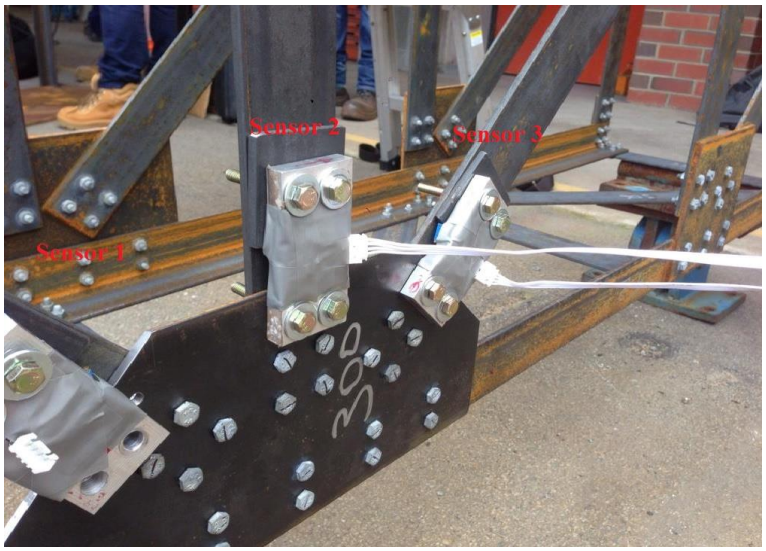

Figure 2 Sensor setup on the target gusset plate

The face of the truss bridge model installed with the sensors is defined as the front face. Figure 3 shows the numbering of joints in the front face of the truss bridge model and the exact bolt removed separately at different joints to simulate the different damage scenarios. For example, for the damage scenario on Joint 1, only the marked bolt on Joint 1 as shown in Figure 3 is removed. Other joints are still in the intact conditions. Damage detection is conducted with the vibrational relative displacement measurements from structural free vibration tests under the intact and damaged states. The rapid release of the static load results in the free vibration of the truss structure. Relative displacements are measured separately from the free vibration tests under both the intact and damaged structural states. Four damage scenarios are considered in this study, i.e. a single damaged bolt in Joint 1, Joint 2, Joint 5 and Joint 6, respectively. The damage index as shown in Equation (6) is computed based on wavelet packet decomposition analysis of measured relative displacement responses. Two measurements from the undamaged model are analysed to obtain the baseline information of the proposed damage index.

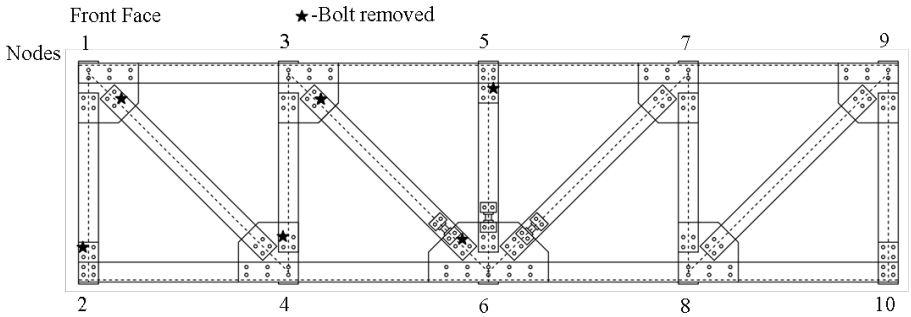

Figure 3 The numbering of joints in the front face of the model and the removed bolt at different joints

The fundamental natural frequency of the intact structure is identified as 8.44Hz by performing a FFT analysis for the measured relative displacement at Sensor 1 under free vibration, as shown in Figure 4. Table 1 shows the identified fundamental frequencies from the undamaged and damaged states with a damaged bolt in Joints 2 and 6. The modal analysis from the measured responses from the damaged structure shows that the identified first

frequency is 8.22Hz as shown in Figure 5 with a local bolt removed at Joint 6. Another damage scenario is that the damage occurs at the support node, i.e. Node 2. The identified frequency is 8.24Hz as shown in Figure 6. The frequency reductions are less than 3%, which is very small. This will make the damage detection with frequency change information difficult and subject to environmental and noise effect. A band pass Infinite Impulse Response (IIR) filter with Chebyshev Type II filter and passband frequency from 1 to 20 Hz is defined to pre-process the measured relative displacements and remove the high frequency noise effect. Those filtered responses are then used for the wavelet packet decomposition and computation of damage index. It is noticed that a level 7 wavelet packet decomposition is performed and the second packet with the frequency range from 7.8Hz - 15.6Hz which covers the fundamental mode is used to calculate the damage index in Equation (6).

Table 1 Identified fundamental frequencies from undamaged and damaged states

Undamaged	Damaged State (Joint 2)		Damaged State (Joint 6)	
Frequency	Frequency	Change	Frequency	Change
8.44 Hz	8.24 Hz	2.4%	8.22 Hz	2.6%

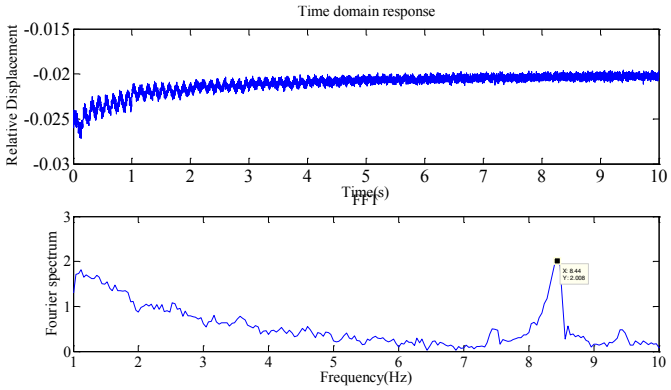

Figure 4 Measured relative displacement from Sensor 1 under free vibration of undamaged structure

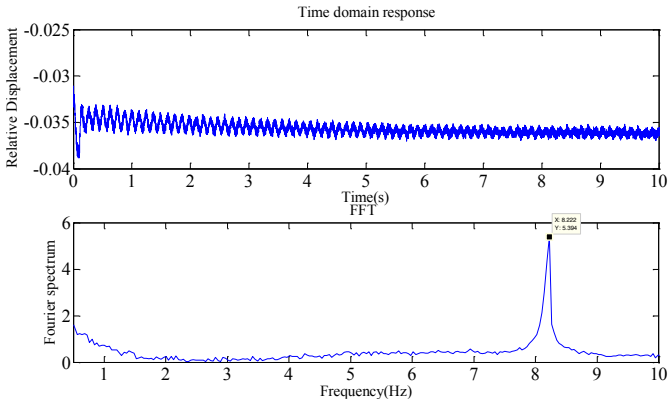

Figure 5 Measured relative displacement from Sensor 1 under free vibration of damaged Joint 6

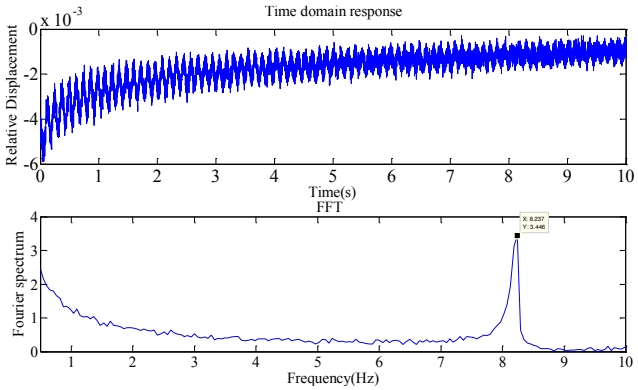

Figure 6 Measured relative displacement from Sensor 1 under free vibration of damaged Joint 6

Only the measured responses from Sensor 1 and Sensor 2 are used in this study as Sensor 3 is targeting the right side of the truss bridge model from Joint 7 to Joint 10. Figure 7 shows the damage detection results with the energy percentage of the above selected wavelet packet to the total wavelet packet energy. It can be observed that the calculated damage index values from Sensors 1 and 2 at different damage scenarios are higher than the baseline values, which demonstrates that the used damage index based on wavelet packet energy percentage is effective to detect the loosen bolt damage in the joint connections of the steel truss bridge. However, Sensor 1 generally has a better performance than Sensor 2 since significantly higher damage index values are observed from Sensor 1. The explanation is that Sensor 1 can detect the relative displacements not only in the horizontal but also the vertical directions because it is installed on the diagonal chord member while Sensor 2 only measures the horizontal relative displacements. It is also seen from Figure 7 that the calculated damage index values from both sensors are higher for the damage scenarios with the loosen bolt introduced in Joints 5 and 6, which are close to the installed sensors. This is expected because the relative displacement sensors are better to detect the local damage in the nearby area. It is also worth noting that Sensor 1 is capable of identifying the damage in the support location, i.e. Joint 2. The damage detection results from free vibration tests demonstrate that the used damage index is very sensitive and effective in various damage scenarios, and the sensor installed on the diagonal chord member connected to the gusset plate has a better performance to detect the local damage effect.

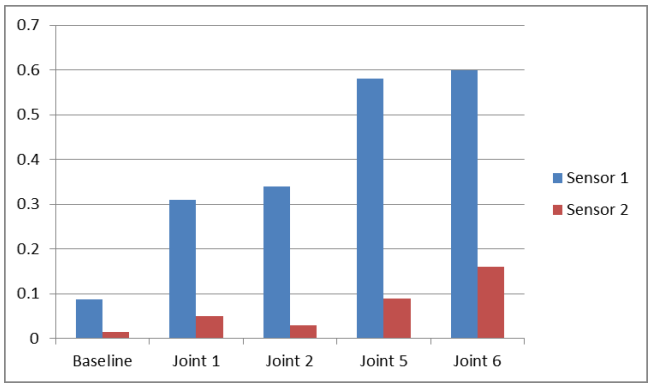

Figure 7 - Damage detection results with wavelet packet energy percentage

CONCLUSIONS

This paper investigates the effectiveness of using a recently developed relative displacement sensor for the damage detection of gusset plate condition in steel truss bridges. The damage detection is conducted by analysing the relative displacement measurements under free vibration tests from both the undamaged and damaged truss bridge models. The energy percentage of specific wavelet packet components to the total wavelet packet energy is used to calculate the damage index and identify the bolt loose damage in the joint connections of steel truss bridges. A steel truss bridge model is fabricated and installed with the developed sensors to detect relative displacements in the central bottom of the gusset plate. Experimental studies are conducted to validate the proposed approach. The relative displacement measurements from free vibration tests are conducted to investigate if the sensor measurements can be used to identify the existing damage in structures by comparing the calculated damage index from various damage scenarios to the baseline index. The results demonstrate the feasibility and effectiveness of using the relative displacement sensor as an effective tool in structural health monitoring to assess the gusset plate condition and structural integrity of truss bridges.

ABSTRACT

Real-time structural health monitoring is very important for truss structures especially those having large-spans. In recent years, many methods have been proposed for damage monitoring of truss structures. However, damage sensitivity of these methods is still required to be improved. In this work an efficient damage localization technique for truss structures is proposed, which is based on the LDL^T decomposition of the flexibility difference matrix and the Damage Locating Vectors (DLV) method. Compared with the present Stochastic DLV (SDLV) method, the proposed method is modified in two ways. First of all, the way of calculating the damage locating vectors is modified by using LDL^T decomposition instead of Singular Value Decomposition. Secondly, in order to compute the flexibility, the mass matrix which is obtained from the finite element model is used to mass-normalize mode shapes identified from ambient excitations. As a result, the proposed LDL^T-DLV method has a higher sensitivity to damage for different types of truss members. The effectiveness of the proposed LDL^T-DLV method is validated with the numerical example of a laboratory-scale Bailey truss bridge.

INTRODUCTION

Monitoring-based structural condition assessment has gained in popularity in the past years, because it can provide abundant information on the structural condition through different kinds of sensors (Ni et al 2012). Vibration-based damage detection is a challenging and important research topic. The fundamental elements of damage detection algorithms are damage localization, damage quantification, and the effects of local damage on the global performance (Dorvash et al 2014). The interest to monitor a structure for purpose of damage detection at an early stage is prevailing in the fields of civil, mechanical and aerospace engineering (Li et al 2013).
Lots of vibration-based damage detection methods (Ni et al 2001; Lei et al 2013; Min et al 2015; Blachowski et al 2015; Cao et al 2015; An et al 2015) have been developed in the past decades. Among these methods, the flexibility-based technique (Pandey and Biswas 1994; An and Ou 2013a) has attracted considerable attention. It is worth to mention that the DLV method (Bernal 2002) is one of the most important flexibility-based methods for damage localization of truss structures. Gao (2005) verified this method using experimental data from a laboratorial truss model. However, the DLV method requires the knowledge of input excitations, which limits its applications. To address this problem, Bernal (2006) proposed the Stochastic DLV (SDLV) method which allows applying the DLV method without the knowledge input excitations. Nagayama et al. (2009) conducted a study based on the SDLV method on a truss structure, in which a lower cord is replaced with an element having a 52.7% cross section loss to simulate the damage. An et al. (2014) conducted a study based on the SDLV method to further investigate the influence of different formulations of the observation matrix on the accuracy of damage detection results. These studies presented great progress, but challenges remain; for example, the damage sensitivity is still required to be improved.
To improve the damage sensitivity of the present DLV method, this paper proposes a damage localization method based on the DLV method and the LDL^T decomposition of the flexibility difference before and after damage. To validate the proposed damage localization method, numerical validation of a laboratory-scale simply-supported steel-truss bridge has been conducted. Some initial conclusions are summarized.

THE PROPOSED LDL^T-DLV METHOD

This section proposes the LDL^T-DLV method based on the LDL^T decomposition, DLV method (Bernal, 2002) and the SDLV method (Bernal, 2006). However, we introduce two modifications. First of all we modify the way of calculating damage locating vectors by using LDL^T decomposition instead of Singular Value Decomposition. Secondly, we use the mass matrix of the structure under consideration to mass-normalize mode shapes identified from ambient excitations.

Change in Flexibility

The flexibility matrix $\mathbf{F}$ of any structural system can be expressed by its modal parameters (natural frequencies and mode shapes)

$$\mathbf{F} = \mathbf{K}^{-1} = \sum_{i=1}^{n} \frac{1}{\omega_i^2} \boldsymbol{\varphi}_i \boldsymbol{\varphi}_i^T \tag{1}$$

where the input vector $\boldsymbol{\varphi}_i$ is the i-th mass-normalized mode shape; ω_i is the i-th modal frequency, and n is the number of degrees of freedom of the structure. In this paper, the mass-normalized mode shapes are obtained using the analytical mass matrix derived by the FE model updating.

After the mode shapes and modal frequencies are identified, the change-of-flexibility matrix, denoted by $\mathbf{F}_\Delta$, can be computed as

$$\mathbf{F}_\Delta = \mathbf{F}_\mathrm{H} - \mathbf{F}_\mathrm{D} \tag{2}$$

where $\mathbf{F}_\mathrm{H}$ and $\mathbf{F}_\mathrm{D}$ are the flexibility matrices of the undamaged and the damaged structure, respectively.

LDL^T Decomposition of $\mathbf{F}_\Delta$

We can determine LU matrix decomposition of $\mathbf{F}_\Delta$. However, since $\mathbf{F}_\Delta$ is symmetric indefinite matrix LU decomposition takes the form of LDL^T decomposition, which is special form of Cholesky decomposition. Moreover LDL^T has better than LU interpretation from damage detection point of view.

So substituting LDL^T for difference in flexibility, we get

$$\mathbf{F}_\Delta = \mathbf{L}\mathbf{D}\mathbf{L}^\mathrm{T} \tag{3}$$

where $\mathbf{L}$: lower unit triangular matrix, $\mathbf{D}$: diagonal matrix of the form.

In the typical task for damage detection some of values on the diagonal $d_{i,i}$ are equal or close to zero. This means that the original matrix $\mathbf{F}_\Delta$ is rank deficient and close to zero values in diagonal of $\mathbf{D}$ matrix indicate null space of $\mathbf{F}_\Delta$.

So, to find number of independent Damage Locating Vectors (or dimension of the null space of difference in flexibility) we select those columns of $\mathbf{L}^{-\mathrm{T}}$ which corresponds to close to zero values in $\mathbf{D}$ matrix. If we order these values at the end of $\mathbf{D}$ matrix we can write it formally as

$$\mathbf{F}_\Delta \mathbf{L}^{-\mathrm{T}} = \mathbf{L}\begin{bmatrix}\mathbf{D}_\mathbf{1} & \mathbf{0}\end{bmatrix} \tag{4}$$

In order to select the vectors which belong to the null space, the following approach is proposed:

1) Calculate the $\mathbf{L}$ and $\mathbf{D}$ matrices from $\mathbf{F}_\Delta$ using a LDL^T decomposition (for example with the ldl() function in MATLAB).
2) Then, calculate the inverse matrix of transpose of lower unit triangular matrix $\mathbf{L}^\mathrm{T}$.
3) Determine auxiliary matrix $\mathbf{V} = \mathbf{L}\mathbf{D}$.
4) Calculate norm of individual columns of $\mathbf{V}$ and then remove those columns of $\mathbf{L}^{-T}$, which correspond to the values of norm of $\mathbf{V}$ greater than some tolerance value τ these columns of $\mathbf{L}^{-T}$ are not belonging to null space of $\mathbf{F}_\Delta$, so they are not DLVs.
5) Denote the number of remaining columns of $\mathbf{L}^{-\mathrm{T}}$ as p,

$$p = \dim(\mathbf{L}^{-\mathrm{T}} : \frac{\|\mathbf{V}_i\|}{\|\mathbf{V}_i\|_{\max}} < \tau) \tag{5}$$

6) Finally, the present columns of $\mathbf{L}^{-\mathrm{T}}$ refer to damage locating vectors

Normalized Accumulated Stress

All the p damage locating vectors are applied as static forces to the FE model. The accumulated stress index is defined as the characterizing stress in the j-th element normalized by the largest stress over all measured elements,

$$\sigma_j = \sum_{i=1}^{p} \left| \frac{\sigma_{ij}}{\sigma_{ij,\max}} \right| \tag{6}$$

where σ_{ij} : the stress in the j-th element caused by the i-th DLV.

Finally, the normalized accumulated stress index NSI is introduced, and the elements whose accumulated stress index satisfies the following inequality are marked as damaged:

$$NSI = \frac{\sigma_j}{\sigma_{j,\max}} \le b \tag{7}$$

where p: the number of the Damage Locating Vectors, b: the threshold, whose recommended value is 0.10.

NUMERICAL VALIDATION

Research Object

The truss model considered in this paper, i.e. the DUT Truss Benchmark Model, was previously presented in detail in earlier studies by An and Ou (2013b), so it is only briefly described herein. Its span, width, and height are 8 m, 0.56 m, and 0.9 m, respectively. The process of FE modeling of this structure has been introduced in the earlier study (An and Ou 2013b). The FE model (Figure 1) consisting of 312 beam elements and 108 nodes has been implemented in the MATLAB environment. Attempts have been made to update the initial FE model, and as a result of this procedure, the first two vertical frequencies (19.1 and 52.5 Hz) of the numerical model have been adjusted to the experimental results (18.4 and 53.3 Hz).

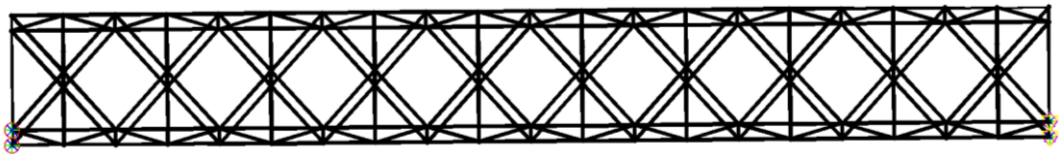

Figure 1 Finite element model of the steel truss model

Damage Cases

The substructure in the rectangle line is selected as the object for investigation. Four numerical damage cases (Table 1) are implemented to identify the corresponding damaged truss members. The sampling frequency of the measurements is 500 Hz.

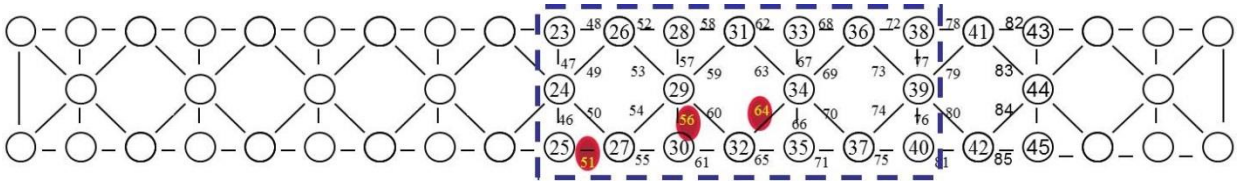

Figure 2 The substructure under investigation

Table 1 Numerical damage cases

	Damage case	Stiffness reduction
Single damage cases	1	Member 51#: 20% stiffness reduction
	2	Member 56#: 30% stiffness reduction
	3	Member 64#: 20% stiffness reduction
Multiple damage cases	4	Member 51, 56 and 64: 30%, 35% and 20% stiffness reduction, respectively

Simulations of Damage Localization

In this section, the same accelerations are used in the same damage case to compare the results based on two methods, i.e. the SDLV method, and the LDL^T-DLV method. The truss is excited using a band-limited white noise up to 150 Hz in the vertical direction at node 47. A band-limited white noise with a 5% noise level is added to simulate the measurement noise.

Damage cases 1~3 are single damage cases which simulate damage of a lower chord, a vertical truss member and a lower diagonal truss member, respectively. Damage cases 4 is a multiple damage case which simulate the damage of all damaged members in damage cases 1~3 simultaneously. Nodes 23~40 in Figure 2 are selected for measurements. In accordance with the SDLV method (Bernal, 2006) and the proposed LDL^T-DLV method, it can be seen from Figure 3 that results based on the proposed LDL^T-DLV method are better than those using the SDLV method.

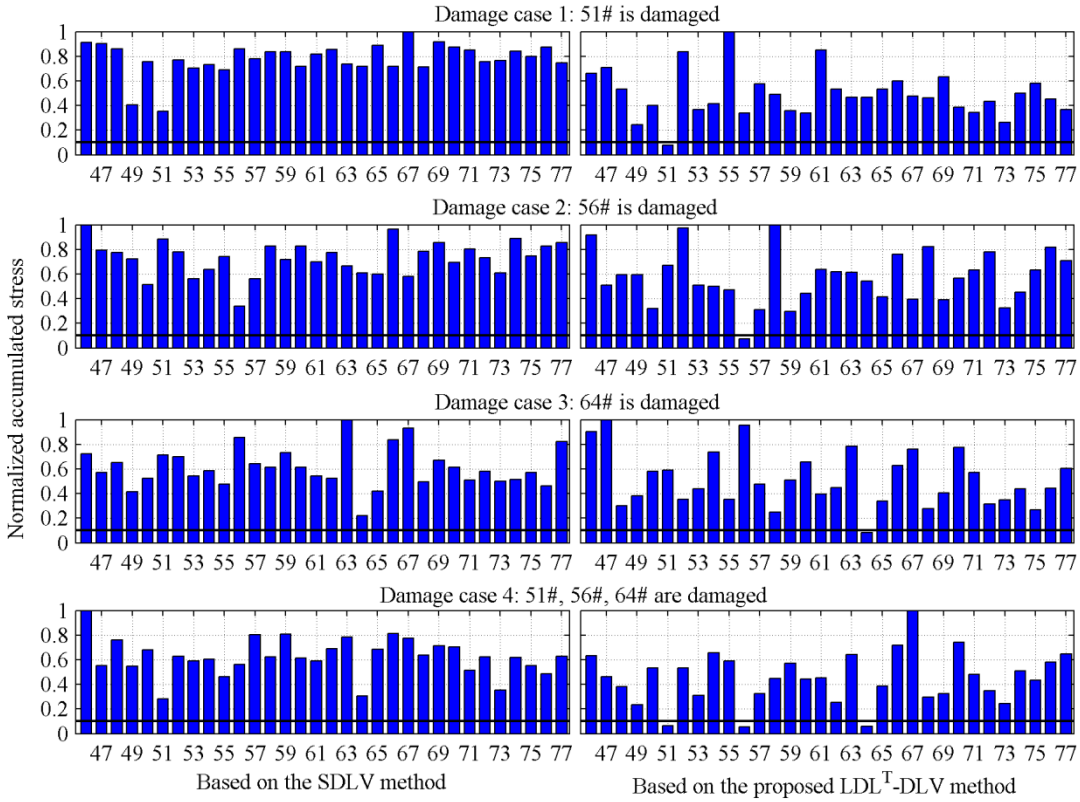

Figure 3 Damage localization results for damage cases 1~4 (5% noise) based on the SDLV method and the LDL^T-DLV method

CONCLUSIONS

This paper proposes a damage localization method for truss structures. The proposed method has been validated using a Bailey bridge benchmark model. The conclusions are summarized as follows:

(1) All the numerical damage localization results indicate that the proposed LDL^T-DLV method can be successfully used in the damage localization of truss structures. Therefore, it can be used in real-time structural health monitoring of truss structures under ambient excitation.

(2) The proposed method has a higher sensitivity to small damage compared with the SDLV method.

(3) Future research will consider the experimental validation of the proposed method based on the DUT Truss Benchmark Model.

ABSTRACT

Structural dynamic displacement is an important indicator of the health condition of long-span bridges. Monitoring of bridge dynamic displacement has been a critical task within the context of structural health monitoring (SHM). Traditionally, the structural displacement measurement methods are contact, wired and time-consuming. With the great progress of image processing technique and vision robot science, the vision-based monitoring systems have been developed rapidly and received a huge amount of attentions in the field of SHM. However, in the practical applications, the environmental factors will affect the operational performance of the vision-based system. In this study, a series of comparative experiments are conducted to explore the robustness of vision-based structural dynamic displacement monitoring under varying illumination conditions by use of various types of vision targets (quick response (QR) code and LED lamp). The experimental results indicate that the robustness of the vision-based system is weakened under poor illumination conditions when the QR code is used to be the vision target in comparison with the vision target of LED lamp.

KEYWORDS

Structural health monitoring, structural dynamic displacement, vision-based system, pattern matching, environmental factors.

INTRODUCTION

Civil engineering structures are prone to vibrate under the external stochastic loadings (e.g., wind, earthquake and traffic), which will result in fatigue damage and cracking in critical structural components. Monitoring of the structural dynamic responses is helpful to update structural models, build damage identification methods, and establish vibration control strategies. Structural vibration monitoring and dynamic characteristics identification have been one of the most important issue within the field of structural health monitoring (SHM) (Ni *et al*. 2010; Ni *et al*. 2012; Ye *et al*. 2012; Ye *et al*. 2013a).

The traditional dynamic displacement monitoring methods need to fix sensors on the target structure which will cause the issues of data transmission, power supply, traffic jam, etc. With the great progress of image processing technique and vision robot science, the vision-based displacement monitoring systems have been developed rapidly and received a huge amount of attentions in the field of SHM (Fukuda *et al*. 2010; Ye *et al*. 2013b; Ye *et al*. 2015). However, the vision-based system may be affected by the varying environmental factors, especially in the field measurements (Schreier and Sutton 2002; Yoneyama *et al*. 2006; Ma *et al*. 2012). In this study, a vision-based multi-point structural dynamic displacement measurement method is proposed. Comparative experiments are conducted between the vision-based measurement system and the traditional measurement system under different illumination levels with two various types of vision targets (quick response (QR) code and LED lamp).

METHODOLOGY

For a vision-based multi-point structural displacement measurement system, the algorithm of multi-point pattern matching is able to effectively locate the targets in an image by matching the predefined patterns (Ye *et al*. 2015). Figure 1 illustrates the procedure for the structural displacement measurement by using the vision-based system. First, the digital camera is fixed in front of the monitoring object and adjusted to make the monitoring target in the field of view. Then, the initial image is captured by the digital camera with the predefined targets. Patterns containing the region of the targets in the image are extracted from the initial image. Meanwhile, the initial coordinates of the centers of the patterns are confirmed. The scale ratio represents the proportional relationship of the actual distance and the pixel coordinate difference. By using the pattern matching algorithm, the process of pattern matching is performed in the succeeding images with the predesignated patterns. When the normalized correlation coefficient in correspondence with each pattern matching reaches the maximum

value, the pattern matching is completed. The best matching position is located and the best matched pixel coordinates are achieved. The pixel coordinate difference is obtained by subtracting from the initial pixel coordinate. Finally, the structural displacement of the target is obtained through multiplying the calculated pixel coordinate difference by the scale ratio.

As illustrated in Figure 1, the vision-based multi-point structural displacement measurement system consists of a high-resolution industrial charge-coupled device (CCD) camera, a zoom lens, a computer, and a Gigabit Ethernet standard LAN wire. In this system, a Prosilica GE1050 camera with a Navidar 12X zoom extender lens serves as the image acquisition equipment.

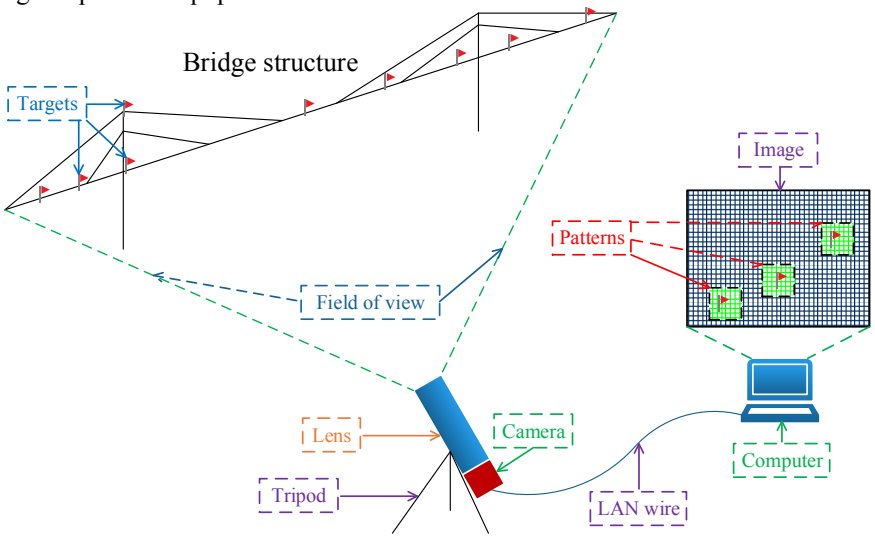

Figure 1 Vision-based system for multi-point structural displacement measurement

EXPERIMENTAL STUDY

Illumination is one of the most important environmental factors which will affect the quality of captured images and the sampling efficiency of the vision-based system. Experiments on the robustness of the vision-based multi-point structural displacement measurement system under different illumination levels are carried out. Basically, a comfortable environment with adequate illumination is desired to acquire satisfactory results of structural displacement. Under an inferior light condition, it is not easy for the digital camera to capture distinct images even though much time of exposure is taken. In this connection, the task of pattern matching will not be effectively fulfilled. In real-world applications, the vision-based system is liable to confront different kinds of illumination conditions which may make the measurement results unstable and inaccurate.

Table 1 Experiment cases with different environmental conditions

Case	Vision target	Illumination (lux)
Case 1	QR code	300
Case 2	QR code	75
Case 3	LED lamp	300
Case 4	LED lamp	75
Case 5	LED lamp	30
Case 6	LED lamp	2

As shown in Table 1, six cases including four levels of illumination (300 lux, 75 lux, 30 lux and 2 lux) and two kinds of vision targets (quick response (QR) code and LED lamp) are arranged to investigate system robustness under the different illumination conditions. As illustrated in Figure 2, the comparative experiments are conducted on a self-made shaking table on which a rigid board attached with two kinds of vision targets (quick response (QR) code and LED lamp) is fixed. Two QR codes (P1 and P2) and two LED lamps are regarded as the measurement targets for the vision-based system, as shown in Figure 2. A magnetostrictive displacement sensor (MDS) is also installed to measure the displacement of the two targets. An illumination sensor is deployed nearby the targets to record the level of illumination. The illumination condition is adjusted by switching the lamps in the room. The displacements of the targets during the vibration process of the shaking

table are simultaneously measured by the vision-based system and the MDS. The vibration frequency of the shaking table is 0.3 Hz and the sampling frequency of the two systems is 10 Hz. The distance between the digital camera and the targets is 2 m.

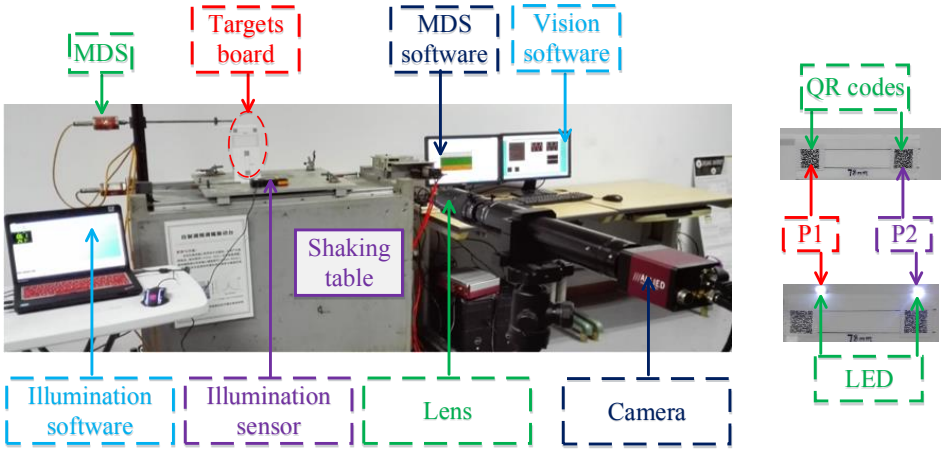

Figure 2 Experimental setup

Figures 3-8 illustrate the displacement time histories of P1 and P2 measured by the vision-based system and the MDS in the aforementioned six cases. It is seen from Figures 3-8 that in all the cases except case 2, the displacement results measured by the vision-based system are in consistent with those obtained by the MDS. However, in the case 2, when the vision targets are QR codes and the illumination is 75 lux, the vision-based system has the difficulty in accomplishing the task of pattern matching and a considerable number of spurious tones are generated. As a result, the inaccurate displacement results are obtained by the vision-based system due to the illumination effect. But in the same level of illumination (case 4), when the LED lamps are regarded as the vision targets, the displacements measured by the vision-based system are still in consistent with those obtained by the MDS. From case 1 and case 2, it is indicated that for the QR codes as the vision targets, a lower illumination will have effect on the measurement accuracy of the vision-based system and the robustness of the system is weaker under this situation. From case 2 and case 4, it is indicated that when the illumination is 75 lux, the LED lamps as the vision targets give a stronger robustness than the QR codes. When the illumination levels are brought down to 30 lux and even 2 lux in case 5 and case 6 and the LED lamps are regarded as the vision targets, the vision-based system still shows a stronger robustness as shown in Figure 7 and Figure 8.

CONCLUSIONS

In this study, a vision-based system is developed for non-contact structural dynamic displacement monitoring. Experimental investigations were carried out on a shaking table, and the performance of the developed vision-based system with two kinds of vision targets was verified by a comparative study between the vision-based system and the MDS. Through analyzing the influence factors, it is indicated that the measurement accuracy and stability of the vision-based system will be affected by illumination when the vision targets are QR codes. When the LED lamps are regarded as the vision targets, the vision-based system shows a strong robustness under different illumination levels. For an accurate and stable monitoring of the structural dynamic displacement with the vision-based system, an appropriate vision target is important. In the future, field tests will be carried out to validate the robustness of the developed vision-based system under more complex environmental conditions (e.g., fog, wind, rain, ground vibration, etc.).

ABSTRACT

A benchmark problem on an existing cable-stayed bridge was recently proposed. Recorded signals are available for standard working conditions and for special events (typhoons!). In this contribution, the authors report their attempt to detect significant variations in the cable tension during these extreme events.

KEYWORDS

Cable-stayed bridge, cable tension, catastrophic events, structural health monitoring, typhoon.

INTRODUCTION

The presence of complex boundary conditions usually imposes difficulties in estimating the cable forces in cable-stayed bridges when using conventional model-based force identification methodologies (Yan *et al* 2015). Multiple models have been exploited to set practical approximate formulations and empirical explicit expressions in order to estimate forces in cables, for instance Ren *et al*. (2005), Nam and Nghia (2011) and Fang and Wang (2012), among the others. The aforementioned model-based methods are applicable to cables with pure pinned or clamped end conditions. However, for existing in-service bridges, the cables are generally protected by steel tubes close to the deck and pylon anchorage zones.
The structural modal properties, for instance frequencies, damping ratios, and mode shapes, are employed for dynamic analysis, for estimating the tension in cables, for detecting the structural damage, and so forth.
The modal identification of the bridge and cable tension estimation are usually achieved by the usage of the ambient acceleration data (Yun *et al*. 2014). Moreover, when typhoon condition are considered, significant variations in the stay-cables can be observed.
A benchmark problem on an existing cable-stayed bridge was recently proposed and it focused on the modal identification (Ni *et al*. 2015; Casciati *et al*. 2015). Particularly, during a typhoon, some frequencies that during service conditions are not detected, were excited. Here-hence, the authors want to verify whether the cables tension varies during these particular events.
Furthermore, recorded signals in different working conditions, both standard and special events (typhoons) are available. In this work, the authors report their attempt to detect significant variations in the cable tension during these extreme events, by updating and calibrating properly a finite element model developed in the MSC® Marc Mentat environment (MSC 2014).

THE TING KAU BRIDGE

The Ting Kau Bridge (TKB) is a three-towers cable-stayed bridge situated in Hong Kong., whose total length is 1177m. In Figure 1, an ambient framework of the bridge is shown. The bridge spans from the Tuen Mun Road to the Tsing Yi Island (Bergermann and Schlaich 1996). It is composed by four spans, of which two are considered as main, while the remaining two are the side-ones. So, the two main spans are 448m and 475m long respectively, whereas the two side-spans are both 127m long. The general layout of the bridge is illustrated in Figure 2.

Figure 1 Location in aerial view

The bridge is divided into two carriageways of width 18.8m, and there are three slender single-leg towers between them with 170m, 198m, 158m height, respectively. Every 4.5m there is the presence of two steel girders along the edges of the deck with steel crossgirders, and a concrete slab on the top of each carriageway. Moreover, a 5.2m gap is present in each carriageway, and it is linked to the others by connecting crossgirders every 13.5m. The deck is supported by 384 stay cables in four cable planes.

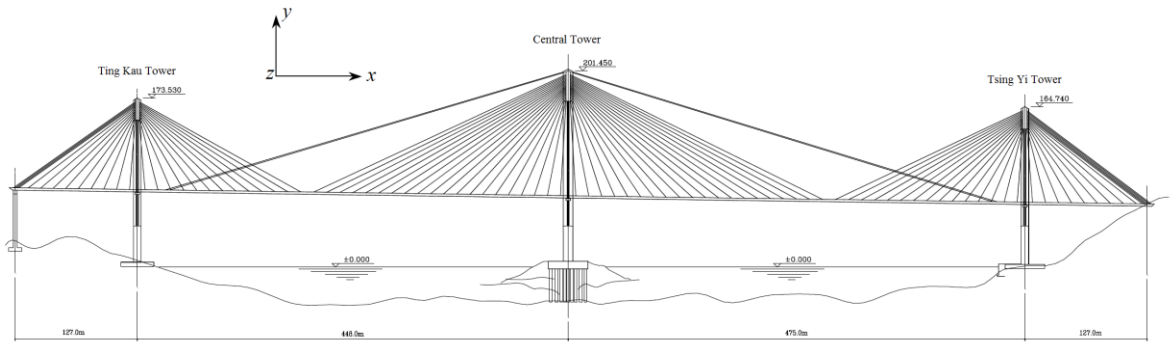

Figure 2 General layout of the Ting Kau Bridge

A sole characteristic of the bridge consists in the arrangement of the three single-leg towers, strengthened by longitudinal and transverse cables, whose function is stabilizing.
Then, 8 longitudinal stabilizing cables used to diagonally connect the top of the central tower to the Ting Kau and Tsing Yi towers, whose length reaches 465m, are installed. Whereas, 64 cables are employed to strengthen the three towers in the lateral direction (Ni *et al*. 2015).
Within a long-term structural health monitoring system conceived by the Hong Kong SAR Government Highways Department, during the construction of the bridge and also after its completion in 1999 (Wong 2004; Ko and Ni 2005), more than 230 sensors have been placed on the TKB.
On the bridge, accelerometers, anemometers, strain gauges, temperature sensors, GPS, and weigh-in-motion sensors are deployed (Wong 2007; Ni *et al*. 2011). A total of 24 uniaxial, 20 biaxial, 1 triaxial accelerometers are installed on the deck of the two main spans and two-side ones, the longitudinal stabilizing cables, the top of the three towers, and the base of the central tower. They form a total of 67 accelerometers and they monitor the dynamic response of the bridge.
In this work, only the accelerometers placed on the deck are considered. Within the benchmark problem, such number was lowered from 24 to 16 sensors, but maintaining the collection of the same modal information. Figure 3 and Figure 4 illustrate the old and the new sensors deployment (Casciati *et al*. 2015).

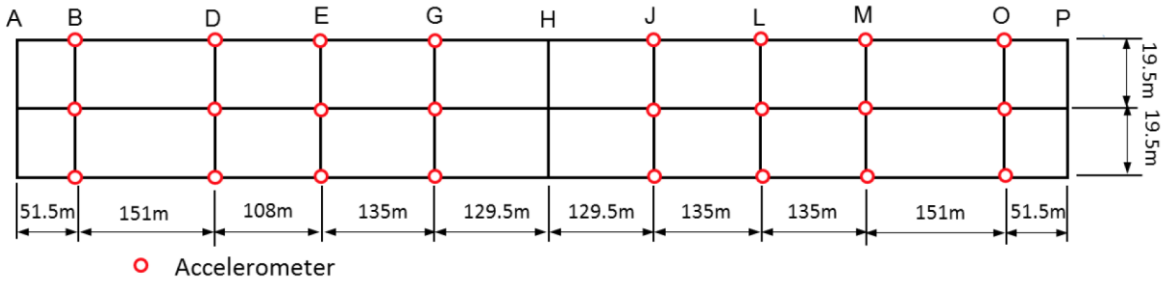

Figure 3 Actual deployment of accelerometers at the bridge deck

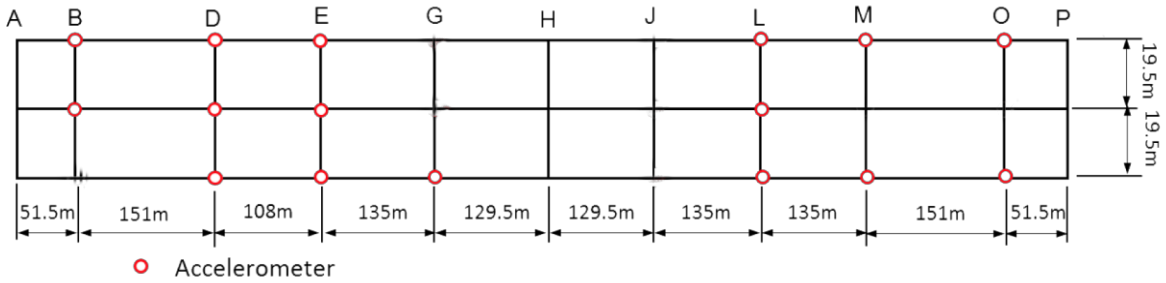

Figure 4 New proposed deployment of accelerometers at the bridge deck

In each section from *A* to *P* in Figure 3 and Figure 4, two accelerometers are installed on the east and west side of the longitudinal steel girders. They measure the vertical acceleration, while a further accelerometer is installed on the central crossgirder and measures the transverse acceleration. The set sampling frequency is equal to 25.6Hz.

GOVERNING RELATIONS

Let consider an inclined cable under tension force T (Figure 5). First, a coordinates system is defined: the x-axis along the cable chord and the y-axis along the perpendicular direction (Nam e Nghia 2011). The cable has a mass per unit length denoted as m, a chord of length l, a finite bending stiffness EJ and it is inclined at an angle α to the horizontal ($0 \le \alpha \le \pi/2$).

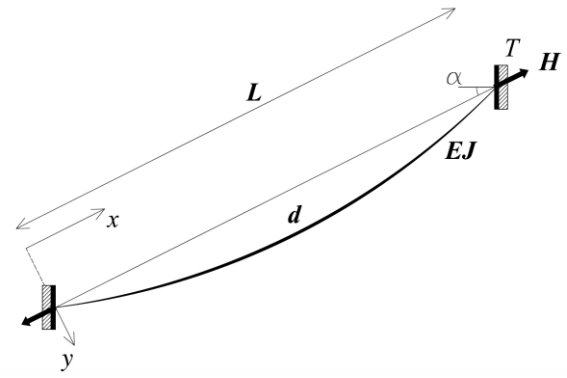

Figure 5 A model of an inclined cable

The dynamic equation of the cable in plane motion $v(x,t)$, in y-direction, is expressed as (Zui *et al*. 1996; Fujino and Hoang 2008):

$$H\frac{\partial^2 v}{\partial x^2} - m\frac{\partial^2 v}{\partial t^2} + h\frac{\partial^2 v}{\partial x^2} - EJ\frac{\partial^4 v}{\partial x^4} = 0 \qquad (1)$$

where $H = T_h/\cos\alpha$ denotes the chord tension, and T_h is the horizontal component of the cable tension, h is the additional tension in the cable caused by the motion. Eq. (1) assumes that the cable tension T is sufficiently large so the static profile of the cable can be described by the parabola (Irvine 1981):

$$y = 4d\frac{x}{l}\left(1-\frac{x}{l}\right) \tag{2}$$

where $d = mgl^2\cos\alpha/8H$ is the sag at mid-span.

Eq. (1) corresponds to the most general case of a cable where both the sag and the flexure in the cable are considered.

ESTIMATION OF CABLE TENSION

The cable tension can be estimated by its relation with the wave number. By considering proper simplifying assumptions of a small flexural rigidity parameter, the cable tension can be estimated in a simpler way.

Consider the flexural rigidity parameter ε (Hoang and Fujino 2007) and the wave number β :

$$\varepsilon = \frac{EJ}{Hl^2} \tag{3}$$

$$\beta = \omega\sqrt{m/H} \tag{4}$$

Some characteristic equations can be derived for anti-symmetric case vibration node, where the sag will generate no additional cable tension:

$$\tan\left(\frac{1}{2}\beta_{0n}l\right) = \beta_{\varepsilon n}, \quad n = 2,4,... \tag{5}$$

$$\tan\left(\frac{1}{2}\beta_{0n}l\right) = \frac{\beta_{\lambda n}}{1-\beta_{\varepsilon n}\beta_{\lambda n}}, \quad n = 1,3,... \tag{6}$$

where β_{0n} is the wave number of an individual node n, $\beta_{\varepsilon n} = \sqrt{\varepsilon}\beta_{0n}l$ and $\beta_{\lambda n} = 1/2\,\beta_{0n}l - \left(4/\lambda^2\right)\left(1/2\,\beta_{0n}l\right)^3$.

Eqs. (5) and (6) are logical extensions of the wave number of odd and even vibration mode of a sag cable proposed by Irvine and Caughey (1974), considering the flexural rigidity of the cable.

THE PROBLEM STATEMENT

The Finite Element Model

In this work, the bridge is modeled by the MSC® Marc Mentat software. The pre-processor of the software is very powerful and a sophisticated model can be built in order to investigate some issues.

The deck is discretized as a series of beam elements. The deck slab is made in reinforced concrete, while the cross beams and the cross girders are constituted by steel. For this reason, a particular attention is dedicated to the difference between the reinforced concrete elements and the steel ones, in order to preserve the real behavior of the structure. The towers, whose height changes from one to another one, are modeled by beam-type elements. The assigned material is also here reinforced concrete. Each tower is fixed. Finally, the 384 cables are modeled as beam-type elements where the shear forces and the bending moment are suppressed in order to simulate the behavior of a truss cable. The material of each cable is steel.

The realized model is composed by 2295 nodes and 4638 elements. Figure 6 illustrates the finite element model built in the Marc Mentat environment.

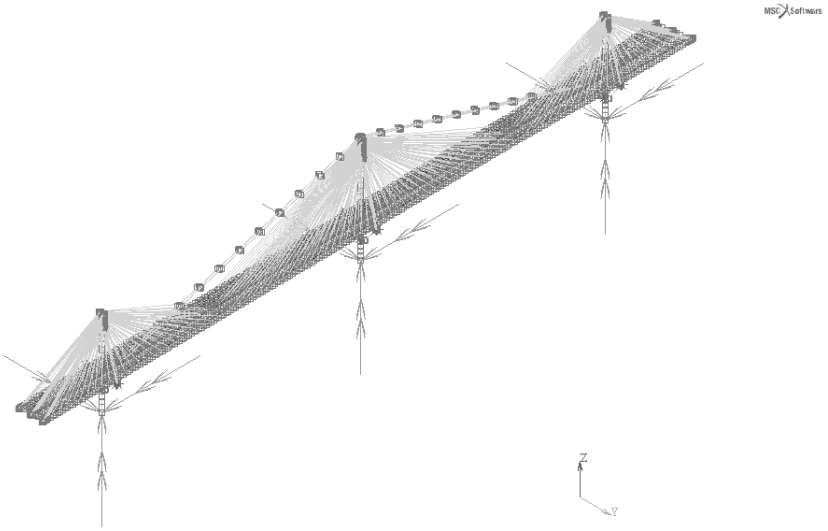

Figure 6 Finite element model of the bridge implemented in MSC® Marc Mentat software

Analysis Results

The results of the analysis reported in this section aim to detect significant variations in cable tension during typhoon event.
First, the model has been tested only by a simply gravity load applied on the each element. Hence, the modal features of the bridge are properly detected. Then, a further step is to test the tension in the cables in order to verify if there are some discrepancies when a typhoon occurs.
For each cable, a proper tension were provided and the finite element model is calibrated for replaying the behavior of the bridge in its current conditions.
Indeed, the attempt is focused on the detection of significant variations in the cable tension during an extreme event, such a typhoon.
For sake of exemplification, the first ten eigenvalues recorded during a typhoon event (named Maggie) are reported in Table 1.

Table 1 Identified modal frequencies of the first ten modes under typhoon condition

Mode No.	Frequency (Hz)
1	0.165
2	0.227
3	0.262
4	0.290
5	0.301
6	0.322
7	0.361
8	0.372
9	0.385
10	0.395

After the calibration of the finite element model, the frequencies are reported in Table 2. The way toward a cable tension variation estimation from these results is currently in progress.

Table 2 Identified modal frequencies of the first ten modes in MSC Marc Mentat environment

Mode No.	Frequency (Hz)
1	0.105
2	0.121
3	0.168
4	0.169
5	0.175
6	0.258
7	0.264
8	0.279
9	0.291
10	0.345

CONCLUSIONS

A benchmark problem on an existing cable-stayed bridge was recently proposed and it focused on the modal identification. Recorded signals for standard conditions and special events, for instance typhoons, are available. In this work, the authors verify that the cables tension is the same during these particular events and the modal features (e.g., frequencies and mode shapes) are detected.
Furthermore, the authors report their attempt to detect significant variations in the cable tension during these extreme events, by updating and calibrating properly a finite element model developed in the MSC® Marc Mentat environment.

Abstract: Infrastructure damage detection is widely adopted to prevent structural collapse and cut down the maintenance for owners with timely repair, but most damage detection methods only obtain marginal performance for in-situ structures due to uncertainties. A non-probabilistic damage detection method for uncertainty quantification is presented in this study. The diagnosis elements are extracted from the coefficient matrix of the vector auto-regressive (VAR) model which is identified from the measured acceleration, and the Mahalanobis distance (MD) of these diagnosis elements between pristine and unknown condition is employed as damage feature. The interval of MD due to physical variability is computed by optimal interval analysis with the differential evolution algorithm. A modified receiver operating characteristic (ROC) curve is developed and the area under ROC is utilized to localize damage. The overlap rate (OR) of MD interval are defined to quantify damage severity. The numerical simulation results demonstrate that the interval analysis method can successfully detect damage when the physical variability is considering.

Damage detection, uncertainty quantification, interval analysis, differential evolution algorithm, overlap rate.

INTRODUCTION

Vibration-based structural health monitoring (SHM) has flourish over the last few decades since it provides global damage information for infrastructure, and tremendous collapses are thereby prevented and maintenance costs may be minimized via condition-based repair strategy (Ni *et al*. 2011). A large number of model-based and data-driven damage detection approaches have been proposed for vibration-based SHM (Liu *et al*. 2014, Xia *et al*. 2014), and most of them have been employed successfully on numerical examples and well-controlled lab-scale structures. For in-situ SHM applications, however, the detection results may be unreliable due to uncertainties (Mao 2012).

Uncertainties stem from many aspects of civil structures, such as inaccessibility of non-stationary excitations, operational variability, changing environment, varying sliding support and colored noise. These uncertainties may have a greater impact on

the dynamic properties of structures than damage can do in early stages, thus uncertainty quantification (UQ) is a non-negligible issue for damage detection of civil structures.

Probabilistic approach is the traditional method to deal with UQ with frequentist statistics and Bayesian inference. Under this circumstance, however, a lot of measured data are needed to identify the type and parameters of the probability distribution. Unfortunately, civil structures can hardly undergo prototype testing due to their huge size and complexity. As a result, interval analysis has gained substantially interest in the community of civil engineering in recent years (Simoen *et al*. 2015).

Interval analysis characterizes an interval to quantify the uncertain variable, that is, the uncertainty is expressed as the lower and upper bounds, so it can be easily adopted in civil engineering. Since most uncertainty sources obey the physical rule, such as the frequency range of vehicle excitation is limit and the environment temperature only varies from -10 to 50 Celsius in a given region, the interval analysis targets to find out the possible fluctuation range of the damage detection indices. The optimal analysis method with differential evolution algorithm is developed in this work to quantify uncertainty for a mass-spring system. Although interval analysis is well established for model updating in civil engineering, its application to damage detection, especially to this data-driven damage approach, is new, thus it provides the promising practicability given requirement of way reduced data amount.

The paper is organized as follows: Section 2 gives a brief overview of interval analysis and develops the interval optimal algorithm. Section 3 describes the proposed approach and its procedure for damage diagnosis. Section 4 provides the application to a numerical simulation. Section 5 summarizes the analysis workflow with concluding remarks.

INTERVAL ANALYSIS

Firstly suggested by several mathematicians for bounding round-off errors, the interval analysis is fully developed by Moore in the book “Interval analysis” in Moore (1966). When a variable x cannot be recognized exactly but is known to lie within a certain interval, it can be expressed as a nonempty set of numbers by

$$x=[\underline{x},\overline{x}]\ ,\quad \underline{x},\overline{x}\in R,\ \underline{x}\le\overline{x} \tag{1}$$

where $\underline{x}$ is the lower bound and $\overline{x}$ is the upper bound, which can be called as infimum and supremum respectively. R denotes the set of real numbers. The midpoint of x can be defined as $x_0=\mathrm{mid}(x)=(\underline{x}+\overline{x})/2$, and the radius of x is expressed as $x_\Delta=\mathrm{rad}(x)=\overline{x}-\underline{x}$. Furthermore, give $x=[\underline{x},\overline{x}]$ and $y=[\underline{y},\overline{y}]$, four basic interval

operations are defined as

$$\begin{cases} x+y=\left[\underline{x}+\underline{y},\overline{x}+\overline{y}\right] \\ x-y=\left[\underline{x}-\overline{y},\overline{x}-\underline{y}\right] \\ x\times y=\left[\min\left(\underline{x}\underline{y},\underline{x}\overline{y},\overline{x}\underline{y},\overline{x}\overline{y}\right),\max\left(\underline{x}\underline{y},\underline{x}\overline{y},\overline{x}\underline{y},\overline{x}\overline{y}\right)\right] \\ y\div x=y\times 1/x \end{cases} \tag{2}$$

where $1/x=[1/\overline{x},1/\underline{x}]$, if $\underline{x}>0$ or $\overline{x}<0$. According to the definition of these arithmetic operations, the result is also an interval enclosing all possible values, such as x=[0,2] and y=[1,4], thus $z=x+y$=[1,6]. The basic operation can be extended to interval vector and matrix operations, but it beyond the scope of this study, more detailed discussions about the theory of interval analysis can be found in Moore *et al*. (2009).

Interval Combination Method

If the rules in Eq. (2) are following, the result of function $f(x_1,x_2,\ldots,x_n)$, where x_i denotes an interval variable, is also an interval. The basic and simple interval arithmetic evaluation of function f is to evaluate all possible combinations of the bounds of interval variables (Rao and Berke 1997):

$$f_t=f(x_1^i,x_2^j,\cdots,x_n^k) \tag{3}$$

where $i,j,\ldots,k$=1,2. The subscript t=1,2,…,2^n and f_t describes the special value of function f when a particular combination of the bounds of the interval variables is employed. Thus the endpoints of function f can be evaluated by

$$f=\left[\underline{f},\overline{f}\right]=\left[\min_t(f_t),\max_t(f_t)\right] \tag{4}$$

Overestimation is a major drawback for interval computations (Muhanna and Mullen 2001). For example, consider $f(x)=x^2$, where x=[-1,1]. According to the combination method and basic interval operation, $f(x)=x\cdot x$, thus f_t equals a set of {1,-1,-1,1} and $f(x)$=[-1,1]. The resulting interval number [-1,1] dose include the true interval number [0,1], however, the combination method expands the bounds of the function

In the process of basic or combination computation, each independent variable is treated dependently, such as the square of x, thus it is the main source for overestimation. Another source is that some of the algebraic laws can be hold only in a weaker form in interval computation (Muhanna and Mullen 2001).

Interval Optimal Method

From the perspective of optimization, computing the bound of function f is to acquire the minimal and maximal value of function f while input variables are restricted in a

bounded region,

$$\begin{cases} \min(f(x_1, x_2, ..., x_n)) \quad \text{and} \quad \max(f(x_1, x_2, ..., x_n)) \\ x_i \in [\underline{x}_i, \overline{x}_i] \quad i = 1, 2, ..., n \end{cases} \tag{5}$$

Since the explicit express of function *f* usually cannot be derived in civil engineering, especially for large-scale structure such as high-rise buildings and large-span bridges. A stochastic search based optimal method named differential evolution algorithm (DE) is implemented to achieve the accurate bounds of function *f* in this article. DE provides global minimum value with a very fast convergence and requires a very limited number of parameters (Storn and Price 1997). A typical DE begins with an initial population consisting of *NP* randomly defined chromosomes X^0,

$$\begin{cases} X_j^0 = \{x_{1j}^0, x_{2j}^0, ... x_{Dj}^0\}^T \quad j = 1, 2, ..., NP \\ x_{ij}^0 = \underline{x}_i + r_j(\overline{x}_i - \underline{x}_i) \quad i = 1, 2, ..., D \end{cases} \tag{6}$$

where X^0_j, also known as solution vector, is a candidate solution for the optimization problem in Eq. (6). r_j is a random number between [0,1] and *D* denotes the dimension of chromosome or parameters. Then three main operators called mutation, crossover and selection are implemented iteratively until convergent rule is reached. The mutation operator perturbs the chromosome in every iterative generation to avoid local minimum, the crossover operator is employed to enhance the potential diversity of the population, and the selection operator only chooses high performance chromosomes to keep the population size constant in the process of iteration. For more information about these three operators, please refer to Das and Suganathan (2011).

There are three control parameters in DE: the population size *NP*, the mutation scale factor *F* and the crossover constant *CR*. A good volume of work has been undertaken to estimate the reasonable parameters, but according to the results of comparative studies (Mousavi *et al*. 2011), *NP* is set to 10D, *F* is chosen as 0.5 and *CR* is set as 0.9 in this study. Since DE has good convergence properties[11], the terminating condition of DE is adopted by a fix iterations strategy as 30.

INTERVAL-ANALYSIS-BASED DAMAGE DETECTION METHOD

Damage Feature

Vector Auto-regression (VAR) is a statistical modeling of multiple time series, typically assumed synchronously obtained (as would be the case for a sensor network) to capture the linear interdependencies between them. A *p*-th order VAR model, denoted VAR(*p*), is

$$\boldsymbol{v}_t = \boldsymbol{c} + \boldsymbol{A}_1 \boldsymbol{v}_{t-1} + ... + \boldsymbol{A}_p \boldsymbol{v}_{t-p} + \boldsymbol{u}_t \tag{7}$$

where $\boldsymbol{v}_t = \{v_{1t}, v_{2t}, ..., v_{kt}\}^{\mathrm{T}}$ is a $(k \times 1)$ vector, the $\boldsymbol{A}_\mathbf{i}$ are $(k \times k)$ coefficient matrices, $\boldsymbol{c}$ is a fixed $(k \times 1)$ vector of intercept terms which is usually ignored since data is normalized before damage detection, and $\boldsymbol{u}_t = \{u_{1t}, u_{2t}, ..., u_{kt}\}^{\mathrm{T}}$ is k-dimensional white noise.

After the coefficient matrices are estimated using the least square algorithm (Lutkepohl 2005), the diagonal in each coefficient matrix is extracted to be a feature vector as follows

$$\boldsymbol{B} = \{\boldsymbol{A}_{11}^{1}, \boldsymbol{A}_{22}^{1}, ..., \boldsymbol{A}_{kk}^{1}, \boldsymbol{A}_{11}^{2}, ..., \boldsymbol{A}_{kk}^{2}, ..., \boldsymbol{A}_{kk}^{p}\}^{\mathrm{T}} \tag{8}$$

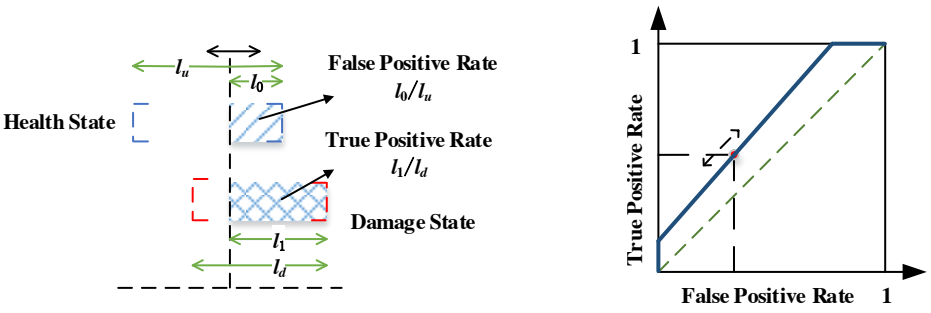
where superscript describes the ith coefficient matrix (i= 1,2,…,p), subscript describes the element in each coefficient matrix and T means vector transpose. In order to reduce the dimension of this feature vectors, Mahalanobis distance (MD) is utilized by

$$D_M(\boldsymbol{B}) = \sqrt{(\boldsymbol{B} - \hat{\boldsymbol{B}})^{\mathrm{T}} \boldsymbol{S}^{-1} (\boldsymbol{B} - \hat{\boldsymbol{B}})} \tag{9}$$

where $\hat{\boldsymbol{B}}$ is the mean vector of baseline sample features; $\boldsymbol{S}$ is covariance of the matrix formed from baseline sample features. The detailed process for extracting the damage feature is available in reference (Huang *et al*. 2013).

Damage Detection Procedure

Even the structure is under the same condition, the damage feature will vary due to the uncertainties. The variation induced by uncertainties can be described by an interval and there are three situations, namely total overlapping, partial overlapping and separation, for intervals obtained from healthy and damaged condition respectively. In order to avoid the type I or type II error for decision-making under partial overlapping situation, a receiver operating characteristic (ROC) curve for interval analysis is proposed based on the concept of ROC curve for probability (Fawcett 2006) as shown in Fig. 1.



(a) (b)

Figure 1. ROC curve of interval analysis for (a) definition of parameters and (b) ROC curve

Once the classifier threshold is set, the true positive rate is the distance ratio between l_1 and l_d and the false positive rate can be acquired using l_0/ l_u as shown in Fig. 1(a). With different thresholds, hence, the ROC curve can be achieved as shown Fig. 1(b). It is worthwhile to emphasize that tedious computation is no longer needed for establishing ROC curve of interval analysis since it is accomplished using distance ratio only, that is, the complex area computation of probability density function is avoided in the case of interval analysis. After the ROC curve is obtained, the area under the ROC curve (AUC) is introduced to detect the presence and location of damage. When the AUC approaches 1, the decision can be made with full confidence, and when its value is 0.5, the decision is just a random guess. A reasonable value for AUC to determine whether damage occurs is set as 0.8 in this study.

Once the location of damage is identified, the distance between midpoints of MD interval under reference and inspection phase is utilized to quantify the damage severity.

The proposed diagnosis technique is summarized in Fig. 2.

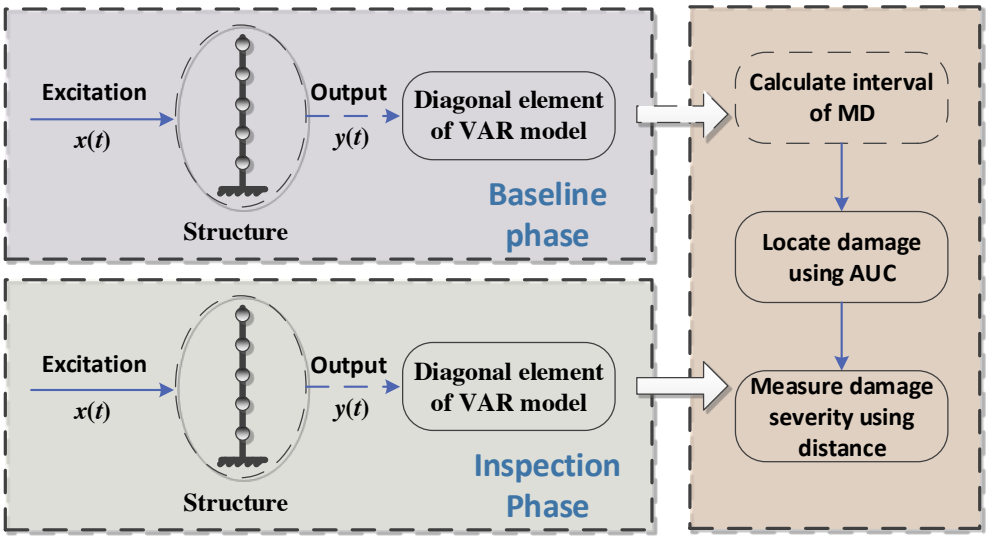


Figure 2. Flowchart of the proposed damage detection method

NUMERICAL VERIFICATION

To illustrate the interval analysis based damage detection method, a relatively simple 4-DOF spring-mass system will serve as a running example, which is shown in Fig.3. The mass values is m_1= m_2=1, m_3=m_4=0.8, the initial spring stiffness is k_1=k_2=1000, k_3=k_4=800. The damping matrix $\boldsymbol{C}$ is set as Rayleigh damping, C=0.2×$\boldsymbol{K}$+0.0005×$\boldsymbol{M}$, which means $\boldsymbol{C}$ is a linear combination of stiffness matrix $\boldsymbol{K}$ and mass matrix $\boldsymbol{M}$. The

excitation which is generated as white noise is applied at the location of mass 4, and the acceleration responses from all mass are recorded as multivariable output.

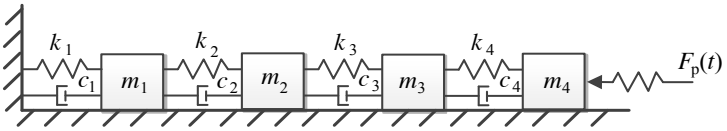

Figure 3. 4 degree-of-freedom mass and spring system

Damage is simulated as loss of spring stiffness of k_1 and four damage cases are considered as shown in Table 1.

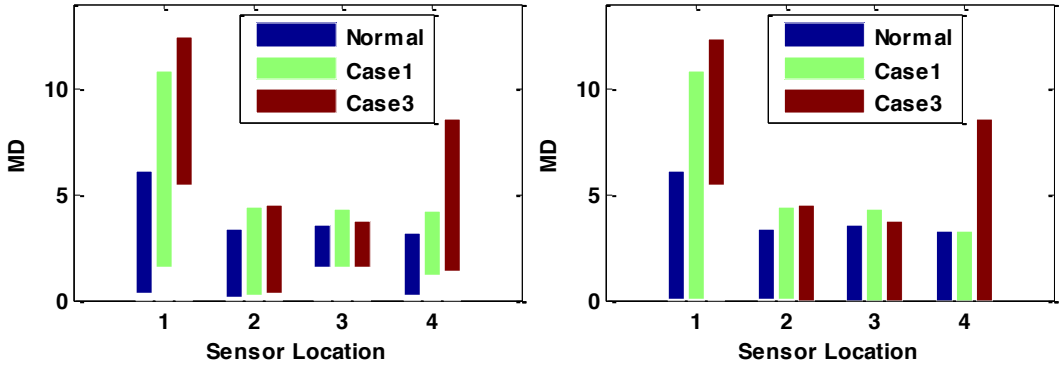
Table 1. Four damage cases

Damage case	0	1	2	3	4
Decline percent of k_2	0%	5%	10%	20%	50%

For the sake of brevity, only physical uncertainty from the structure are introduced as variation of spring stiffness from k_1 to k_3 and the amplitude is set as k_1= k_2 = [950, 1050], k_3= [760, 840], that is, k_1 to k_3 will vary about 5 percentage around their normal value due to uncertainties. The acceleration responses are computed by Newmark-β method and the interval of Mahalanobis distance, which is shown in Fig. 4, is calculated according to the procedure in Fig. 2.

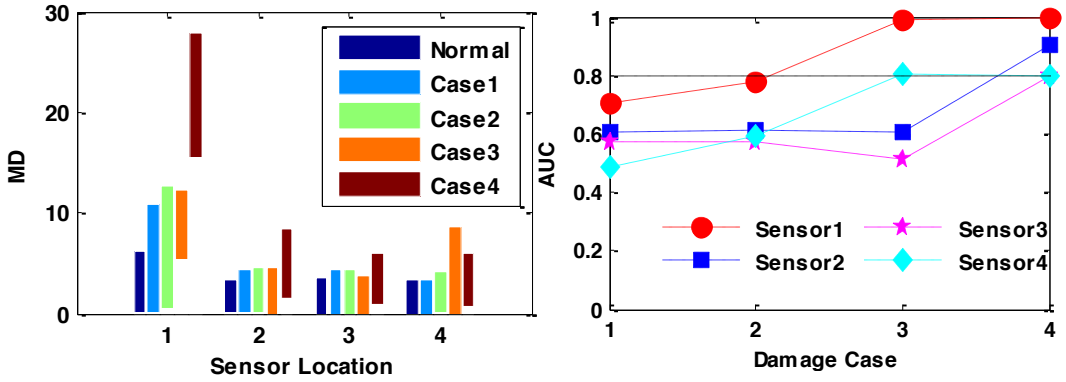
It is observed from Fig. 4 that the lower bounds or infimums calculated from interval combination method are larger than the infimums from optimal method, especially at sensor 1, 3 and 4. But level of uncertainty, which is simulated with the 5% fluctuate of k_1, k_2 and k_3, is at the same level with or greater than the damage level of case 1, the lower bounds of MD interval should be zero under this situation. So the type I error can be easily triggered using the interval combination method.

The MD interval and AUC are evaluated using optimal method based on DE are given in Fig.5. It is seen from the figure that the MD interval of sensor 1 is further away from normal condition than other sensors. This information is showing us that some changes have happened around sensor 1. And this phenomenon can be verified by AUC index in Fig.5 (b). It should be notice that the AUCs at several sensors are slightly higher than the threshold with the increase of damage severity at k_1.



(a) (b)

Figure 4. Interval results under damage case 1 and 3 for (a) Interval combination method and (b) optimal method based on DE.



(a) (b)

Figure 5. Results under different cases using optimal method for (a) interval and (b) AUC.

The distances between midpoints for all sensors are presented in Fig. 6. As can be observed in this figure, the distance of midpoints will rise if the physical damage severity increases. Hence, it is evidenced that the proposed index is successful at quantifying the damage even under the influence of uncertainty.

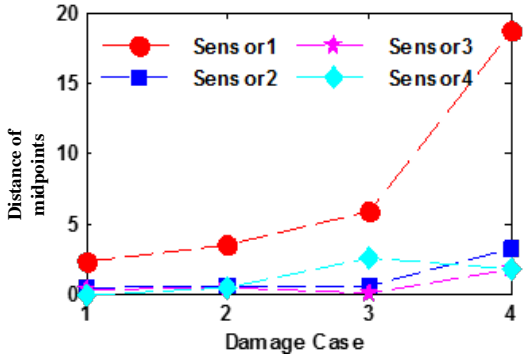


Figure 6. Damage severity identification using midpoint of interval.

CONCLUSION

A non-probabilistic damage detection method for uncertainty quantification using interval analysis is presented in this study. The diagonal elements of VAR model is extracted and then the Mahalanobis distance of these diagonal elements under baseline and inspection phase is employed as damage sensitive feature, and then the interval of MD is evaluated using optimal interval algorithm using DE. The ROC curve for interval analysis is defined and then the area under ROC is utilized to localize damage. The damage severity is inferred with the distance of MD interval between baseline and inspection phase.

A four degree-of-freedom mass-spring system is used for validation and the uncertainty is simulated with the variation of stiffness at three springs. It is shown that damage can be localized and quantified successfully. The ROC curve for interval analysis is proposed in this paper and less computation is needed to quantify the uncertainty for damage detection.
The interval analysis demonstrates reasonable promise for detecting damage under physical variability, and future work will be focused upon other types of uncertainty such as measurement uncertainty and modeling errors.

ABSTRACT

This paper investigated the evaluation of the concrete damage degree due to steel bar corrosion for reinforced concrete structures. Brillouin optical fiber time domain analysis (BOTDA) sensors were developed to monitor the steel bar corrosion expansion strain. Electrochemical accelerating experimental results showed the sensors could be used for early detection and the lifelong monitoring. The damage factor was proposed to quantitatively evaluate the concrete damage degree before initial cracking and during the development of cracks. Finite element analysis was performed on concrete specimens to map the monitoring results with the damage factor, which supported the capability of the damage factor.

KEYWORDS

Corrosions, BOTDA, damage factor, cracking, finite element (FE).

INTRODUCTION

Steel bar corrosion reduces the ultimate and yield strength of steel, weakens the bond properties between reinforcement and concrete, and greatly affects the seismic performance and static load capacity of reinforced concrete structures (Gong *et al*. 2004; Fang *et al*. 2006). The rust (with Fe_2O_3 as the main component) that is produced by steel bar corrosion causes volume expansion and hoop tensile stress on the concrete, which subsequently leads to deformation and cracks (Lu *et al*. 2011; Feliu *et al*. 2005).

Given that the use of smart sensors and industrialization of wireless sensor networks have attracted significant research attention, structural health monitoring has become a key factor in the operational security of major engineering structures(Li *et al*. 2011). The cutting-edge optical fiber sensing technology has been widely adopted in optical communication and structural health monitoring over the recent years. This technology has also been successfully applied in civil engineering, hydraulic engineering, and other areas (Wu *et al*. 2000; Naruse *et al*. 2000). Optical fiber presents many advantages, such as its light weight, anti-interference ability, resistance to corrosion, and facilitation of the real-time monitoring long-distance and large-scale structures. Therefore, this technology is expected to overcome the defect of traditional steel bar corrosion monitoring method and its application urgent needs to be improved in this field (Chen and Dong *et al*. 2012; Yashiro *et al*. 2008).

This paper bring forward a new assessment of concrete cracking due to steel corrosion, namely, define the damage factor of reinforced concrete structures, which can both evaluate the damage degree before and during the development of cracks.

BASIC PRINCIPLE OF BRILLOUIN OPTICAL FIBER TIME DOMAIN SYSTEM

Figure1 shows a schematic of the BOTDA system. If the frequency difference between the pump and the probe waves is tuned to around the Brillouin frequency shift at some location along the test fiber, the probe signal is amplified at that point due to stimulated Brillouin scattering between the pump and the probe lights. Therefore, it is possible to measure the distributed temperature and the strain measurement by measuring the time-dependent probe light power for various values, and by obtaining the Brillouin frequency shift distribution along the fiber length (Kurashima and Horiguchi 1992).

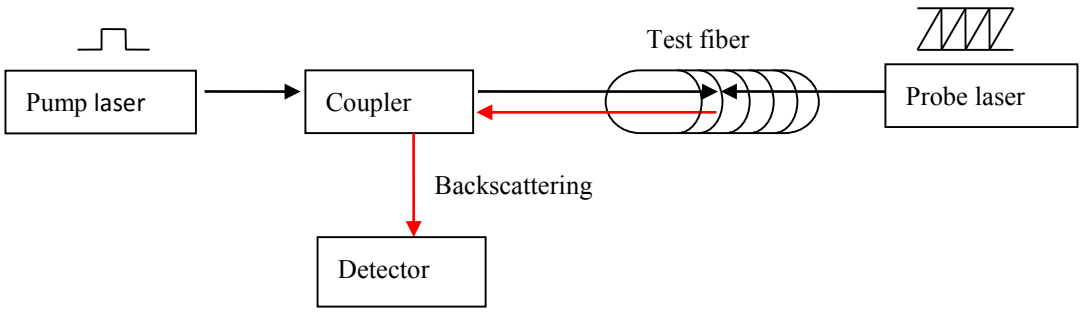

Figure 1 Configuration of Brillouin optical fiber time domain analysis (BOTDA) system

The Brillouin frequency shift is expressed as:

$$\nu_B = 2n\nu_a / \lambda \tag{1}$$

Where n denotes the refractive index, v_a denotes the velocity of sound, and λ denotes the wavelength of light.

The relationship of the Brillouin frequency shift at a certain location along the fiber with its corresponding temperature and strain change can be described as follows:

$$\nu_B = k_{ft}\Delta T + k_{f\varepsilon}\Delta\varepsilon + C \tag{2}$$

Where k_{ft} denotes the temperature coefficient of Brillouin frequency shift, kfε denotes the strain coefficient of Brillouin frequency shift, ΔT denotes temperature change, $\Delta\varepsilon$ denotes strain change, and C is a constant.

Therefore, the local temperature and strain conditions along the fiber can be measured based on the Brillouin frequency shift.

EXPERIMENTS

Accelerating Corrosion Experimental Method

The impressed current technique in accelerated corrosion studies is used in this study. The concrete specimen with sensor was placed into the electrochemical accelerated corrosion experiment system, as can be seen form Figure 2. To accelerate reinforcement corrosion, direct current was impressed on the rebar by means of a power

supply. The power supply has a steady current of 60 mA. The direction of the current was adjusted so that the reinforcing steel served as the anode, while the stainless steel plate served as the cathode.

In this study, it assumed that the corrosion of rebar is uniform. The specimens were semi-immersed in 30mm-depth in a 3.5% sodium chloride solution in a plastic tank in such a manner that the solution was in contact with the bottom of the specimens. This arrangement ensured that the reinforcement was totally above the solution, ensuring that cracks formed due to rebar corrosion were representative of the real-life situation and the cracking time was longer than total immersion. The BOTDA analyser was Swiss-made DiTeSt STA100 Series, which was used for sensor signal acquisition every 30 minutes automatically during the electrochemical accelerated corrosion experiment. The BOTDA analyser connected with the optical fiber in the specimen.

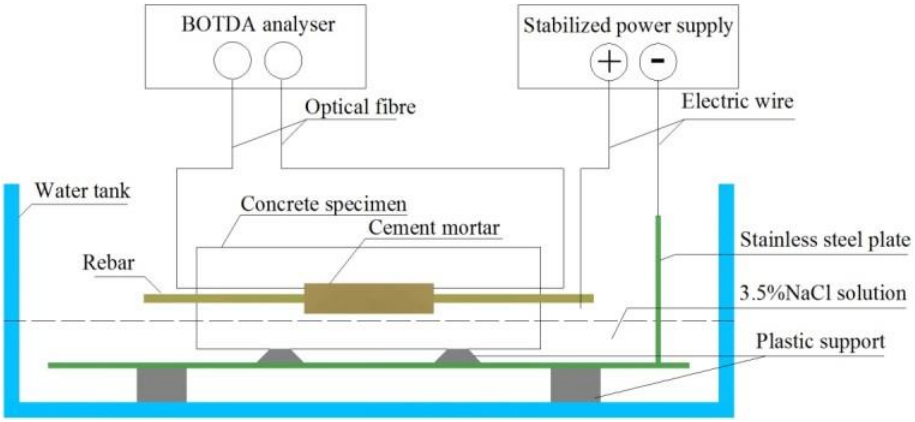

Figure 2 Schematic illustration of the electrochemical accelerated corrosion experiment system.

Design of the BOTDA Steel Corrosion Sensor

Figure 3 shows the design of the BOTDA steel corrosion sensor. The fabrication procedures are described as follows: (1) Process a 500mm-long and 20mm-wide HRB335 rebar. (2) Pour a 5 mm layer of mortar directly on the rebar with one day curing before form removal. The mortar was a 190/500/630 mixture of water, cement, and sand, respectively. (3) After curing three more days, a 3.0m-long, bend-insensitive optical fiber was winded for several turns on the inner layer of the mortar with pre-stress, ensured that the fiber is tight with the surface of the mortar. Both ends of the fiber were fixed on the mortar with modified acrylate adhesive. The fiber was lead out bilaterally with armored optical cable along the rebar. (4) A layer of mortar (a 260/500/630 mix of water, cement, and sand, respectively) was cast outside of the fiber. An additional amount of water was mixed to guarantee the fluidity of the mortar, which could help prevent the occurrence of damage during the pouring of concrete specimens. The mortar was cured for one day before form removal and three days more before normal use.

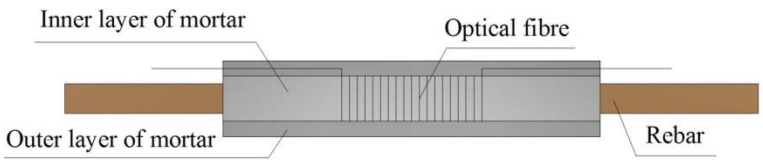

Figure 3 Schematic illustration of the BOTDA steel corrosion sensor

Design of Concrete Specimens with Embedded Sensors

The concrete specimens, namely, B-1 were embedded with steel bar corrosion sensors. The size of concrete specimens was 140 mm × 140 mm × 180 mm and the strength grade was C50. The cement grade was CEM 42.5, the W/C was 0.34. Concrete mix, formed with water, cement, sand, gravel, and water reducer in proportion of 170:500:630:1021:5.0. Figure 4 shows the design of B-1. After being vibrated on the vibration table, the concrete specimens were cured for 28 days at room temperature before the experiment was performed.

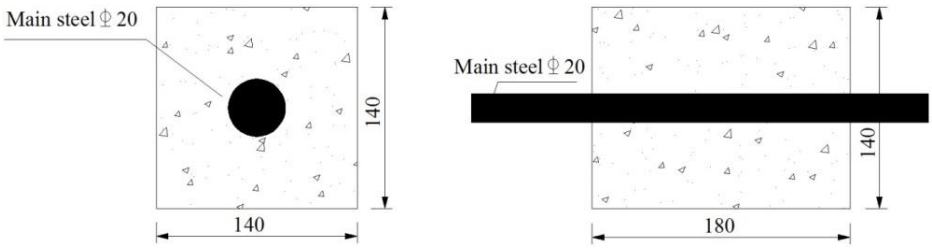

Figure 4 Design of the concrete specimen B-1 (mm)

Analysis of Experiment Results

The experiment was performed until the largest crack was formed on B-1, which damaged the steel bar corrosion sensor. Figure 5 shows the distance–time–strain relationship on the specimen. These graphs were obtained by interpolating the experiment data, which could be smoothened without changing the overall shape.

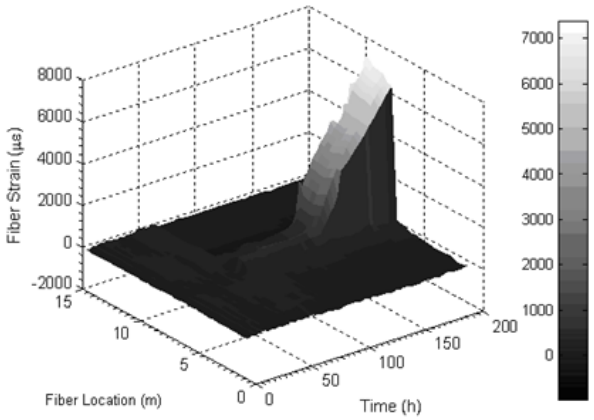

Figure 5 The distance–time–strain relationships of fiber on specimens B-1

According to the theory of valid sampling points, select the fiber strains which are located 8.14 m, 8.55 m, 8.95 m, and 9.36 m from the ends of the fiber as effective monitoring steel bar corrosion expansion strain results. The average value of the effective results for B-1 is shown in Figure 6. The fiber strains slowly developed during the early stages of the experiment. The steel bar corrosion began to accelerate after as cracks formed throughout the concrete, which gave way for the solution to seep into the concrete. The fiber strain of B-1 began to rise at about

130 hours. The fiber was damaged at 7100 με, and the steel bar corrosion sensor stopped working by the end of the experiment.

The sensors present several advantages for monitoring steel bar corrosion. The sensor demonstrates a favourable sensitivity and can effectively monitor the condition of corroded steel during the initial and concrete cracking stages of the corrosion experiment. The monitoring results of the BOTDA sensor reflect the condition of the corroded specimens that the condition can be able to quantitatively evaluate. These results have been verified by the manufacturing process of the sensor and the experimental data analysis results. Bend-insensitive optical fiber in this study uses the stable SiO2 as its main component. The durability of this sensor facilitates long-term steel bar corrosion monitoring of reinforced concrete structures even under harsh environments.

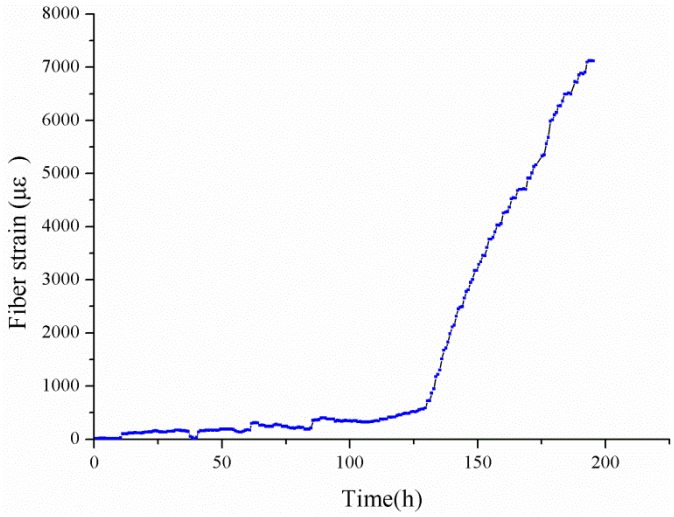

Figure 6 The expansion micro strain collected by BOTDA versus time relationship for the specimen

EVALUATION OF CORROSION DAMAGE TO REINFORCED CONCRETE MEMBERS

Damage Factor

In order to evaluate the concrete corrosion damage using corrosion expansion strain monitored by the sensors, this paper presents a new definition of damage factor. The damage factor of reinforced concrete can quantitatively evaluate the concrete damage caused by rebar corrosion before initial cracking and during the development of cracks due to steel bar corrosion expansion. This factor can also be extended to evaluate the complete cracking through the reinforced concrete cover.

The damage factor D is a dimensionless metric that evaluates damage degree to reinforced concrete members. D is equal to 0 when no steel bar corrosion expansion stress is observed in the concrete, and D is equal to 0.5 when the steel bar corrosion expansion stress generates an interfacial concrete cracking, initially. When $0 < D < 0.5$, the concrete members do not crack despite the presence of corrosion expansion stress in the concrete. D is equal to 1.0 when cracks develop through all the concrete cover. When $0.5 < D < 1.0$, cracks begin to develop inside of the concrete. In this study, it is assumed a linear relationship between D and the strain of rebar corrosion monitored by fiber optical Brillouin sensing in the interval of $0 < D < 0.5$ and $0.5 < D < 1.0$, and D is become higher with the increasing of the strain.

In case of corrosion damage evaluation for one specific reinforced concrete specimen, finite element analysis should be performed to obtain the relationship between corrosion expansion strain and damage factor D, in advance. Therefore, according to the relationship, quantitative damage factor D can be obtained using expansion strain monitored by the sensor proposed.

Finite Element Analysis with ABAQUS

Introduction to ABAQUS analysis

Finite element analysis with commercial FE code ABAQUS analyses the concrete cracking process due to corrosion expansion and establishes a relationship between the equivalent strain of a circumferential section and damage factor, which so as to map the steel bar corrosion monitoring results to the concrete damage degree. The concrete behaviour around a corroding reinforcing bar is dominated by tensile cracking at a low level of compressive stresses. A crack forms when the maximum principal tensile stress exceeds the tensile strength of the concrete (Jang and Oh 2010).

The concrete was simulated by unit a 4-node bilinear plane strain quadrilateral (CPE4). The finite element analysis adopted the displacement mode and assumed a uniform rebar corrosion that generated equal pressure on the interfacial concrete. Therefore, the displacement was applied on the interface to simulate the steel rebar corrosion expansion loaded to the concrete. Fig. 7 shows the distributions of corrosion-induced expansion displacement around a rebar. In the finite element analysis, the three-dimensional physical specimens used in the simulated and accelerated corrosion tests were idealised as two-dimensional models. Taking into account both symmetry of the specimen, the assumed pinned restraint boundary conditions as Figure 7.

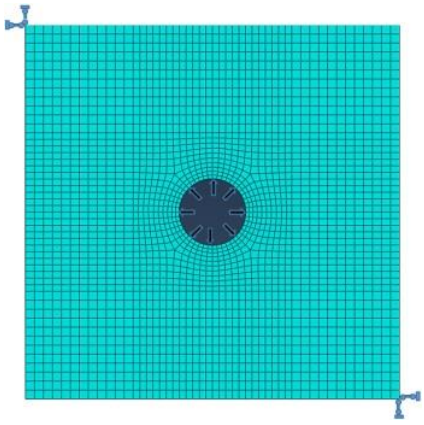

Figure7 Finite element discretization of the specimen imposed boundary conditions and displacement load

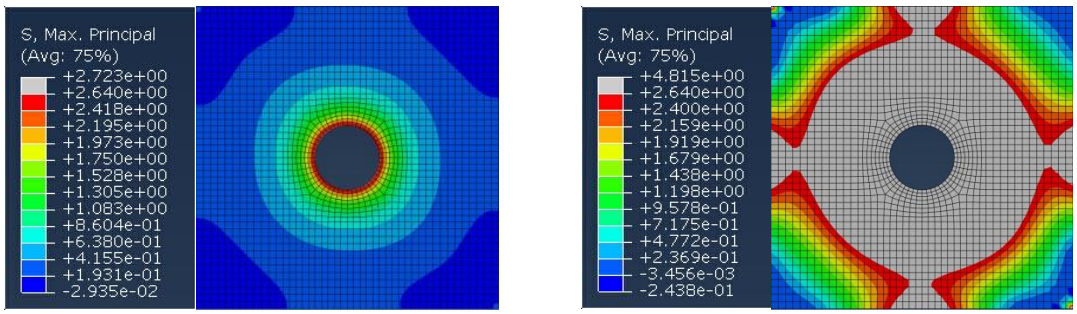
Simulation analysis

The simulation process was divided into two stages, namely, interfacial concrete cracking (concrete around mortar layer) and cracks through all concrete cover. Concrete was considered to be cracked when maximum principal tensile stress exceeds its ultimate tensile strain. The relationship of displacement U given to the interfacial concrete and strain measured by fiber as: $U/r = \varepsilon$, r is the radius of rebar plus the thickness of mortar layer.

The corrosion expansion strain was simulated at 0.00145mm, when the interfacial concrete began to crack. Figure 8 shows the distribution of concrete stress under a certain corrosion expansion displacement. The strain of fiber was 97με when the interfacial concrete cracked. As can be seen from Fig. 8, the corrosion expansion strain was simulated at 0.01012mm, when the cracks through all the concrete cover, and the expansion strain of fiber induced by corrosion were 670με.



(a) interfacial concrete cracking (b) cracks through all concrete cover

Figure 8 Stress distribution around a steel bar for specimen B-1

Mapping the Finite Element Analysis Results to the Damage Factor

The concrete strain after cracking included the crack width strain and the concrete strain between cracks. These two sections were merged to calculate the equivalent strain of the concrete section. While only concrete strain existed before concrete cracking and this part was used to calculate the equivalent strain of the concrete section. The fiber was still in the linear elastic stage during the concrete deformation, but the strain was not entirely equal at each position. Here, we assume that the fiber strain of steel bar corrosion monitoring is the same as the average strain of the fiber, which is the equivalent strain of the circumferential concrete section that is close to the reinforced surface at 5 mm.

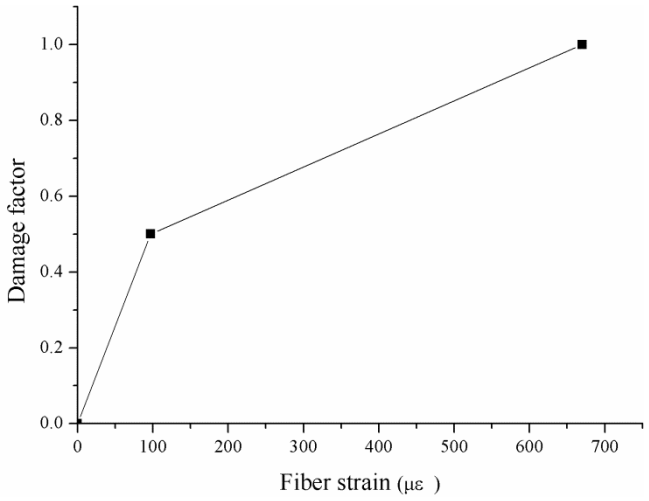


Figure 9 Mapping the strain of the corrosion monitoring fiber to the damage factor

The relationship between the equivalent strains of the concrete section was calculated based on the above assumptions and damage factor was descripted in Figure 9. It shows the simulation diagram of specimen B-1, which can also be as the mapping of the fiber optic monitoring strain results to the damage factor. In this study, it assumed that there is a linear relationship between fiber strain and expansion of corrosion rebar.

From Figure 9, it can be calculate that, when 0<D<0.5, the linear equation as follow:

$$y=0.00515x \quad (3)$$

When 0.5≤D<1, the linear equation as follow:

$$Y=0.00087x+0.41561 \quad (4)$$

The strain of fiber when the interfacial concrete began to crack due to corrosion expansion corresponded to the 97 με, and cracks through all the concrete cover corresponded to the 610 με. These results were generally consistent with the corrosion monitoring results. The sensor can detect the steel corrosion strain more than 70 times of the initial cracking strain and 10 times of the strain that corresponds to the cracks through all the concrete cover, which has a wide monitoring range. The monitoring results of the BOTDA steel corrosion sensor reflect the condition of the corroded specimens, which can also be verified by the finite element simulation results. The finite element analysis results enabled the damage factor to evaluate the steel corrosion damage degree. The accuracy of the finite element analysis directly determined the extent of the damage evaluation.

Mapping the Steel Corrosion Monitoring Results to the Damage Factor

According to the steel bar corrosion expansion strain–time relationship (Figure 6) , the mapping of finite element analysis results to the corrosive damage factor (Figure 9) for the specimen B-1 and equation (3) , (4), it has achieved the mapping of steel bar corrosion monitoring strain to the damage factor, as shown in Figure10.

Figure 6 and Figure 10 express the similar meaning. Figure. 6 evaluates the corrosion expansion condition of the concrete specimen from the view of the corrosion expansion strain that cannot identify the exact corrosion damage state of concrete. Figure 10 can quantitatively evaluate the corrosion damage of the specimens in such a way that the results can be easily understood by professionals.

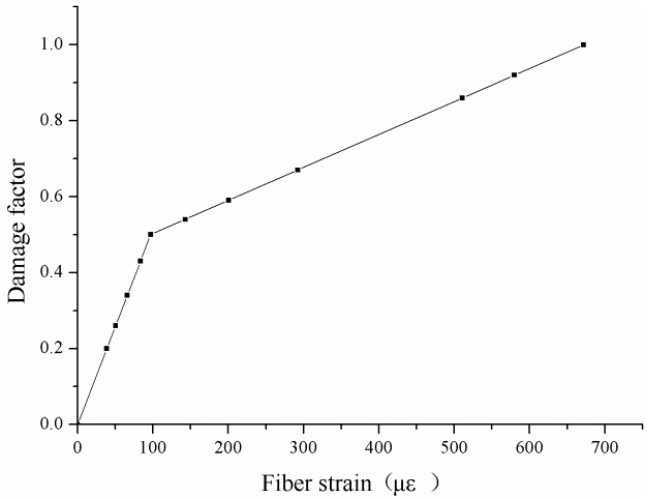

Figure 10 The mapping of the corrosion monitoring strain to the damage factor

CONCLUSIONS AND FUTURE WORK

A new type of sensor for monitoring steel bar corrosion was developed in this paper based on the BOTDA sensing

technology. The steel corrosion sensor had a high sensitivity, a large measuring range, a high durability, and a high stability, all of which could facilitate the monitoring of the entire corrosion process, beginning from the initial cracking phase to the cracks extended to the concrete surface. The sensor could operate for long hours after the concrete surface cracking, which could be used for monitor the crack width.

The damage factor was proposed to quantitatively evaluate the damage degree from the early stages of the corrosion expansion stress to the initial cracking of the inner concrete. This factor could also evaluate the concrete cracking process even when the cracks expanded on the surface. The definition of damage factor could be extended to evaluate the width of the cracks on the surface of the reinforced concrete structure members.

A finite element analysis was performed to establish a mapping relation between the fiber strain and the concrete stress before concrete cracking, and between the fiber strain and crack depth after concrete cracking in the reinforced concrete structure members. That is, the monitoring data of the fiber sensors were mapped to the damage factor, which enabled the damage factor to evaluate the corrosion damage to the structure members. The finite element analysis results were consistent with those of the steel corrosion monitoring experiment, which proved the rationality of the analysis and the effectiveness of the corrosion monitoring results.

Some aspects of the study were not been thoroughly investigated in this paper. The ability of the finite element analysis to analyze the conditions and width of concrete cracks after concrete surface cracking must be further validated. Future studies must be conducted to address the limitations of this research.

KALMAN FILTER BASED ESTIMATION OF NEUTRAL-AXIS POSITION OF BRIDGE DECK SECTIONS USING STRAIN MONITORING DATA

Y.Q. Ni* and H.W. Xia
Department of Civil and Environmental Engineering, The Hong Kong Polytechnic University,
Hung Hom, Kowloon, Hong Kong. *Email: ceyqni@polyu.edu.hk

ABSTRACT

The neutral-axis position has been recognized as a damage indicator for bridge deck assessment because of its high sensitivity to local damage on deck sections. It can be estimated when strain responses at the top and bottom of a deck cross-section under traffic loading are measured. However, the accuracy of neutral-axis position estimation directly using the measured strain responses might be significantly distorted in the presence of measurement noise and varying traffic load patterns. In this study, a Kalman filter (KF) estimator is formulated to locate the neutral-axis position from measured strain responses under traffic loading. Its capability for consistently locating the neutral-axis position under varying traffic load patterns is verified using the field monitoring data of traffic-induced strain responses acquired from the suspension Tsing Ma Bridge under diverse load scenarios (highway traffic, railway traffic, and their combination). The results indicate that the proposed KF estimator gives rise to consistent neutral-axis position estimation results which are independent of load conditions and patterns.

Bridge deck, structural health monitoring, neutral-axis position, strain measurement, Kalman filter based estimation.

INTRODUCTION

In-service bridge structures are subject to age-related deterioration, service demands for increasing traffic flow and heavier truck loads, natural or man-made disasters, leading to concerns regarding the safety and serviceability of the bridges. Continuous awareness of the evolution of the structural condition of in-service bridge structures is of great value for their owners as it allows making informed decisions on the maintenance and management of the infrastructure assets. Long-term structural health monitoring (SHM), on a continuous basis, provides plentiful information regarding structural behavior by various sensors and traces the health status of existing structures in a real-time way so that early warnings could be signaled before catastrophic failure happens (Aktan *et al*. 2001; Mufti 2002; Ko and Ni 2005; Fujino *et al*. 2009; Ni *et al*. 2011).

Real-time monitoring of strain is emerging as a critical strategy in the assessment, inspection and decision making on maintenance/repair of bridge structures (Catbas and Aktan 2002; Chakraborty and DeWolf 2006; Adewuyi *et al*. 2009; Liu *et al*. 2009; Wang and Yim 2010; Ni *et al*. 2012; Xia *et al*. 2012). Strain data can be directly used to indicate the safety reserve of a bridge component or provide information on the load-carrying capacity of the whole bridge; they would be better suited to characterize local damage of a bridge than vibration data when strain gauges are appropriately deployed. The limitation on the spatial resolution of strain measurement using conventional strain gauges (vibrating-wire type and electrical-resistant type) is being broken down by the development of distributed fiber Bragg grating (FBG) and Brillouin optical fiber (BOF) sensing techniques (Li *et al*. 2004; Bastianini *et al*. 2007; Glišić and Inaudi 2007; Wu *et al*. 2008; Ansari 2009; Bao and Chen 2011).

Bridge deck that directly carries traffic load is one of the most critical parts of a bridge system. Deterioration of bridge deck can cause public inconvenience, travel delay, economic impact, and even life lost, giving rise to the most severe problem for the highway industry today. For example, the deck trusses of the I-35W Bridge over the Mississippi River in Minneapolis, Minnesota, USA collapsed on August 1, 2007 without warning (NTSB 2008). As a result of the catastrophic failure, 13 people died and 145 people were injured. This accident highlights again the importance of incorporating structural monitoring technologies into current bridge management programs to prevent similar tragedies in the future. In selecting monitoring-based indices for bridge deck condition assessment, their sensitivity to damage and robustness with respect to random traffic load patterns are two main factors of concern.

The neutral-axis position of bridge deck sections has been proposed as a damage indicator for bridge deck assessment because it reflects the local cross-section property and shifts when damage on the deck cross-section occurs (Chakraborty and DeWolf 2006; Cardini and DeWolf 2009; Xia 2011). Although the strain responses at different points of a deck cross-section under varying traffic loading evolve with time, their ratio would keep constant in the absence of damage and it can be used to derive the neutral-axis position. It has been demonstrated that the strain-derived neutral-axis position is considerably sensitive to local damage on the deck (Xia 2011). However, the accuracy of neutral-axis position estimation directly using the measured strain data might be significantly distorted in the presence of measurement noise and varying traffic load patterns. In this study, a Kalman filter (KF) estimator is formulated to reliably locate the neutral-axis position from measured strain responses under traffic loading. Its capability for consistently locating the neutral-axis position under varying traffic load patterns is verified using the field monitoring data of traffic-induced strain responses from the instrumented Tsing Ma Bridge (TMB) which carries both highway and railway traffic.

NEUTRAL-AXIS POSITION AND KF ESTIMATOR

Direct Estimation of Neutral-axis Position

Beam-like bridge deck behaves like a flexural beam when traffic loads cause it to bend. According to the Euler-Bernoulli beam theory, the plane cross-sections of a bending beam remain plane after deformation and the strain distribution is linear over the depth of the cross-section. The strains at the bottom and top locations of the section are denoted by ε_b and ε_t, respectively, as shown in Figure 1. Following the geometric relation, the ratio of ε_b to ε_t can be expressed as

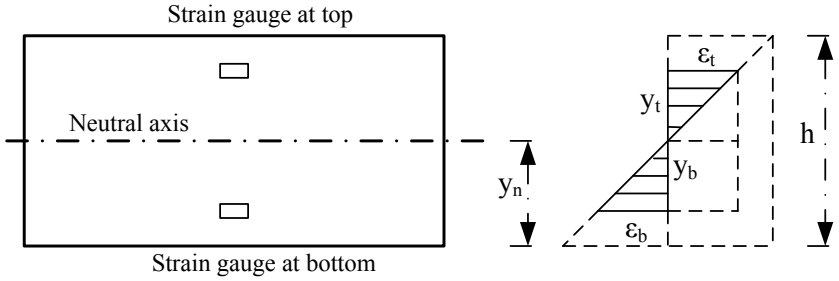

Figure 1 Flexural strain distribution on beam cross-section

$$\frac{\varepsilon_b}{\varepsilon_t} = \frac{y_b}{y_t} \tag{1}$$

where y_b is the distance between the bottom and the neutral axis; and y_t is the distance between the top and the neutral axis. From Eq. (1), we can obtain

$$\frac{\varepsilon_b}{\varepsilon_b + \varepsilon_t} = \frac{y_b}{y_b + y_t} = \frac{y_h}{h} \tag{2}$$

where y_n denotes the neutral-axis location of the cross-section; and h is the depth of the cross-section.

Eq. (2) relates the neutral-axis position in ratio (y_h/h) with the strains at the bottom and top of a cross-section. Under traffic loads, bending behavior dominates the response of beam-like bridge deck. When the strain responses at the top and bottom points are measured, the neutral-axis position can be estimated by

$$\hat{r} = \frac{\varepsilon_b}{\varepsilon_b + \varepsilon_t} \tag{3}$$

It is known (Xia 2011) that the efficiency of the above formula in estimating the neutral-axis position can be ensured only on condition that the measurement data are noise-free.

KF-based Estimation of Neutral-axis Position

The KF is purposed to use measurements observed over time (containing noise and other inaccuracies) to produce values that tend to be closer to the true values of the measurements (Kalman 1960; Brown and Hwang 1997). In this study, the neutral-axis position in ratio ($r = y_n/h$) is taken as the state variable to be estimated.

Because there is neither deterministic disturbance nor control scalar, the discrete model of the state in concern can be expressed by

$$r_k = \Phi_k r_{k-1} + w_k \tag{4}$$

where Φ_k is the propagation scalar that propagates the state from one sampling instant to the next; and w_k is the white process noise. The measurement equation is given as

$$z_k = H r_k + v_k \tag{5}$$

where H is the measurement scalar that relates the state to the observation z_k; and v_k is the measurement noise. The discrete KF equation for the system described by Eqs. (4) and (5) is

$$\hat{r}_k = \Phi_k \hat{r}_{k-1} + K_k (z_k - H\Phi_k \hat{r}_{k-1}) \tag{6}$$

and the error in the estimate can be expressed as

$$\tilde{r}_k = r_k - \hat{r}_k = r_k - \Phi_k \hat{r}_{k-1} - K_k (H r_k + v_k - H\Phi_k \hat{r}_{k-1}) \tag{7}$$

Noting that the state at time k can be replaced by an alternate expression at time k-1, it is obtained that

$$\tilde{r}_k = r_k - \hat{r}_k = r_k - \Phi_k \hat{r}_{k-1} - K_k (H\Phi_k r_{k-1} + H w_k + v_k - H\Phi_k \hat{r}_{k-1}) \tag{8}$$

or

$$\tilde{r}_k = (1 - K_k H)\tilde{r}_{k-1}\Phi_k + (1 - K_k H) w_k - K_k v_k \tag{9}$$

By squaring and then taking expectations of both sides of Eq. (9), we obtain the following covariance equation

$$P_k = (1 - K_k H)^2 M_k + K_k^2 R_k \tag{10}$$

where $P_k = E(\tilde{r}_k^2)$, $Q_k = E(w_k^2)$, $R_k = E(v_k^2)$, and $M_k = P_{k-1}\Phi_k^2 + Q_k$.

The KF gain K_k that minimizes the variance of the error in the estimate can be found by taking the derivative of Eq. (10) with respect to the gain and setting it equal to zero:

$$\frac{\partial P_k}{\partial K_k} = 2(1 - K_k H) M_k (-H) + 2 K_k R_k = 0 \tag{11}$$

Solving the above equation for the gain yields

$$K_k = \frac{M_k H}{H^2 M_k + R_k} = M_k H (H^2 M_k + R_k)^{-1} \tag{12}$$

Substitution of the optimal gain into the covariance equation gives

$$P_k = \frac{R_k K_k}{H} = \frac{M_k H - H^2 M_k K_k}{H} = M_k - H M_k K_k = 0 \tag{13}$$

or, more simply,

$$P_k = (1 - K_k H) M_k \tag{14}$$

The derivation given above shows that the gain of the KF is chosen to minimize the variance of the error in the estimate. The optimal gain at each step can be iteratively obtained by using Eqs. (10), (12) and (14).

VERIFICATION USING FIELD MONITORING DATA

Instrumented Tsing Ma Bridge (TMB)

The Tsing Ma Bridge (TMB) with a main span of 1,377 m, as shown in Figure 2, is a suspension bridge in Hong Kong carrying both highway and railway traffic. The deck of TMB is a double-deck box with truss stiffening and non-structural edge fairing as illustrated in Figure 3. The longitudinal diagonally braced trusses on north and south sides of the cross-section consist of top chords, diagonal struts and bottom chords. In the longitudinal direction, the bridge deck continuously expands from the Ma Wan abutment to the Tsing Yi abutment. On the Ma Wan abutment, the bridge deck is supported on hinge bearings which allow the rotation of bridge deck other than the displacement; whereas an expansion joint is provided on the Tsing Yi abutment to accommodate the longitudinal displacement of the deck due to temperature variation. The constraint condition of the bridge deck on the internal piers and towers allows free movement of the deck in the longitudinal direction.

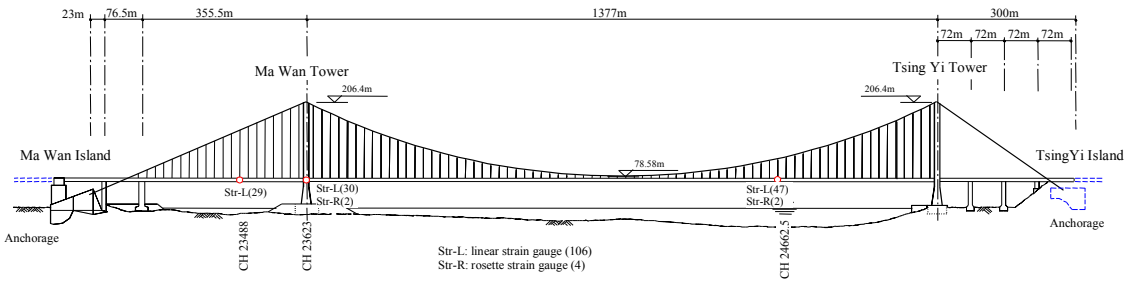

Figure 2 Tsing Ma Bridge and sections instrumented with strain gauges

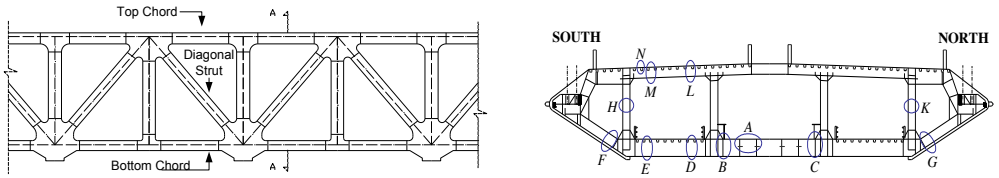

(a) (b)

Figure 3 Deck trusses of TMB: (a) elevation view; (b) cross-section view

As part of a long-term SHM system instrumented on TMB (Wong 2007; Wong and Ni 2011), 110 strain gauges were installed to measure dynamic strain response at three bridge deck sections denoted by CH23488, CH23623 and CH24662.5 (chain mileages of the deck sections of TMB) as shown in Figure 2. The deployment locations of strain gauges include the chord members (top chords, diagonal struts and bottom chords) of the longitudinal trusses, cross-frame chord members, bracing members, deck trough and rocker bearings at one tower. The strain gauges installed on the deck truss members include single, pair and rosette sensors. The strain data were continuously acquired at sampling rates of 25.6 Hz and 51.2 Hz, respectively.

Extraction of Traffic-induced Strain Responses

Figure 4 illustrates typical one-day monitoring data of strain responses of the longitudinal top and bottom chords on deck section CH24662.50 under weak wind condition. It is seen that the magnitude of the strain responses acquired at about 2:00 to 5:00 am is relatively small since railway traffic ceases to operate during this time period. It is also observed that there is a trend ingredient (low-frequency component) in the strain time histories, which is attributed to the daily cycle effect of temperature variation after confirming its synchronism with the longitudinal displacement time history concurrently measured at the expansion joint. The ingredient caused by the temperature effect, although considerably large, contributes little to the stress because the majority of temperature-induced strain is released by movement and rotation of the bridge deck at the expansion joint and bearings.

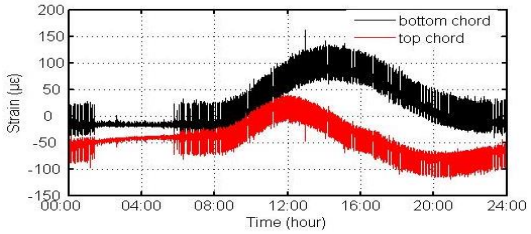

Figure 4 Total strain responses of top and bottom chords on deck section CH24662.5

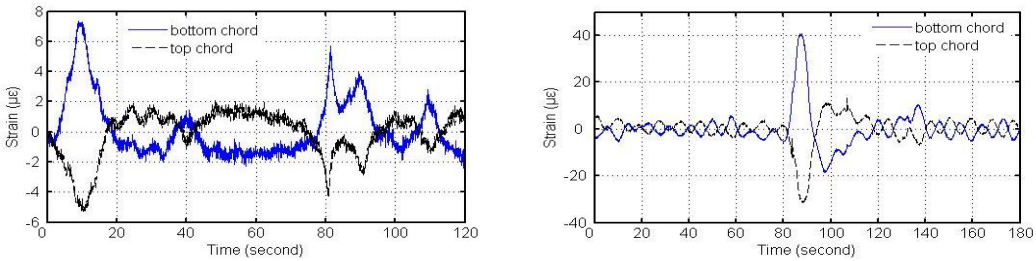
A multi-component decomposition method (Ni *et al*. 2011), which uses the de-correlation and perfect reconstruction (PR) properties of discrete wavelet transform and embeds a correlation criterion for physical source extraction, has been developed to infer the temperature-induced ingredient from raw measurement data of strain and extract the traffic-induced strain response. Figure 5 shows the extracted traffic-induced strain responses of the longitudinal top and bottom chords on deck section CH24662.50 after eliminating temperature effect. From Figures 4 and 5, it is observed that the measured raw (total) strain responses do not display the flexural behavior owing to the presence of temperature effect. After eliminating temperature effect, the strain responses (which are mainly caused by traffic loading) at the top and bottom chords of the same deck section

evolve with time in almost identical amplitudes but opposite directions, indicating flexural bending behavior of the bridge deck under traffic loading.



(a) (b)

Figure 5 Traffic-induced strain responses of top and bottom chords on deck section CH24662.5: (a) under highway traffic; (b) under railway traffic

Estimation of Neutral-axis Position under Different Load Patterns

In the absence of damage, the estimated neutral-axis position should be independent of the traffic load patterns. It is testified herein using the field monitoring data from TMB. Figure 6 shows the traffic-induced strain responses experienced by the longitudinal top and bottom chords on deck section CH24662.50 for a typical day (24 hours) under weak wind condition, which are extracted from raw measurement data after eliminating temperature effect. As afore-mentioned, the strain responses acquired during about 2:00 to 5:00 are relatively small because of no railway traffic. It evidences that the strain responses are sensitive to traffic load patterns.

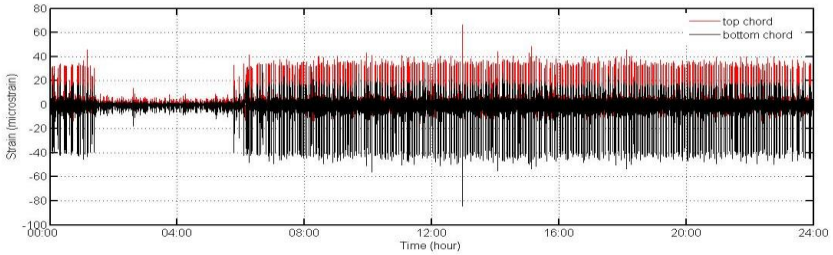


Figure 6 Traffic-induced strain responses experienced by top and bottom chords on deck section CH24662.5 for a typical day

Four segments of the strain response time histories with different traffic load patterns are selected for the present study: (i) 00:00 to 02:00; (ii) 03:00 to 05:00; (iii) 05:00 to 07:00; (iv) 10:00 to 12:00. The KF estimator is executed to estimate the neutral-axis position of the deck section from these four segments of strain data, respectively. Figure 7 shows the traffic-induced strain responses during 00:00 to 02:00 (segment 1), which include a transition of traffic pattern from having to not having railway traffic. Although this transition pattern is remarkably reflected in the strain responses, it does not affect the neutral-axis position estimated by the KF estimator as shown in Figure 8. Figure 9 illustrates the strain response data acquired during 03:00 to 05:00 (segment 2). Because there is no railway traffic in this time period, the magnitude of the strain responses is much lower than other segments, and a relatively low signal-to-noise ratio is expected for this segment of monitoring data. The neutral-axis position estimated by the KF estimator during this time period is shown in Figure 10.

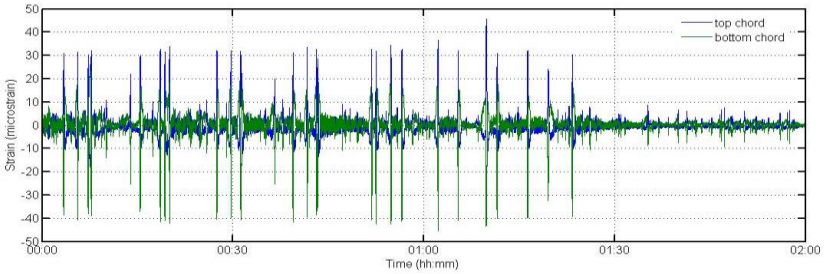

Figure 7 Traffic-induced strain time histories during 00:00 to 02:00

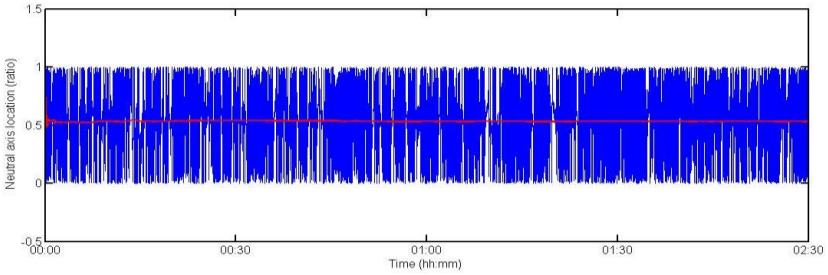

Figure 8 Estimated neutral-axis position from strain data acquired during 00:00 to 02:00

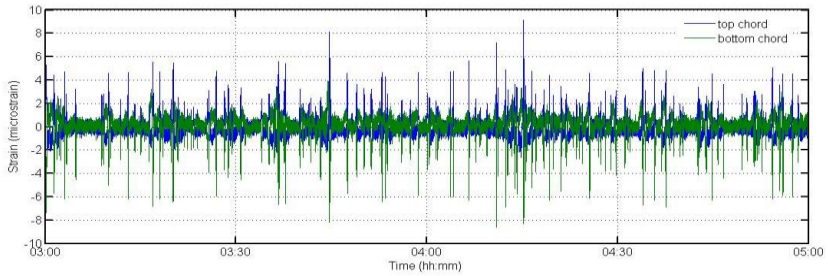

Figure 9 Traffic-induced strain time histories during 03:00 to 05:00

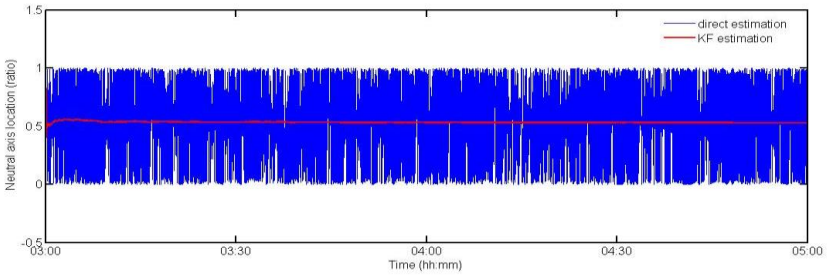

Figure 10 Estimated neutral-axis position from strain data acquired during 03:00 to 05:00

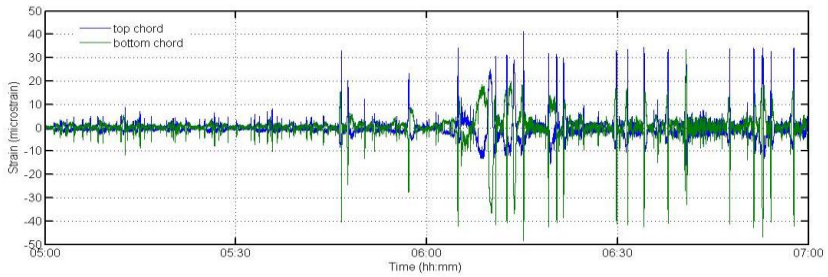

Figure 11 Traffic-induced strain time histories during 05:00 to 07:00

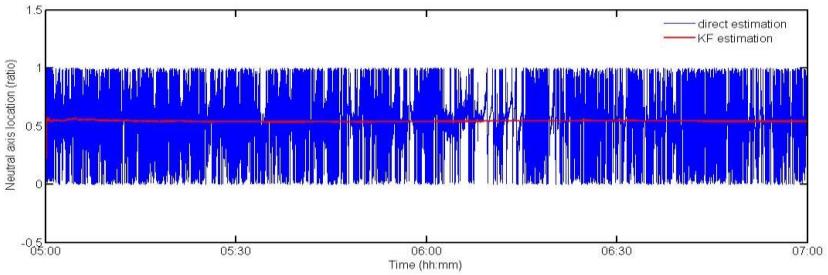

Figure 12 Estimated neutral-axis position from strain data acquired during 05:00 to 07:00

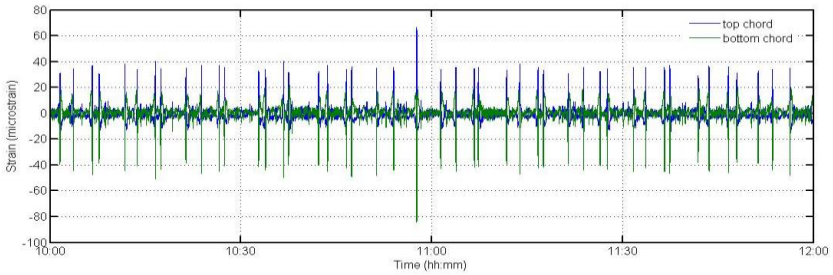

Figure 13 Traffic-induced strain time histories during 10:00 to 12:00

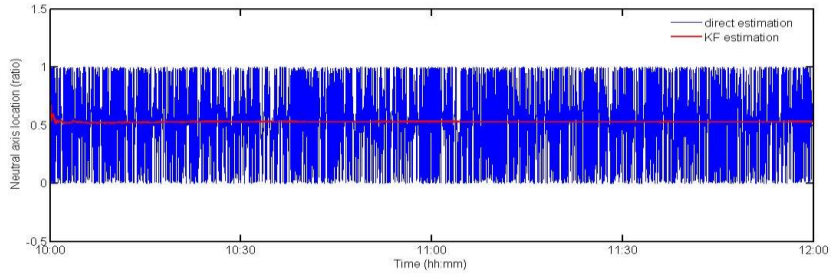

Figure 14 Estimated neutral-axis position from strain data acquired during 10:00 to 12:00

In the time period of 05:00 to 07:00 (segment 3), there is a traffic pattern transition from not having to having railway traffic as shown in Figure 11. Figure 12 illustrates the neutral-axis position estimated by the KF estimator during this time period, which is not affected by the traffic pattern transition. Figure 13 shows the traffic-induced strain responses in the time period of 10:00 to 12:00 (segment 4), where the load pattern is characterized by mixed highway and railway traffic. The estimation results of the neutral-axis position by the KF estimator are illustrated in Figure 14. No observable variation in the estimated neutral-axis position is found.

The estimated neutral-axis position by using the whole-day (24-hour) data is illustrated in Figure 15. It is observed that there are no remarkable transition patterns appearing in the sequence of the estimated neutral-axis position although they do exist in the strain response time histories. Table 1 summarizes the estimated values of the neutral-axis position when using different segments of strain monitoring data. The estimated neutral-axis position ranges from 0.5408047 to 0.5476296 (-0.49% to 0.77% of the mean value) under different traffic load patterns (highway traffic, railway traffic, and their combination). It is concluded that the proposed KF estimator can achieve consistent and robust estimation of the neutral-axis position using strain monitoring data obtained under different traffic load patterns. The application of using the estimated neutral-axis position for damage detection of bridge deck is addressed elsewhere (Xia 2011).

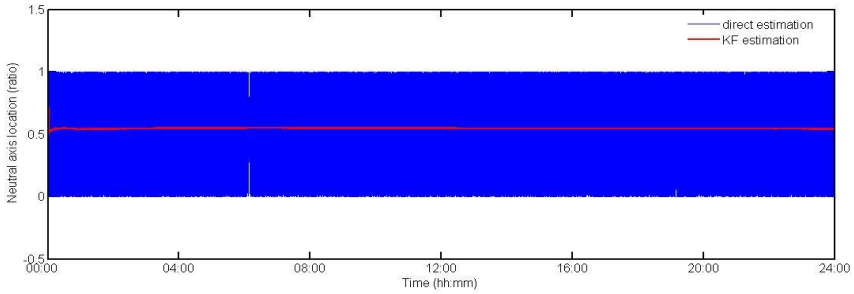

Figure 15 Estimated neutral-axis position from strain data acquired during 00:00 to 24:00

Table 1 Estimated neutral-axis position in ratio under different traffic load patterns

Time period	Estimated neutral-axis position in ratio
00:00 to 02:00	0.5423849
03:00 to 05:00	0.5476295
05:00 to 07:00	0.5425693
10:00 to 12:00	0.5408047
00:00 to 24:00	0.5438627

CONCLUSIONS

Because of its high sensitivity to local damage, the neutral-axis position estimated from strain responses under traffic loading has been considered as a damage indicator for bridge deck assessment. However, the presence of measurement noise and varying traffic load patterns might significantly affect the accuracy of neutral-axis position estimation. In this study, a KF estimator was formulated to locate the neutral-axis position of bridge deck from measured strain responses under traffic loading. Its capability for consistently locating the neutral-axis position under varying traffic load patterns was verified using the field monitoring data from the instrumented TMB. The field monitoring data from TMB evidences the flexural bending behavior of the bridge deck under traffic loading. The validation study using the field monitoring data shows that the estimated neutral-axis position from the traffic-induced strain response data of TMB remains almost unchanged under different traffic environments (highway traffic, railway traffic, and their combination), verifying the robustness of the proposed KF estimator to varying traffic loading and the independence of the neutral-axis position on traffic load patterns.

ABSTRACT

Concrete bridge is widely used in highway infrastructure in China, especially in short and medium span bridges. Concrete bridges are prone to fatigue failure under the coupled actions of repeated vehicles loads, environment and material degradation. In recent years, the traffic volume and vehicle weights of highway bridges have been continuously increasing, so concrete bridge fatigue problem becomes more serious. This paper introduces advanced fatigue safety monitoring techniques and fatigue performance assessment methods for short and medium span concrete girder bridges. Weigh-in-motion (WIM) system was used to record the real traffic volume, and then the acquired load spectrum was applied on typical concrete bridges through Matlab to analyze the fatigue performance of different bridge types. From the analysis results, several typical short and medium span concrete girder bridges are selected to conduct long-term service monitoring. The cross section types include hollow slab girder, T-girder and short box girder, and the structure types contain simple supported bridge and continuous girder bridge. WIM technique, dynamic strain monitoring technique and acoustic emission technique are used to monitor the key details. Fatigue performance is assessed and analyzed based on monitoring data, considering traffic increase, overload and corrosion factors.

KEYWORDS

Concrete girder bridge, fatigue safety monitoring, traffic load, corrosion fatigue, fatigue assessment.

INTRODUCTION

In recent years, as the traffic volume and vehicle weights of highway bridges are continuously increasing in China, concrete bridges are subject to serious fatigue problems (Wang et al. 2010, Wang et al. 2012, Wang et al. 2013a). With service life increasing, concrete material aging and mechanical behavior deterioration will appear gradually, as shown in Figures 1. Affected by service environment and traffic effect, fatigue damage of reinforced concrete (RC) bridges could become prominent after years' in-service. The initiation and accumulation of fatigue damage will lead to rebar fatigue and fracture failure.

Figure 1 Corrosion and damage in concrete girder bridges

Fatigue and fracture study of concrete bridge was carried out in America and Europe 60 years ago. Oh studied cumulative damage theory of concrete structures under variable-amplitude fatigue loading (Oh 1991). Tilly studied the reduction coefficient of fatigue strength of rebar in different corrosion levels, which was used to evaluate durability and remaining life of concrete bridges (Tilly 1988). Based on fatigue failure mechanism of concrete bridges, fatigue life assessment approaches using S-N curves and fracture mechanics were proposed by Schläfli and Brühwiler to evaluate the fatigue safety of highway and railway bridges in Swiss (Schläfli & Brühwiler 1998). In China, researchers began to pay attention to fatigue problems in concrete bridges in recent years when many concrete bridges are suffered from several diseases and the service performance cannot be guaranteed. Technique fusion of Weigh-In-Motion (WIM), dynamic strain monitoring and acoustic emission

was adopted by Wang to monitor concrete girder bridges. Fatigue safety assessment methods based on S-N curves and fracture mechanics were developed to assess the service safety (Wang et al. 2013b). Zhu proposed a simplified numerical simulation method for the deterioration process of in-service reinforced concrete (RC) bridges and the reliability and availability of this method was verified by a simple supported RC girder bridge (Zhu 2012). Based on current research achievements, relevant design codes and specifications should be developed to guide engineering fatigue design and in-service maintenance.

This paper introduces advanced fatigue safety monitoring techniques and fatigue performance assessment methods for short and medium span concrete girder bridges. Weigh-in-motion (WIM) system was used to record real traffic volume, and then the acquired load spectrum was applied on typical concrete bridges through Matlab to analyze the fatigue performance of different bridge types. From the analysis results, several typical short and medium span concrete girder bridges are selected to conduct long-term service monitoring. The cross section types include hollow slab girder, T-girder and short box girder, and the structure types contain simple supported bridge and continuous girder bridge. Fatigue performance is assessed and analyzed based on monitoring data, considering traffic increase, overload and corrosion factors.

FATIGUE MONITORING TECHNIQUES AND ASSESSMENT METHODS

Fatigue Safety Monitoring Techniques

WIM is an advanced weighing system which includes two piezoelectric sensors, one induction coil sensor and a data acquisition unit. A temperature sensor is set in pavement, which can acquire real temperature information to provide proper temperature compensation to the system. The controlling unit set beside the bridge is linked to the piezoelectric sensors and the induction coil. When vehicles pass the bridge, the induction coil picks up different responses, and the piezoelectric sensors send the information to the acquisition unit. Then the controlling unit can calculator the specific information of the passed vehicle and record the information. The system can record comprehensive information about the vehicles moving through, such as weight, speed, direction, axle number and so on.

Fatigue damage of concrete girder bridge is caused by the coupled actions of environment, cyclic vehicle loads and material degradation. Long time continuous monitoring is a reliable way to study the structural response in a certain period, which is also a popular method to assess the fatigue performance for existing bridges. Fatigue stress monitoring can record the stress history of fatigue sensitive details, and the stress spectrum can be calculated by rain-flow method to assess the fatigue performance. In situ monitoring, strain gauges was attached on the concrete surface and the dynamic strain acquisition is controlled by computer through network cables.

Fatigue Life Assessment by S-N Curve

The hypothesis of the linear damage accumulation was derived by Miner, which was often referred to as the Palmgren-Miner rule (Miner 1945). It defined that $D=1$ indicated failure, where D was the damage degree in material. This rule also assumed a linearly accumulative fatigue damage process. Namely in each stress range level σ_i, the damage fraction D_i was linearly proportional to n_i, where n_i was the number of cycles at σ_i and D_i was the ratio of n_i / N_i. N_i means the total number of cycles that would cause failure under that stress range level. The following linear damage accumulation rule is a sum of all the damage fractions for all stress range levels (Equation 1).

$$D = \sum D_i = \sum \frac{n_i}{N_i} \tag{1}$$

According to the above analysis, damage accumulations of RC bridges were linearly calculated with the damage threshold value D_c. Thus, the cumulative fatigue damage of RC bridge under fatigue loads for one year can be estimated as Equation 2.

$$D_T = \sum \frac{n_i}{N_i} \tag{2}$$

Where D_T is the fatigue damage amount in the certain period T, n_i is the number of cycles at the stress range level $\Delta\sigma_i$ in the certain period T, N_i is the total number of cycles that would cause failure under the stress range level $\Delta\sigma_i$. Then the bridge fatigue life Y can be given as Equation 3.

$$Y = \frac{D_c}{D_T} \times T \tag{3}$$

Where D_c is the critical fatigue damage and it is defined as 1.0 when the fatigue failure will occur.

Fatigue Life Assessment Based on Fracture Mechanics

For steel reinforcement, fracture mechanics describes crack growth as a function of material parameters, crack size geometry and geometry of specimen. Fracture of rebar occurs, when the depth of crack reaches $a = a_{fr}$ and the applied stress σ_0 is equal to the resistance of the remaining cross section. In a fatigue test with a constant stress range that stress corresponds to the superior stress level, thus $\sigma_0 = \sigma_{sup}$. The brittle fracture and fracture by yielding are two existed fracture modes (Herwig 2008).

In order to calculate the crack propagation, the initial flaw on a cylindrical steel bar is assumed as a semi-circular crack, which has a depth of $a = a_i$. The plane, in which the semi-circular crack lies, is perpendicular to the steel axis. The stable crack growth from initial crack is assumed as follows (Figure 2).

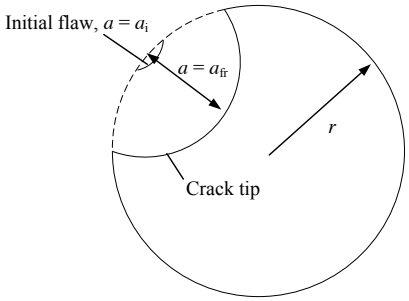

Figure 2 The cross section of rebar with initial flaw and crack propagation

Then the Paris Law given in Equation 4 is obtained by transformation.

$$\frac{da}{dN} = C\Delta K^m \tag{4}$$

Where *C* and *m* are parameters based on the material.

FATIGUE PERFORMANCE ANALYSIS FOR TYPICAL CONCRETE GIRGER BRIDGES

Concrete Hollow Slab Girder Bridge

Concrete hollow slab girder bridge is appropriate for the span length ranging from 4m to 25m. Four different span lengths were chosen to calculate the fatigue stress spectrums in this paper, the span length is 10m, 13m 16m and 20m, respectively. In engineering application, several hollow slab girders are hinged together to form the bridge, the transverse distribution coefficient of outer slab girder is larger than other slab girders when a vehicle passes through the bridge. Therefore, to ensure structural safety, the transverse distribution coefficient of the outer slab girder under eccentric loading case was adopted to calculate the fatigue stress. Analysis result is shown in Table 1, it can be learned that hollow slab girder bridges with larger span have lower fatigue stress range and tend to suffer less fatigue damage. As for the longitudinal steel bar in the mid-span section, the stress level is relatively low since the maximum stress reaches just 12MPa.

Concrete T-girder Bridge

Considering the most disadvantage live loading case and different span length, the fatigue stress range of the T-girder bridges with five T-girders in transverse direction were obtained. Simple supported and continuous concrete T-girder bridges with different span length and different span numbers are taken into considered. The span length for simple supported bridge is 20m, 25m, 30m, 35m and 40m, the span length for continuous bridge is 20m, 30m and 40m with 3 or 4 spans. For continuous girder bridge, the fatigue stress range of side span is higher than that of mid-spans, so fatigue stress range of steel bar in side span is calculated, and the results are shown in Table 2. For simple supported concrete T-girder bridges, fatigue stress level of 20m-span and 25m-span girders are similar, the maximum fatigue stress is 23MPa. With the span length increase, the maximum stress tend to decrease, which indicates the simple supported T-girder bridge with larger span length tends to

suffer less fatigue damage under the same vehicle spectrum. As to continuous concrete T-girder bridges, fatigue stress level is obviously lower than simple supported bridge (Table 2(b)). Similar as simple supported bridges, continuous T-girder with larger span length tend to have lower fatigue stress and suffer less fatigue damage. However, the span numbers have little influence on the fatigue stress. Based on the calculation results, it indicates that shorter span T-girder bridges suffer more fatigue damage.

Concrete Box-girder Bridge

According to general usage status, concrete box-girder bridge with four box-girders in transverse direction is selected to analyze the fatigue stress. The span length for simple supported bridge is 10m, 13m, 16m and 20m,

the span length for continuous bridge is 20m, 30m and 40m with 3 or 4 spans. Similar to the hollow slab girder bridges and T-girder bridges, the transverse distribution coefficient of the outer box girder under eccentric loading case is adopted to calculate the fatigue stress. From the analysis result (Table 3), simple supported concrete box-girder bridge tends to suffer higher stress, but the maximum stress decreases with the span length increase. For continuous concrete box-girder bridge, the span numbers have little influence on the fatigue stress.

CASE STUDIES: FATIGUE SAFETY MONITORING AND ASSESSMENT FOR EXISTING CONCRETE GIRDER BRIDGES

Concrete Hollow Slab Girder Bridge

Miazui Bridge (Figure 3) is a typical prestressed concrete (PC) hollow slab girder bridge, which was open to traffic in 2015. The layout is 7×20m, the concrete deck is continuous while the slab girder is simple supported. The width of the bridge is 8.5m including 2 lanes in two directions, and the cross-section contains 6 slab girders with hinge joints connecting each other. Based on the manual traffic monitoring result, there are many heavy trucks passing across the bridge, so dynamic strain monitoring is conducted continuously for several days. Strain gauges are mainly arranged on the bottom plate of the mid-span cross section.

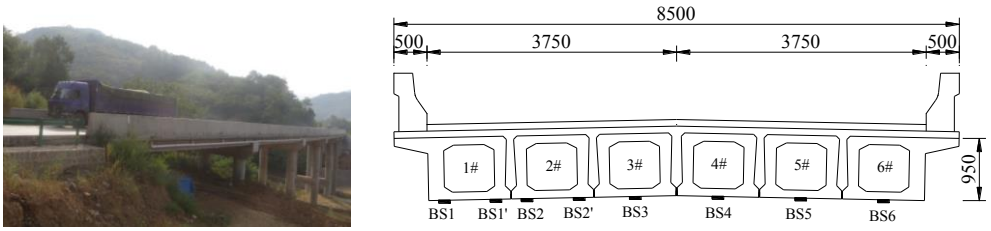

Figure 3 Miaozui Bridge (Unit: mm)

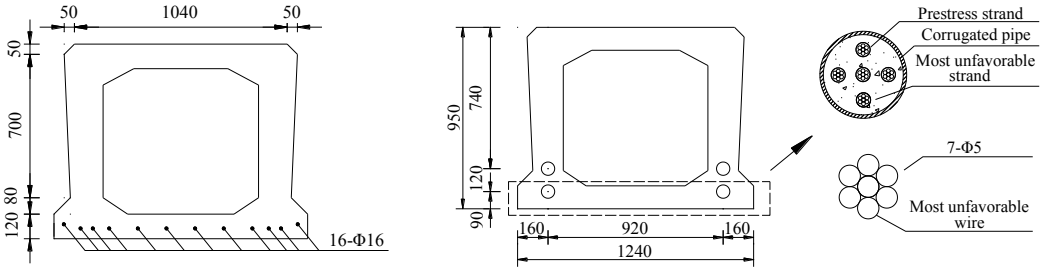
In order to assess the fatigue performance of hollow slab girder bridge, fatigue stress of longitudinal steel bar and prestress strand (Figure 4) are selected to analyze the fatigue stress under real traffic load. According to plane strain assumption, strain of longitudinal steel bar and most unfavorable wire is calculated. Since the steel bars and prestress steel tendons or strands in the lower position are subject to more fatigue damage, the lowest longitudinal steel bar and the lowest prestress steel wires or strands are selected to evaluate the fatigue life. S-N curve for longitudinal steel bar used in this paper is from European Convention for Constructional Steelwork

(ECCS 1985), S-N curve for prestress steel wires is proposed by Song (Song 2006), and S-N curve for prestress steel strand is suggested by Ma (Ma 2000). The diameter of longitudinal steel bar is 16mm, the yield strength is 335MPa. In fatigue performance assessment based on fracture mechanics, fracture toughness K_{IC} is taken as $50\text{MPa}\cdot\sqrt{m}$, fracture constants C, m are taken as 2×10^{-13} and 4, respectively. Threshold value of fatigue crack propagation ΔK_{th} is $2.0\text{MPa}\cdot\sqrt{m}$, the initial crack depth is assumed as 0.5mm since no crack has been detected.



(a) Longitudinal steel bar (b) Prestress strand layout

Figure 4 Longitudinal steel bar and prestress strand layout layout (Unit: mm)

Considering contributions of low stress ranges, fatigue life of the lowest steel bar in PC hollow slab girder bridge is 170002 years for girders under the heavy lane, and fatigue life of lowest prestress steel wire is 12883 years (Table 4). Based on LEFM, fatigue life of the lowest steel bar in PC hollow slab girder bridge is 29082 years for girders under the heavy lane, and fatigue life of lowest prestress steel wire is 13198 years. Since Miaozui Bridge was open to traffic only several months, the traffic volume is relatively small, fatigue life of longitudinal steel bar and most unfavorable prestress wire is far longer than design service life. But if fatigue crack occurs on concrete and corrosion occurs on the steel bar or the prestress wire, the fatigue life will decrease sharply. The fatigue life will also decrease if the traffic volume increases in the future.

Table 4 Fatigue life evaluation of PC hollow slab girder bridges

Object	Fatigue life (Year)	
	S-N Curve	LEFM
Steel bar	170002	29082
Prestress steel wire	12883	13198

Concrete T-girder Bridge

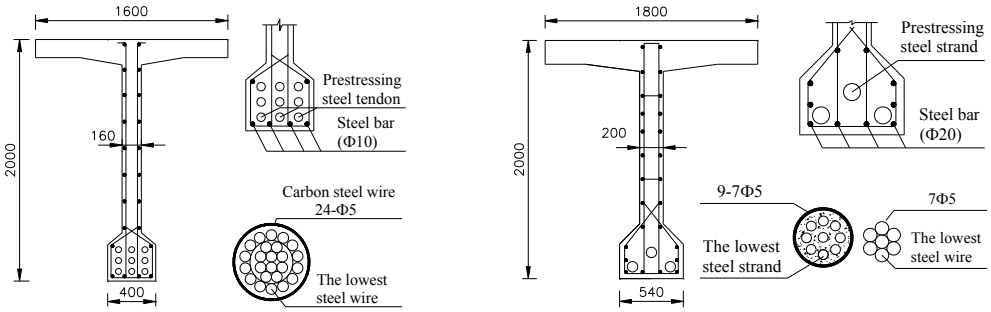
Two typical prestressed concrete (PC) T-girder bridges, i.e., a simple-supported PC girder bridge and a continuous PC girder bridge are chosen to evaluate the fatigue life using different methods. The simple-supported PC girder bridge shown in Figure 5(a) is a freeway bridge, which contains two separate parts composed of 12 T-girders with the total width of 26.2m. The continuous one was open to traffic in 2013, which is parallel to the old simple-supported PC girder bridge. As shown in Figure 5(b), the cross-section contains 8 T-girders with the total width of 19.75m. The every span length of both bridges is all 30m. These two bridges are in the same district, the traffic volume and vehicle kinds are similar.

To evaluate the fatigue life of the PC T-girder bridges, in-situ dynamic strain monitoring was conducted continuously over one month, and traffic volume was recorded manually. Figure 6(a) is the cross section of simple supported PC T-girder bridge, which is built in 1992. Carbon steel wires are used in prestress steel tendons, and every tendon contains 24 wires with 5mm in diameter. Longitudinal steel bar in the bottom part of T-girder is 20mm in diameter. Figure 6(b) is the cross section of continuous PC T-girder bridge, prestressing steel strands (9-7Φ5) and 20-diameter steel bars are used in T-girders.

(a) Simple supported PC T-girder bridge (b) Continuous PC T-girder bridge

Figure 5 The two PC T-girder bridges

In order to considering contributions of corrosion and low stress ranges, fatigue categories of steel bars and prestress steel wires or strands are lowered to the 65% (Walker 1975). Considering contributions of low stress ranges, fatigue life of the lowest steel bar in simple supported PC girder bridge is 4421 and 9380 years for girders under the heavy lane and light lane, respectively; and fatigue life of lowest prestress steel wire is 1390 and 1616 years. Fatigue life of lowest steel bar in continuous PC girder bridge is 145389 and 333211 years for girders under the heavy lane and light lane, respectively; and fatigue life of lowest prestress steel wire is 32100 and 46751 years. Based on LEFM and the depth of initial cracks are assumed as 1.0mm considering the corrosion pit flaws, fatigue life of the lowest steel bar in simple supported PC girder bridge is 1094 and 1287 years for girders under the heavy lane and light lane, respectively; and fatigue life of lowest prestress steel wire is 1734 and 2326 years. Fatigue life of lowest steel bar in continuous PC girder bridge is 29186 and 39763 years for girders under the heavy lane and light lane, respectively; and fatigue life of lowest prestress steel wire is 24773 and 26661 years, as indicated in Table 5.



(a) Simple supported PC Girder (b) Continuous PC Girder

Figure 6 Critical Steel Bar and Steel Wire in PC Girder Bridges

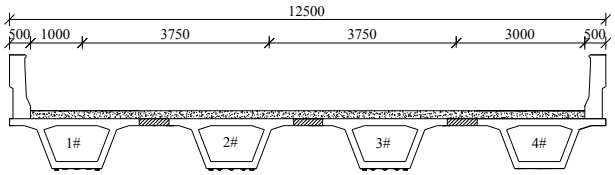
Table 5 Fatigue Life Evaluation Results of PC Bridges

Bridge	Position	Object	Fatigue life (Year)	
			S-N Curve	LEFM
Simple supported PC bridge	Heavy Lane	Prestress steel wire	1390	1734
		Steel bar	4421	1094
	Light Lane	Prestress steel wire	1616	2326
		Steel bar	9380	1287
Continuous PC bridge	Heavy Lane	Prestress steel wire	32100	24773
		Steel bar	145389	29186
	Light Lane	Prestress steel wire	46751	26661
		Steel bar	333211	39763

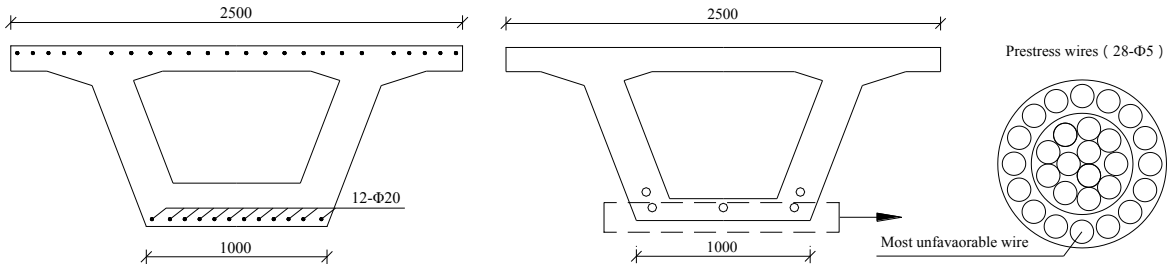
From the two PC bridges evaluation results, it can be concluded that under the similar traffic load, the fatigue life of continuous PC girder bridge is longer than simple supported PC girder bridge. For PC girder bridges, fatigue life of steel bar and wire calculated by LEFM method or S-N Curve method is more large than the bridge design service life (100 years), but the fatigue life should be shortened sharply considering the overloading, concrete crack, corrosion fatigue and durability damage.

Concrete Box-girder Bridge

A separated interchange bridge (Figure 7(a))with box girder is selected to assess the fatigue performance, which was open to traffic in 2004. The span layout is 7×20m continuous PC box girder, the width of the bridge is 12.5m with four box girders in transverse direction. Since there are many heavy trucks passing across this bridge, diseases like fatigue cracking, corrosion and deck damage occurred on the bridge. In order to ensure the structure safety, bridge owners adopted prestress carbon fiber reinforced plate (CFRP) and steel plate to strengthen the bridge. Continuous dynamic strain monitoring is carried out to assess the strengthening effectiveness and fatigue performance of bridge structure after strengthening. The diameter of longitudinal steel bar in the bottom plate is 20mm, the yield strength is 335MPa. Carbon steel wires are used in prestress steel tendons, and every tendon contains 28 wires with 5mm in diameter. Longitudinal steel bar and prestress strands layout are shown in Figure 7(b).



(a) Cross-section layout



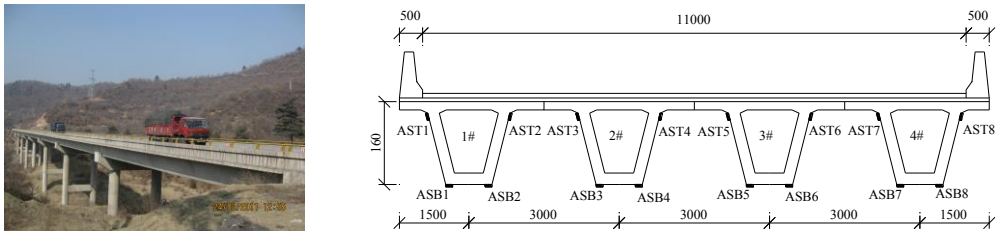
(b) Longitudinal steel bar and prestress strands layout
Figure 7 Separated interchange bridge

Considering contributions of low stress ranges, fatigue life of longitudinal steel bar in box girder is 1940 and 11574 years for side girder and mid-girder, respectively (Table 6). Fatigue life of most unfavorable prestress steel wire is 106687 and 228219 years. Based on LEFM and the depth of initial cracks are assumed as 0.5mm considering the corrosion pit flaws, fatigue life of longitudinal steel bar in box girder is 5888 and 16185 years for side girder and mid-girder, respectively. Fatigue life of most unfavorable prestress steel wire is 4700 and 12858 years. From the fatigue performance assessment results, it can be concluded that fatigue life of steel bar and wire calculated by LEFM method or S-N Curve method is more large than the bridge design service life (100 years) after strengthening.

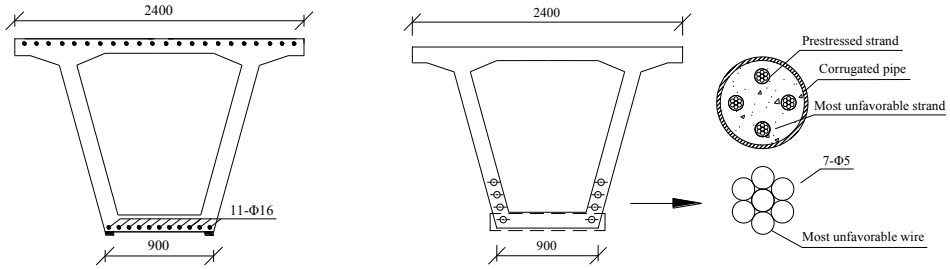
Yaoxian Bridge is a continuous PC box girder bridge open to traffic in 2006 (Figure 8(a)), which is an important bridge of provincial road 305 in Shaanxi Province. The span layout is 4×30m+4×30m, and the cross-section contains four girders in transverse direction. Since the bridge is near a coal mine, the vehicle load of the bridge is diverse, ranging from full-load trucks to small cars, which makes this bridge suffer great stress level. The diameter of longitudinal steel bar in the bottom plate is 16mm, the yield strength is 335MPa. The prestress strand used in the bridge is $4-\Phi j15.2$, the yield strength is 1860MPa. Longitudinal steel bar and prestress strands layout are shown in Figure 8(b). In order to assess the fatigue performance of concrete box girder bridge, situ dynamic strain monitoring was conducted continuously for 21days.

Table 6 Fatigue life assessment of separated interchange bridge

Girder number	Position	Object	Fatigue life (Year)	
			S-N Curve	LEFM
1	Side girder	Steel bar	1940	5888
		Prestress steel wire	106687	4700
2	Mid-girder	Steel bar	11574	16185
		Prestress steel wire	228219	12858



(a) Cross-section layout



(b) Longitudinal steel bar and prestress strands layout

Figure 8 Yaoxian Bridge

Longitudinal steel bar and most unfavorable prestress wire are selected to evaluate the fatigue performance, fatigue stress spectra can be calculated by plane strain assumption. Based on S-N curve method, low stress ranges are considered the contribution to fatigue damage. Fatigue life of longitudinal steel bar in PC box girder bridge is 1428 years, and fatigue life of most unfavorable wire is 12942 years (Table 7). Based on LEFM, fatigue life of longitudinal steel bar in PC box girder bridge is 578 years, and fatigue life of most unfavorable wire is 14023 years. Fatigue life of longitudinal steel bar and most unfavorable prestress wire is longer than design service life. But according to existing experience, if fatigue crack occurs on concrete and corrosion occurs on the steel bar or the prestress wire, the fatigue life will decrease sharply.

Table 7 Fatigue life evaluation of Yaoxian Bridge

Object	Fatigue life (Year)	
	S-N curve	LEFM
Steel bar	1428	578
Prestress steel wire	12942	14023

CONCLUSIONS

Concrete bridges are prone to fatigue failure under the coupled actions of repeated vehicles loads, environment and material degradation. In recent years, the traffic volume and vehicle weights of highway bridges have been continuously increasing, so concrete bridge fatigue problem becomes more serious. Fatigue performance of typical concrete girder bridges with different cross-section and structure types are assessed, and several typical short and medium span concrete girder bridges are selected to conduct long-term service monitoring. Fatigue stress of concrete girder bridges will decrease with the span length increase, and the span number shows little

influence on the fatigue stress. Among three typical sections, fatigue stress of T-girder bridge is higher than hollow slab and box girder bridge. Structure type effect the fatigue performance very much, while continuous concrete bridge shows better fatigue performance than simple supported bridge. Based on the situ monitoring result, fatigue life of longitudinal steel bar and most unfavorable prestress steel wire is assessed by S-N curve and LEFM method. Fatigue lives of selected monitoring bridge are all longer than the design service life (100 years). The assessment results are based on the present traffic volume and structure conditions, the fatigue life will decrease sharply if fatigue cracks or corrosion occurs. Since concrete girder bridges are easy to suffer material or structure diseases, fatigue safety problems need to be paid more attention in the future.

ABSTRACT

Damage assessment of a steel structure involves acquiring and identifying dynamic characteristics of the structure and using these characteristics to evaluate behavior and performance. To ensure the objective assessment three major issues need to be developed: sensing system, system identification and feature extraction. In this study, a unsymmetrical 3-story steel structure (fabricated with one week column in the first floor) subjected to a series of earthquake excitations with increasing level of excitation back to back. In between the earthquake excitation white noise excitation was also applied. Both the traditional sensing system (accelerometer and LVDT) and the optical tracker system were implemented in the structure to collect the vibration-based responses. First, the traditional system identification using global response data is used (subspace identification) to extract system natural frequencies and mode shapes from different set of seismic responses. Besides, to evaluate whether optical tracker array data from local measurement could be used to identify deterioration or damaged-induced changes in damage assessment, principal component analysis was applied to extract the curvature ad the earthquake–induce local stress of the structural member. From which the local stress distribution from different seismic event can be estimated. The relationship among the local displacement profiles, stress distributions and the global dynamic characteristics of the structure are investigated. The results reveal that the local flexibility was an excellent objective for both local and global condition assessment. Finally, discussion on the identified global dynamic characteristics from global measurement in relating to the calculated structural integrity index using optical sensing array data and local element strain on the identification of damage severity are presented.

KEYWORDS

Optical sensor, signal processing, damage detection, principal component analysis, null-space damage index.

INTRODUCTION

Structural health monitoring for systems involve three major key levels as defined: Leveel-1: detect the existing of damage; Level-2: detect and locate the damage; Level-3: detect, locate and quantify damage. To reach these three major levels sensing system, signal processing and feature extraction techniques play a very important rule. For sensing system, generally, to monitor the civil infrastructure during earthquake excitation accelerometers are the most common sensors to collect the vibration signals from the vibration of the structures. With the developed system identification techniques structural natural frequencies, damping ratios and mode shapes can be identified using acceleration data from global monitoring view point. To detect the damage location as well as damage severity usually requires data from multiple sensors (or dense sensor array) on some specific local area of the structure. Sensors such as strain gage, FBG or PZT can be used as a sensing array to collect the vibration data from a specific local area.

The research objective of this paper is to identify the local damage features from the vibration-based measurement of a reinforced concrete frame and a 3-story steel frame subjected to base excitation. With the availability of high resolution distributed sensing system, optical tracker on light targets, the damage features as well as the damage severity can be identified. Correlation of the local damage in relating the global damage features extracted from traditional instrumentation was discussed.

STRUCTURAL DESCRIPTION AND INSTRUMENTATION

Two different types of structural models are designed and tested in NCREE shaking table: one is the two-bay one story RC frame and the other one is the 3-story steel frame. Both structures were subjected to shake table test with different intensity level from the base.

The test specimen of RC frame was a one-storey two-spanned RC frame with an overall height of 2 m, and an approximate weight of the frame was 6454 kg. The frame consisted of a T-beam of 4.7 m × 0.7 m, as well as 3 columns with cross-section dimension of 20 cm × 20 cm. To catch the global behavior of the dynamic response of the frame, a total of four specimens were constructed with the same design details. The specimen was subjected to a single direction excitation. For the shake table test, 12 accelerometers were used to measure the acceleration response (*Figure 1*) and four lateral LVDTs (Linear Variable Differential Transformers) were instrumented to acquire displacement response. The sampling frequency for above devices is 200Hz. o collect the local dynamic response, Twenty-four optical sensors (the sampling frequency = 100Hz) were also instrumented on the central column for the acquisition of displacement information. The OPTOTRAK® Certus (as shown the number in *Figure 2*) was selected as the optical tracker which can tract the light source from 24 targets attached on the specimen. At both end of the center column, a dense optical array sensor is deployed in grid size (5cm x 20cm). The spatial dynamic displacement data is collected from the optical sensing system which consists of two major devices. One is the Target-based Photogrammetry that provides the ability to conduct dynamic measurement functions. The other device is OPTOTRAK® Certus which is the full 3-D optical tracker. It can track the optical laser flashed by the target system that marks on the specific points of the structure. The tracker has the ability to track how these three dimensional measurements change over time for dynamic motion measurement with RMS accuracy up to 0.1 mm. The size of the target is small enough so that it can placed in an network array.

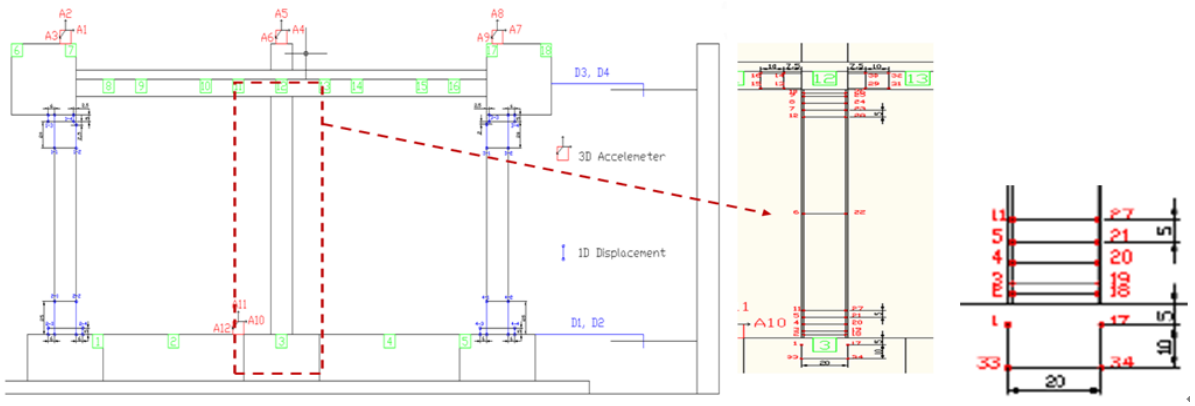

Figure 1 Different types of instruments on the test specimen including.
The optical sensing system is distributed on the central column.

Figure 2 Optical sensing system; (a) target (light source); (b) optical tracker;

The other test specimen is the two 3-story 350 cm in height steel structures, Specimen 1 and Specimen 2 respectively. The two steel structures are constructed with the same member size except Specimen 2 in which one column in the first floor (i.e. column at the north-west corner designed with smaller web thickness). Therefore, specimen 1 is a symmetric structure while specimen 2 is an anti-symmetric structure. The floor area is 1.5 m x 1.1 m. The total weight of each structure is 2.94 ton (include additional 0.5 ton on each floor). Three different types of instrumentation were used to collect the vibration response of the structure: accelerometer, LVDT and NDI optical tracker. The distribution of accelerometer and the LVDT is shown in *Figure 3a*. Detail description of NDI optical tracker is shown in *Figure 3b*. Due to the limitation of measurement technique only two columns of the first floor of specimen 2 are installed with the NDI measurement system. The spectrum compatible acceleration record (from Ch-Chi earthquake station TCU071) is used as the desired base excitation of the shaking table. The test protocol for the RC frame and the two steel structures are shown in *Table 1a* [Loh et al. 2011] *and 1b*, respectively**.** For the testing of steel structures the base excitation is arranged back to back

with different input intensity level. In between the earthquake excitation white noise excitation (with peak acceleration of 50 gal) was also applied to serve as the reference state of the structure before and after each earthquake excitation. In these experiments all the response measurement is with 200 Hz sampling frequency.

LOCAL FEATURE EXTRACTION USING NDI DATA

To extract the local features from the 3-dimensional optical tracker distributed on the local structural member, the principal component analysis (PCA) was applied to reduce the data and extract the major principal components [Jolliffe, 2002]. With is technique and applied to the NDI data collected from the seismic response of 2-bay one story RC frame and a 3-story steel frame structure.

Analysis of 2-bay One Story RC Frame

Based on the NDI data collected from the central column of the 2-bay RC frame during the shaking tabled test, Figure X plots the distribution of the first four major principal vales of the four specimen. It is observed that the singular values of the first 3 PCs contribute over 99% of the entire signal. The 1st PC is a rigid-body motion, the 2nd PC is a shear deformation, and the 3rd PC is a bending-like deformation for the RC specimens. *Figure 4* shows the singular value distribution of all cases, and we can see that the more intense the excitation is, the less singular value the 1st PC (rigid body motion) contributes. Since the rigid body motion of a structure does not cause damage for a structure, therefore, the less the contribution of the rigid body motion is the more severe the damage may be. *Figure 5* shows the first 3 PCs of RC specimen RCF 6 and RCF 2. To analyze the stress/strain induced by ground shaking in the column, the rigid body mode needs to be removed. Since very dense optical sensors are distributed at the top and bottom of the center column with grid arrangement (or block arrangement), the average strain for each block can be calculated [Chao et al. 2013]. *Figure 6* shows the comparison of the calculated shear strain (γ_{xy}) of each block from each test specimen. the results show that larger shear strain was observed for RCF3 specimen which is consistent with the excitation level. Besides, the block axial strain can also be calculated:

$$\varepsilon_{yy} = \frac{\left(Ly_{1,d} - Ly_{1,0}\right) + \left(Ly_{2,d} - Ly_{2,0}\right)}{\left(Ly_{2,d} - Ly_{2,0}\right)} \tag{1}$$

where L is the length and width of the block and the suffix d and 0 represent the deformed state and original state of the block. Since ε_{yy} was calculated from each block the curvature of the column can be estimated by using $\kappa = (\varepsilon_1 - \varepsilon_2)/h$ to estimate the curvature in which ε_1 and ε_2 indicate the axial strain calculated from blocks in the central column. Since the test specimen was a one-story frame, which can be regarded as a simplified cantilever beam. A deformed cantilever beam divided into several segments and the displacement is mainly caused by the slope induced from the curvature near the fix end, and the curvature near the free end is close to zero, as shown in *Figure 7*. As a result, one can calculate the displacement caused by each segment and the accumulated slope from the curvature near the fix end. Thus, we can get the deformation of the frame. Comparison on the frame lateral displacement using NDI data (indirect estimation) and using LVDT (direct measurement) is shown in *Figure 8*. Good agreement was observed.

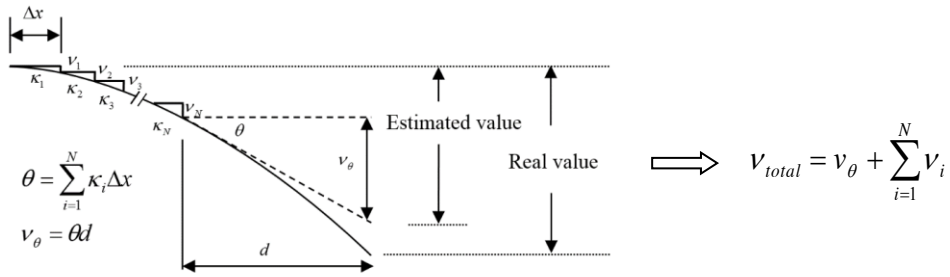

Figure 7 Estimate lateral displacement of a cantilevel beam using curvature-displacement relationship.

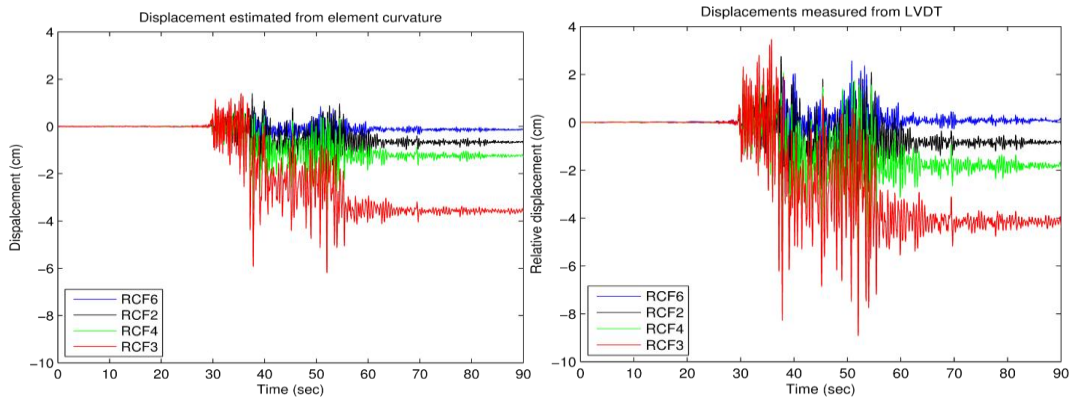

Figure 8 Comparison on the frame lateral displacement using NDI data indirect estimation (left) and using LVDT direct measurement (right)

Analysis of 3-story Steel Frame

An optical sensing system (NDI-Optical tracker) with 28 light sources was installed on the two columns of the first floor of Specimen 2. The optical tracker can detect the 3-D displacement of each light source which can provide the information for the identification of local member property during earthquakes. The measured data set is firstly arranged in data matrix to perform the principal component analysis (PCA). *Figure 9* shows the

extracted four principal components (PC) of the two columns. According to the results from PCA, the 1st PC belongs to the rigid body motion. Reconstruct the data matrix without 1st PC, one can obtain the deformation response of the columns. This extracted column deformation can be used to identify the stress distribution along the monitor column from each seismic excitation.

It is assumed that the deformed shape $v(z)$ of the column can use the 3rd-order polynomial (i.e. bending moment *M(x)* along the column height is assumed as a 1st-order polynomial) to fit the measurement under the assumption of linear static deformation theory. Based on the discrete monitoring NDI data, the continuous deformation $v(z)$ of the column can be obtained (this is under the assumption of the response of an equivalent linear system). The deformed shape of the column, for case of EQ6 loading, is fit by a 3rd-order polynomial and plotted as the green line in *Figure 10*. Then the stress distribution along the column height can be obtained from the deformed shape of the column:

$$\sigma(z) = \frac{M(z)}{I} h = hE \frac{dv^2(z)}{dz^2} \tag{2}$$

where z is the height of the column and *h* is the thickness of the column. By taking double differentiation of the deformation function, one can get the moment function $M(x)$. In this study, the numerical differentiation is employed, which is defined as [Boashash, 1992]*:*

$$\theta'(k) = \begin{cases} \frac{1}{12} \times (-25\theta(k) + 48\theta(k+1) - 36\theta(k+2) + 16\theta(k+3) - 3\theta(k+4)) & for \quad k = 1,2 \\ \frac{1}{12} \times (\theta(k-2) - 8\theta(k-1) + 8\theta(k+1) - \theta(k+2)) & for \quad k = 3,...,N-2 \\ \frac{1}{12} \times (25\theta(k) - 48\theta(k-1) + 36\theta(k-2) - 16\theta(k-3) + 3\theta(k-4)) & for \quad k = N-1, N \end{cases} \tag{3}$$

Figure 11 shows the distribution of earthquake-induced stress along the column for case of EQ2 (250 gal) and EQ5 (700 gal). A36 steel was used to construct the structure and the yield stress of the steel column is 275 Mpa. The column size is with cross section of 0.15 m × 0.025 m and the moment of inertia is 1.9531e-7 m^4. With these data one can estimate the stress at any location of the column. *Figure 12* plots the estimated maximum stress at the top of the column with respect to different level of earthquake base excitation (under the assumption of equivalent linear system). It is observed that the column stress exceed the yield stress when the excitation exceed pga>400 gal (after the test case of EQ3).

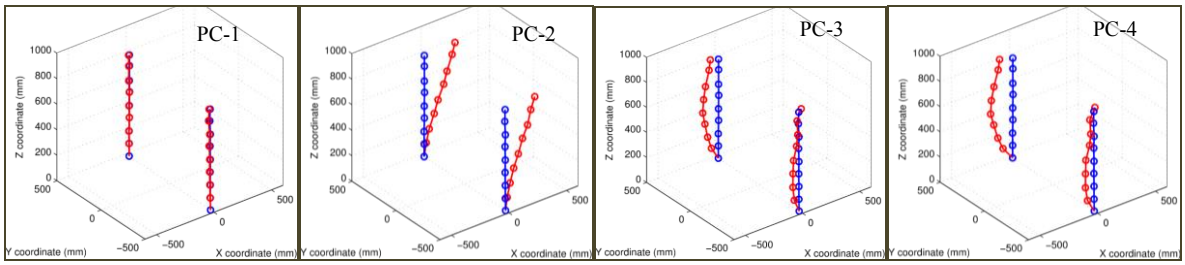

Figure 9 Identified four major principal components from NDI data of 3-story steel frame.

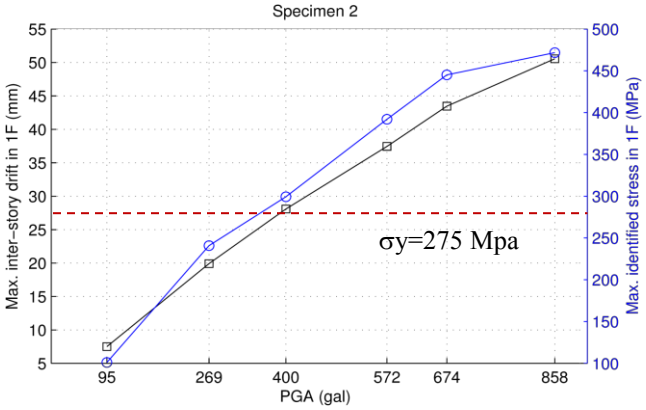

Figure 12 Plot the identified maximum stress at the top of the 1st floor column and the max. inter-story drift.

CORRELATIONS OF LOCAL PROPERTIES WITH GLOBAL DYNAMIC CHARACTERISTICS

Two-bay One-story RC Frame

Comparison on the calculated block strain (axial strain ε_{yy} and shear strain γ_{xy} from the test of specimen of RCF3) and the identified strength and stiffness degradation factor (using Bouc-Wen nonlinear hysteresis model is shown in *Figure 13*. It is observed that there is a high correlation between the change of strain and the stiffness/strength. The significant change of block shear strain and axial strain is mainly due to the change of strength degradation. This change is also consistent with the reduction of system fundamental natural frequency identified using recursive ARX model.

3-story Steel Frame

Based the global measurement data (i.e. acceleration measurement) and apply the subspace identification to identify the system natural frequencies of the structure, it is found that the system natural frequencies did not change much even for the structural system subjected to a series of earthquake excitation as shown in Table 2. From the analysis of NDI data of the first floor column, it is observed that after the EQ3 test (with PGA=400 gal) the maximum stress at the top of the first column will reach the yield stress. Based on the ambient vibration data collected from the test specimen after each earthquake excitation, the null-space damage detection algorithm was applied (using global acceleration measurement). *Figure 14* shows the null-space damage index with respect to each test case (white noise excitation). It is observed that a significant increase of the null-space damage index after test case of WN6 (i.e. after the earthquake excitation of EQ4, PGA=570 gal). It demonstrated that the local information identified from the NDI data is close to the global damage information.

CONCLUSIONS

The objective of this research is to analyze the displacement data collected from the multivariate dense light targets through optical tracker from the seismic response of two structures. Through the proposed local structural integrity index (element curvature, element strain and null-space damage index), detail observation and analysis from the NDI data local damage severity can be identified. The optical sensors provided a good

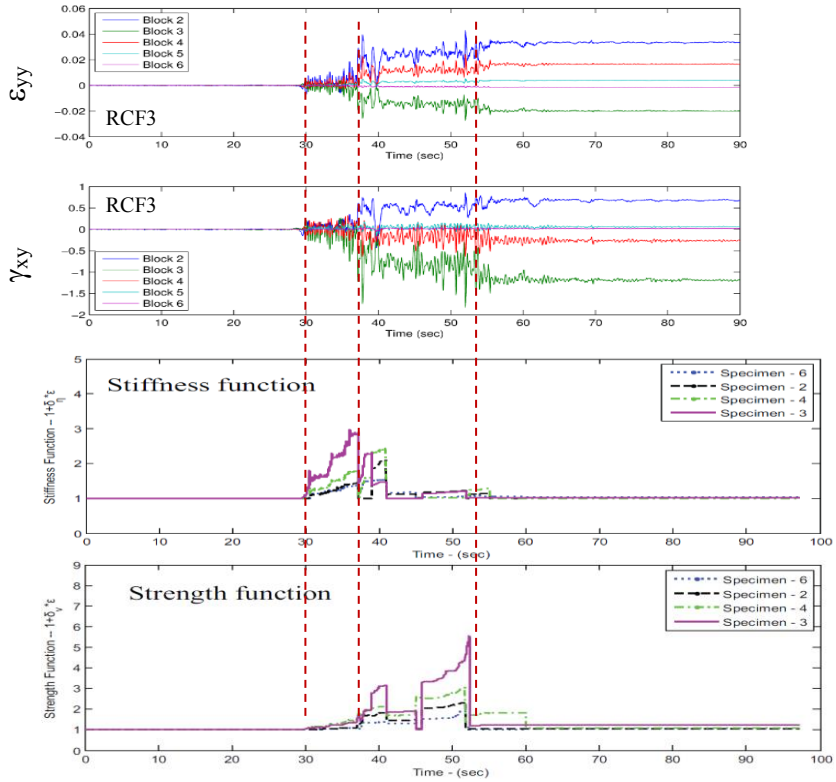

Figure 13 Comparison between the estimate block axial/shear strain and the identified system stiffness/strength degradation

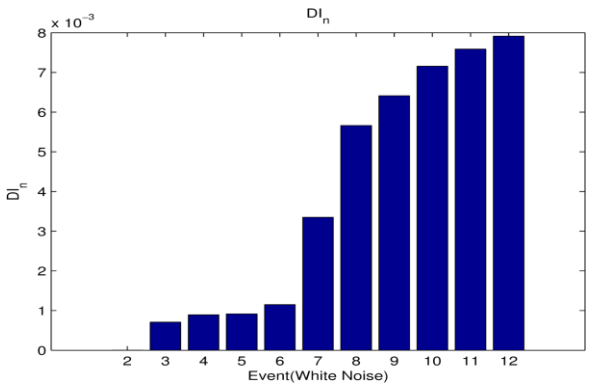

Figure 14 Plot of null-space damage index from different test cases (from white noise excitation) using acceleration response measurement.

ability for recording the local behavior of a structure. Analysis through proper signal processing techniques, physical local feature could be extracted. PCA could be employed to reduce the noise effect on the data and made clearer identification results in strain data. Rigid body motion, which was the 1st PC of the structure, can be also removed. Therefore, the real time history of displacement could be extracted and used to estimate the stress distribution of the element. Besides, a good correlation on the damage features using global information and local measurement can be established.

ABSTRACT

Inspection of a pre-stressed concrete variable cross-section box girder bridge discovered the phenomenon of padding in expansion joint, corrosion of steel plate and local edge failure in pot type rubber bearing, and cracks of box girder. They are the main sources of structural uncertainty for structural performance evaluation, and how to quantificationally evaluate their influences on bridge performance is important. In this article, an approach using the Markov Chain Monte Carlo sampling technology and the Response Surface Method is proposed to deal with the uncertainty problem. First, a population of finite element (FE) models will be established by sampling the main uncertainty sources through the Markov Chain Monte Carlo technology. Then, the posterior probability of each FE model will be evaluated by using the measured static responses and identified structural dynamic characteristics. Especially, the second order response surface method will be used in this step to improve the computation efficiency. Through the above procedures, probability features of the defined key parameters representing structural uncertainty, including the stiffness of expansion joint, the stiffness of pot type rubber bearing and the elasticity modulus of the box girder will be estimated, which will provide valuable information for reliable structural performance evaluation.

INTRODUCTION

The performance of civil engineering structures under operational and environmental conditions would decrease over time and especially the degeneration of structural critical areas might lead to monolithic catastrophic failure, so the bridge structures need periodical inspection and structure health monitoring (Jang et al 2013; Gheitasi and Harris 2015).Vibration-based test is an important tool for structure health monitoring, and modal parameter identification based on vibration data have been developed for a long time. Although identified structural modal parameters reveal structural dynamic characteristics, they cannot directly support structure performance evaluation and subsequent decision making about structural maintenance and management.

Finite element modeling and updating using the monitoring results has been widely investigated. Initial finite element model generally cannot well fit field test data. Utilizing monitoring data to update the finite element model is an effective way to produce a better FE model for further structural prediction. Ching and Beck (2004) proceeded finite element model updating through Bayesian theory combining structural monitoring data. Chakraborty and Sen (2014) updated the FE model using the response surface method. Papadimitriou and Papadioti (2013) utilized the component mode synthesis technique for finite element updating. Even the finite element updating technology has been developed for a long time, its application in engineering practice is still limited. The basic reason is that the procedure of almost all finite element model updating methods is searching for an optimal model best fitting field test data, while it is very challenging to find a single optimal model really simulating the studied structure due to various kinds of uncertainty existing in stages of field test, data processing and finite element modeling (Döhler et al. 2014, Hasançebi and Dumlupınar 2013).

Even though great efforts have been performed to deal with the uncertainty problem during the finite element updating, the challenging "Non-Unique" problem still exists. Namely, multiple models with different intrinsic parameters may fit observed data well. A few researchers have made effort trying to solve the above problem. Koh and Kim (2013) firstly relegated the key parameters by the PCA method, then using K-means method to cluster the multiple models. Zhang et al. (2013) proposed the Markov chain Monte Carlo sampling method to sample the key parameters, from which a population of finite element models are generated, then all those models are weighted their posterior probabilities calculated from the Bayesian theory and the monitoring data.

The idea of using the multiple models, not the single optimum model, for structural evaluation and prediction is promising, however, the challenging problem is that it requires huge computational cost to analyze the whole population of finite element models. In this article, the response surface method (RSM) method is adopted into the multiple model method to improve its computation efficiency. From the proposed method, not only the values of the identified structural parameters and predicted structural responses, but also their probabilistic distributions are provided to deal with the uncertainty problem.

The structure of the article is as shown below. First, basic information of a pre-stressed concrete box girder bridge and its field test including bridge inspection, truck load test and ambient vibration test are described. Then, the FE modeling of the bridge and its sensitivity analyses are performed. Four key parameters including elasticity modulus of concrete, stiffness of expansion joint, stiffness of longitudinal bearing and stiffness of vertical bearing are chosen for further investigation in next step from the sensitivity analysis. Subsequently, the multiple model method using the MCMC sampling and RSM technologies are proposed, from which bridge performance evaluation under serviceability limit states is implemented. Finally, the conclusions are drawn.

BRIDGE DESCRIPTION AND FIELD TEST

Bridge Description

The studied structure is a three-span pre-stressed concrete variable cross-section continuous box girder bridge, with a 55 m main span, and two 37.5 m side spans (Figure.1a). Its typical transversal cross-section is shown in Figure.1b. Pot rubber bearings are set between bridge piers and abutments. Expansion joints are set at the box girder ends (Xu et al. 2012; Ren et al. 2007). Bridge inspection, truck load static test, and ambient vibration test were performed on the bridge to evaluate its safety conditions.

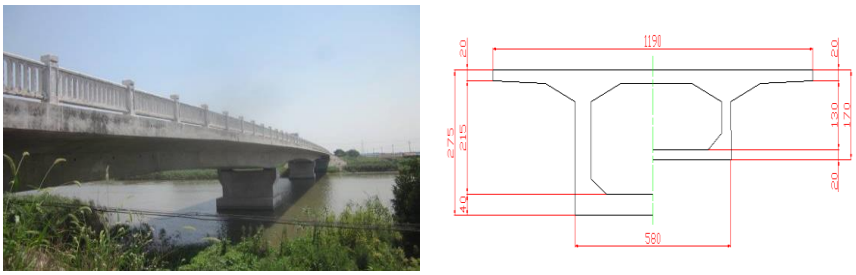

Figure 1 the studied bridge

Bridge Inspection

Regular inspections of concrete strength, rebar corrosion, chlorine ion contents, concrete resistivity, carbonation resistance of concrete, deck station, bearing station and pile foundation were performed on the bridge. Figure. 2 shows the phenomenon of blocked expansion joint, corrosion of steel plate and local edge failure in pot type rubber bearing, and cracks on box girder. Figure. 3 shows longitudinal cracks on bottom slab and diagonal cracks on the web.

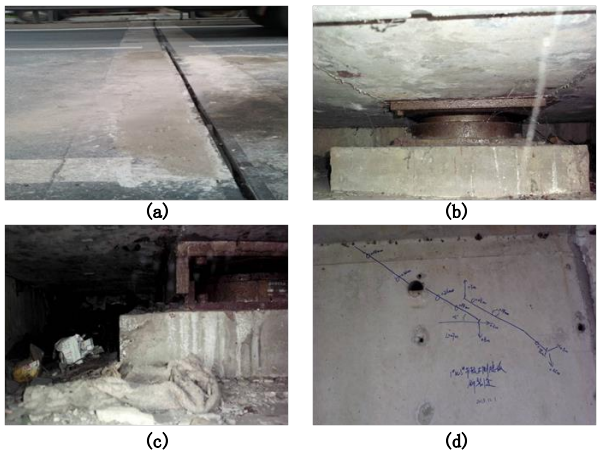

Figure 2 Bridge inspection results (a) blocked expansion joint (b) steel plate corrosion (c) local edge failure (d) cracks on the box girder

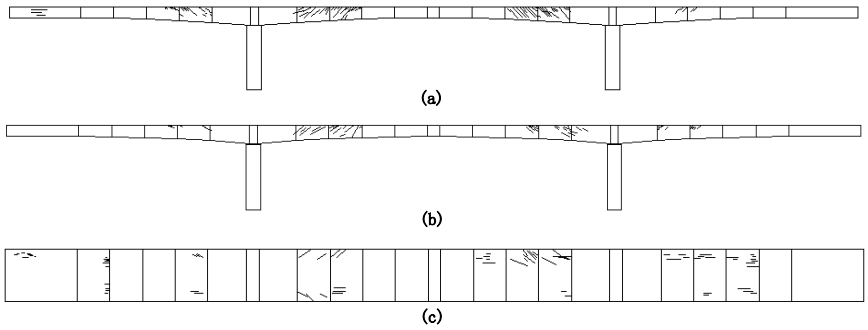

Figure 3 cracks distribution (a) upstream web (b) downstream web (c) bottom slab

Truck Load Test

Static test using four trucks were conducted on the bridge on November 2013 (Figure.4). The averaged axle loads of the test trucks are 70 KN for front axles and 280 KN for rear axles. The axle intervals of the test trucks are 360 cm for front axles and 140 cm for rear axles. Prism displacement sensors and strain sensors were deployed at the side span center, (cross-section 1-1), main span center (cross-section 2-2) and the 1/4 point of the main span (cross-section 3-3). Hence there are six load cases in three cross-sections using balance load and unbalanced load. Under the truck loads, structural deflections and strains were observed. Six load cases were implemented during the truck load test. The test cross-section of case 1 and case 2 is 1-1, case3 and case4 is 2-2, case 5 and case 6 is 3-3 as shown in Figure.4 (a). The way of truck load of case 1, case 3 and case 5 is balance load as shown in Figure.4 (c) and case 2, case 4 and case 6 is unbalance load as shown in Figure.4 (b). In addition to static tests, several running tests were executed by moving the trucks at different speeds over the bridge.

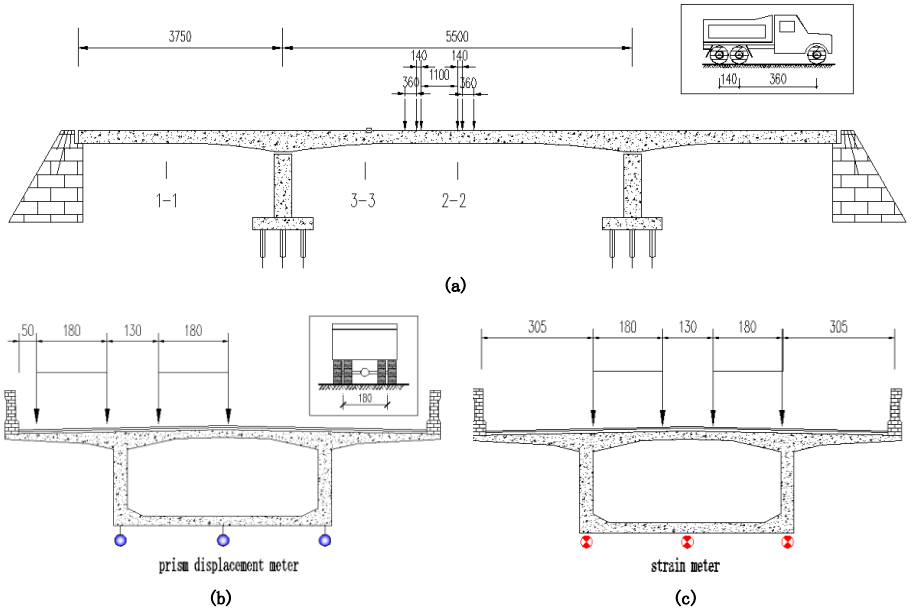

Figure 4 Truck load distribution (a) longitudinal location (b) unbalance load (c) balance load

Ambient Vibration Testing

Ambient vibration test was performed on the bridge to identify its dynamic characteristics. As shown in Figure. 5, the studied bridge was instrumented with 20 PCB 393B05 accelerometers. NI PXIe-1082 system was used for data acquisition. Figure. 6 shows two time histories of the recorded accelerations at the middle and the 1/4 point of the main span. Vibration data was processed to extract modal parameters of the bridge by the complex mode indication function (CMIF) method, which utilizes the singular value decomposition technology to enhance the uncertainty of identified results. Three modes of the bridge were identified, and the corresponding frequencies are 1.93Hz, 3.38Hz and 4.59 Hz respectively.

FE MODELING AND SENSITIVITY ANALYSIS

Bridge FE Modeling

A linear 3D finite element model of the studied bridge was developed using large general finite element software ANSYS. Figure.7 shows an isometric view of the developed FE model, the detail cross-sections of bearing parts and mid-span of main span, and longitudinal section of 1/2 hole bridge.

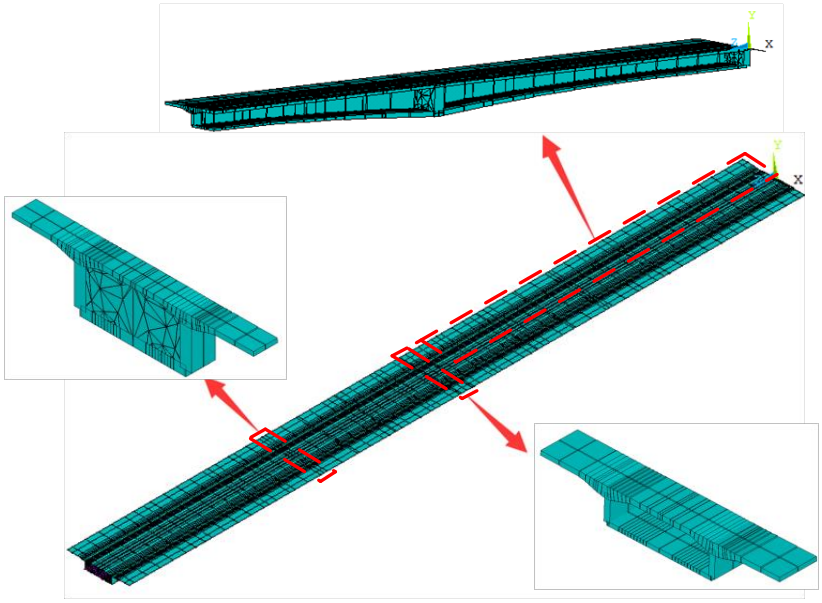

Figure 7 Finite element model of the studied bridge

A three-dimension finite element model of the studied bridge was constructed through the software ANSYS. Figure. 7 shows an isometric view of the developed FE model, the detail cross-sections of bearing parts and longitudinal cross-section of 1/2 main bridge. In the FE model, concrete is modeled by SHELL63 element which is defined by four nodes. The pre-stressed reinforced bars are modeled by LINK8 elements, which has the property of uni-axial tension-compression components with three DOFs at each node. The pre-stress is applied by falling temperature method. The cracks on the web and bottom slab (Figure.3) of the bridge deck are modeled by using a reduction coefficient to the elasticity modulus of the corresponding elements.

The boundary conditions are modeled by using linear spring elements. The expansion joint and pot rubber bearing are modeled by tension-compression linear spring (COMBIN14) elements. Linear springs are used to simulate the longitudinal, vertical and lateral support directions of reality rubber bearing. Because the stiffness of bridge pier is huge, effect of pier is not considered and the bottom of rubber bearing is fully-constrained.

The material properties are set as follows: elasticity modulus of concrete and reinforced steel bar are 3.5E4MPa, and 1.95E5 MPa respectively, and their Poisson's ratio are 0.2 and 0.3 respectively. The stiffness of the expansion joint, the longitudinal, vertical, and lateral stiffness of pot rubber bearing are set to be 5E5, 1E8, 1E11, 1E8 MPa, respectively.

The FE analysis results and field test results are compared in Table 1. It is seen that the error distribution is random and they are less than 10 percent.

Table 1 Comparison of FE analysis and field test results

Frequency	1st order	3%	displacement	Case 1	0.5%	strain	Case 1	11%
	2nd order	5%		Case 2	0.5%		Case 2	9%
	3rd order	8%		Case 3	2%		Case 3	3%
MACVALUE	1st order	0.8%		Case 4	1%		Case 4	1%
	2nd order	6%		Case 5	0.5%		Case 5	7%
	3rd order	6%		Case 6	3%		Case 6	7%

Sensitivity Analysis

Sensitivity analysis is a good way to identify the most sensitive parameters that affecting the FE analysis results. (Jung and Kim 2013). The objective function in the sensitivity analysis is defined in Eq.1 in terms of the difference between analytical and experimental results, in which the identified frequencies and mode shapes in the first three modes, observed displacements and strains in six test cases are used.

$$\mathrm{obj}=\sum_{i=1}^{3}\frac{\left|\omega_{ai}-\omega_{ei}\right|}{\omega_{ei}}+\sum_{i=1}^{3}\left(1-\mathrm{MAC}_{i}\right)+\sum_{i=1}^{6}\frac{\left|\delta_{ai}-\delta_{ei}\right|}{\delta_{ei}}+\sum_{i=1}^{6}\frac{\left|\varepsilon_{ai}-\varepsilon_{ei}\right|}{\varepsilon_{ei}} \quad (1)$$

$$MAC_{i}=\frac{\left|\Phi_{ai}^{T}\Phi_{ei}\right|^{2}}{\left(\Phi_{ai}^{T}\Phi_{ai}\right)\left(\Phi_{ei}^{T}\Phi_{ei}\right)} \quad (2)$$

where ω_{ai} and ω_{ei} are analytical and identified frequencies of the i th mode, respectively; Φ_{ai} and Φ_{ei} are analytical and identified modal shapes of the i th mode. The MAC value between Φ_{ai} and Φ_{ei} is defined in Eq.2. δ_{ai} and δ_{ei} are analytical and observed displacements of the i th test case; ε_{ai} and ε_{ei} are analytical and observed strains in the i th case, respectively. Weight factors of frequency, mode shape, displacement and strain are considered consistently in Eq.1 (Wang et al 2013).

9 structural parameters in finite element model representing main sources of uncertainty are selected for sensitivity analysis. They are elasticity modulus of concrete, elasticity modulus of crack1- crack4 zones (EMCZ), stiffness of expansion joint, stiffness of longitudinal, vertical and transverse bearing, respectively. Each parameter is set to 7 selected values in the sensitivity analysis. For example, the distribution of elasticity modulus of concrete is Gaussian distribution, and the 7 selected values are [3.0, 3.25, 3.4, 3.5, 3.6, 3.75, $4]\times10^{10}\mathrm{Pa}$, respectively. The distribution of stiffness of expansion joint is logarithmic distribution, and the 7 selected values are 0.5×10^{5} , 0.5×10^{6} , 0.5×10^{7} , 0.5×10^{8} , 0.5×10^{9} , 0.5×10^{10}, $0.5\times10^{11}\mathrm{N/m}$, respectively. Figure.8 shows the sensitive analysis results for each studied parameter. It is seen that the influence of expansion joint is the largest, followed by longitudinal bearing stiffness and vertical bearing stiffness and overall elasticity modulus. The influence of elasticity modulus in four crack regions is small, and there is no obvious influence from lateral stiffness of bearing. Therefore, stiffness of expansion joint, longitudinal and vertical bearing, and overall elasticity modulus, are selected for further study in next section.

MULTIPLE MODEL METHOD

The goal of the traditional deterministic method is to find the single FE model best matching experimental data, and then use it for structural response prediction. Due to the uncertainty existing, the predicted deterministic responses may have a big bias with actual results, so it is hard to accurately assess structural performance. In this section, a multiple model method is proposed to sample the key parameters of structure and provide the structural probabilistic information for engineers. The purpose of the multiple-model approach is not to find the single optimal model, but to generate a number of FE models by stochastic sampling. In the multiple-model method, response surface model is used to replace the FE model for computational efficiency. The Markov

Chain Monte Carlo technique is first performed to sample the key structural parameters representing main sources of uncertainty. Then a FE model population is generated using the samples, and the posterior probability of each model is evaluated by calculating the correlation between its simulation results and measurements through the Bayesian theorem. Finally, all those FE models from the stochastic sampling with their posterior probabilities are used for structural identification and performance evaluation.

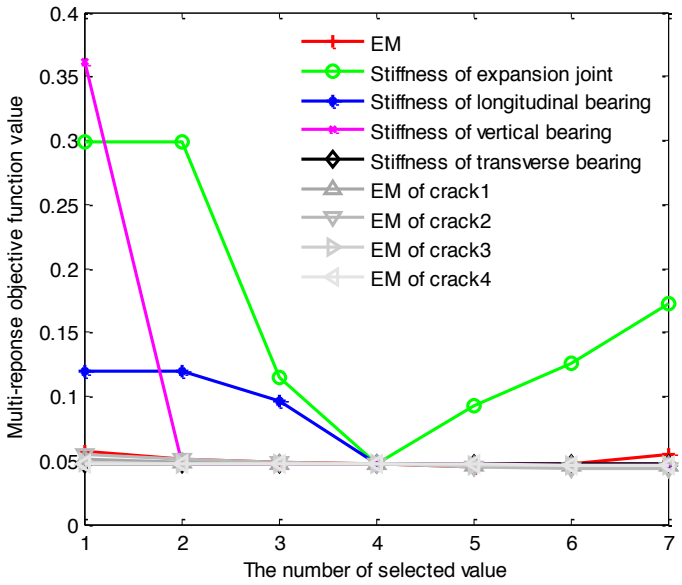

Figure 8 Sensitivity analysis result

ANSYS Batch Tool is used to operate ANSYS in background under MATLAB control in this paper, and MATLAB functions are called in ANSYS at the same time. The flow chart of the multiple models method is shown in Figure.9.

Computational speeds can be lifted dramatically with the combination of ANSYS and MATLAB. For example, running xlb.dat document once needs 20min in ANSYS Interface, but 6min in ANSYS Batch; and running self-edit function (RejectModal.m) needs 10s in MATLAB Interface, but 1s in MATLAB Command Window.

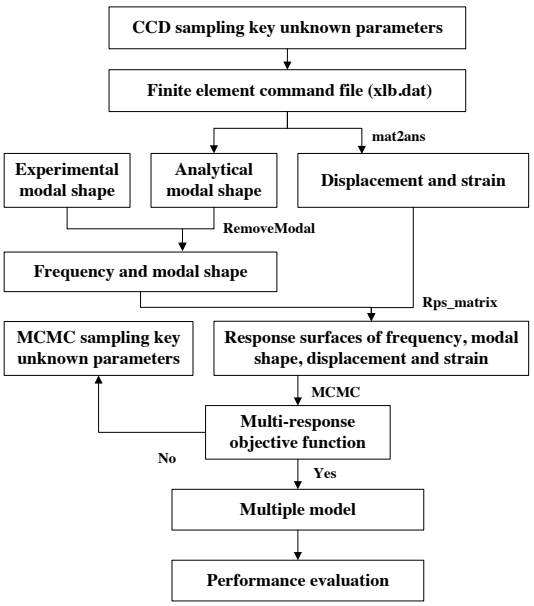

Figure 9 Flow chart of the multiple model method

MCMC Sample

Utilizing the Markov chain Monte Carlo (MCMC) sampling method can rapidly converge to the objective function $\pi(\mathbf{x})$ under the framework of Bayesian theory. The MCMC sample utilizing the chain sample could overcomes the impact of high dimensional parameters. The process is a recursive procedure and the steps are as follows:

1）Randomly generated initial parameters θ_0.

2）Assuming that θ_{i-1} is the k[th] parameter of the Markov chain, candidate parameter θ_c is generated by proposal distribution $q(x)$:

$$\theta_c = q(\theta_c / \theta_{k-1}) \tag{3}$$

3）Accept probability of candidate parameter θ_c is:

$$\alpha(\theta_{k-1}, \theta_c) = \min\left\{1, \frac{\pi(\theta_c) q(\theta_c / \theta_{k-1})}{\pi(\theta_{k-1}) q(\theta_{k-1} / \theta_c)}\right\} \tag{4}$$

4）If θ_c is accepted, so $\theta_k = \theta_c$. Or repeat the 2 - 3 steps until θ_c is received。

5）Make k = k+1, repeat the 2-4 step until the process converges

In a multiple models framework, objective function π is elected as model probability conditioned by known structural information G; proposed distribution q is elected as the prior distribution of the key unknown parameters; the key unknown parameter θ in the studied bridge is combination of elasticity modulus, stiffness of expansion joint, bearing longitudinal stiffness and bearing vertical stiffness.

$$\pi(\theta) = P(M(\theta)|G); \; q = P(M(\theta)) = \prod_1^4 P(\theta_j) \tag{5}$$

$P(\theta_j)$ is the prior distribution of jth parameter.

According to Bayesian theory $P(M/G) = \frac{P(G/M)P(M)}{\int P(G/M)P(M)}$, Considering that $\int P(G/M)P(M)$ is constant，

combining (4) and (5) we have:

$$\alpha(\theta_{i-1}, \theta_c) = \min\left\{1, \frac{P(G|M_c(\theta_c))P(M_c)}{P(G|M_{i-1}(\theta_{i-1}))P(M_{i-1})}\right\} \tag{6}$$

Assuming that the error of the model belongs to normal distribution and independent from each other:

$$P(G|M_i(\theta_i)) = \frac{1}{\sqrt{2\pi\sigma^2}} exp\left(-\frac{obj^2}{2\sigma^2}\right) \tag{7}$$

To further improve the sampling efficiency, an extended M-H algorithm is adopted. Two novel ideas, Adaptive Metropolis (AM) and Delayed Rejection (DR), are successfully combined to improve the computational efficiency of the M-H algorithm. Please refer to the details of the reference (Haario 2006).

Response Surface Method

MCMC method could improve sampling efficiency, but it is still difficult to establish multiple models library considering the studied bridge such large scale FE model. Response surface method (RSM) is utilized in the proposed method to improve its computation efficiency. RSM is performed to establish an appropriate prediction model and to determine the regression coefficients describing the linear and quadratic contribution of each parameter and their interactions. RSM is very good at copping with the issue with implicit multi-response object function for its satisfied accuracy and good efficiency. Because the amount of sample set used to reconstruct the response surface is small (Zhao and Qiu 2013).

The second order RSM is reconstructed by Central Composite Design (CCD) method, F test of variance analysis is used to identify the parameter, and the second order polynomial response surface is as follows:

$$y = \beta_0 + \sum_{i=1}\beta_i x_i + \sum_{i=1}\sum_{j=1}\beta_{ij} x_i x_j + \sum_{i=1}\beta_i x_i^2 \quad (8)$$

Where x is structural parameter such as elasticity modulus, spring stiffness, and so on; y is response result such as frequency, displacement, strain; β is fitting coefficient of structural parameters.

RESULTS FROM MULTIPLE MODELS

First of all, four MCMC key unknown parameters of the studied bridge are needed to confirm as shown in Table 2. And then, 20 thousands samplings are implemented through MCMC sampling method and response surface technology.Figure.10 shows convergence situation of four structural parameters and probability distribution of four parameters after rejecting first 5 thousands sampling. It can be seen that results are convergent after 5 thousands sampling. So the frequency, mode shape, displacement and strain of multiple models can be get, which is made up of 15 thousands sampling. The comparison of first two order frequencies (Figure.11) and displacements of case1 (Figure.12) and case2 and strains of the case3 and case4 (Figure.13) between analytical and measuring values is list as follow. The results show correctness of multiple model through MCMC sampling and RSM.

Table 2 The convergence and distribution key structural parameters

	Elasticity modulus (MPa)	Stiffness of expansion joint (N/m)	Stiffness of longitudinal bearing (N/m)	Stiffness of vertical bearing (N/m)
MCMC initial value	2.9×10^{10}	5×10^{7}	1×10^{10}	1×10^{13}
Distribution type	normal	normal	normal	normal
Distribution interval	$[2.9\times10^{10}, 4.1\times10^{10}]$	$[3\times10^{7}, 7\times10^{7}]$	$[1\times10^{6}, 1\times10^{11}]$	$[1\times10^{9}, 1\times10^{14}]$

BRIDGE PERFORMANCE EVALUATION UNDER SERVICEABILITY LIMIT STATE

According to Chinese Code for Highway Bridge Loading Capacity Detection Evaluation（JTG/T J21-2011）, checking coefficient of concrete loading capacity Z1 is shown in Table 3. The deteriorate coefficient of concrete structure loading capacity ξ_e=0.01, reduction coefficient of steel cross-section ξ_s=1.0, and live load updating factor ξ_q=1.0. Through considering coefficients above, checking coefficient of concrete loading capacity Z1=1.09. So reduction effect is not considered in checking results.

Table 3 Checking coefficient of concrete loading capacity Z1

	Detection index	D_j	Weigh coefficient α_j	$D=\sum\alpha_j D_j$	Checking coefficient Z_1
Main beam	defects	3	0.4	1.8	1.11
	strength	1	0.3		
	Natural frequency	1	0.3		

Two failure modes are considered under serviceability limit state, which are appearance failure due to large main beam mid-span displacement and concrete compressive strength failure. Design load of bridge is applied in finite element model of the studied bridge. And then two response surfaces of displacement and strain of mid-span are established. Multiple model of the studied bridge established above is substituted to this two response surfaces. Probability of displacement and strain is implemented in Figure.14.

According to Chinese Code for Design of Highway Reinforced Concrete and Prestressed Concrete Bridge and Culverts（JTG D62-2004）, concrete compressive strength should not be more than $0.5f_{ck}=16.2\text{MPa}$, and displacement should not be greater than $\frac{L}{600}=9.167\text{cm}$. Figure.14 shows the bridge still has some redundancy.

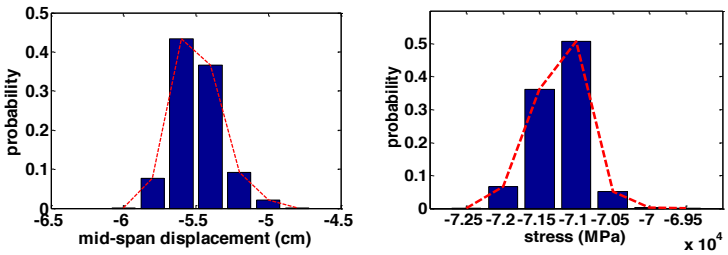

Figure.14 Bridge performance evaluation (a) mid-span displacement (b) concrete compressive stress

CONCLUSION

(1) A multiple model method through MCMC sampling and the response surface technology is proposed. The "Non-Unique" problem in the finite element updating field caused by uncertainties is solved by using a population of FE models, not a single optimum model for structural performance evaluation.

(2) Inspection of the studied bridge found the padding of expansion joint, corrosion of steel plate, local edge failure in pot type rubber bearing and cracks of box girder. However, how they influence structural performance is not clear. Sensitive analysis and the proposed multiple model method are performed to study how they influence structural performance.

(3) The results from the multiple model method are used to evaluate the load capacity of the studied bridge, which shows that the bridge still has sufficient redundancy.

Abstract

Numerous vibration-based structural damage detection methods have been developed over the past decades. These methods are grounded on the fact that structural damage may cause changes in vibration characteristics. However, most previous model updating techniques adopt the Tikhonov regularization (or l_2 regularization) approach, which causes the damage detection solution distributed to many structural elements. However, this result does not match the practical situation in which damage usually occurs only at several locations.

This study utilizes the sparsity condition of structural damage and develops a new damage detection method based on the latest sparse recovery or sparse reconstruction theory. A novel l_1 regularized model updating method will be developed to identify sparse damage with the use of the first several natural frequencies. This process enables the structure of interest to be modeled with a relatively large number of elements, such that the local damage is directly represented by the stiffness reduction in the corresponding element. Thus, the damage index to be identified can be regarded as a sparse vector with several non-zero items at the damaged locations but with many zeros at others. One laboratory structure is employed to verify the proposed method. Such parameters as the number of damaged elements, severity of damage, number of frequencies, and uncertainty in measurements will be studied.

COLLAPSE SIMULATION OF A TYPICAL SUPER-TALL RC FRAME-CORE TUBE BUILDING EXPOSED TO EXTREME FIRE

Ming-jian YING [1], Xin-zheng LU [1, *]
[1]Key Laboratory of Civil Engineering Safety and Durability of China Education Ministry, Department of Civil Engineering, Tsinghua University, Beijing, P.R. China, 100084

ABSTRACT

The previous fire accidents proofed that reinforced concrete (RC) structures may experience progressive collapse subjected to extreme fires. In consequence, the study on the extreme fire-induced progressive collapse of RC structures is important for the safety of buildings. However, limited study has been performed on the extreme fire-induced progressive collapse of super-tall buildings. In this work, a finite element (FE) model and the corresponding elemental deactivation technology is proposed to simulate the extreme fire-induced progressive collapse of a typical super-tall RC frame-core tube building. The simulation discovered that the collapse of the building is initiated by the flexural failure of perimeter columns because of the thermal expansion of the floor system. The mechanism that discovered can provide a reference for related research of the fire safety of RC buildings.

KEYWORDS

Extreme fire, super-tall building, frame-core tube structure, progressive collapse, collapse mechanism

INTRODUCTION

Fire is a major threat to building safety. During an actual fire, the progressive collapse of the entire structure may occur following the local failure of structural components if the fire is extreme. However, limited research is available regarding the fire-induced collapse mechanisms of super-tall RC buildings in the literature. Consequently, the collapse resistances of super-tall RC buildings exposed to extreme fire are still unclear. Considering the dense population and high value inside super-tall buildings, the fire-induced progressive collapse of super-tall buildings can result in unacceptable financial losses and losses of life (Menzies 2001). Therefore, the study on the progressive collapse of typical super-tall RC buildings under extreme fire has a high significance. Fire-induced progressive collapse incorporates the behavior of the entire structure. Therefore, fire-induced progressive collapse should be analyzed from the perspective of the overall structure. Numerical simulation is one of the best methods to study the behavior of the overall structure.

Analyzing the fire-induced collapse of RC structures is much more complicated because of the complicated constitutive model of concrete and the non-uniform, time-changing temperature field distribution in each component section (Li *et al*. 2015). In addition to the challenges of simulating complicated temperature fields and constitutive models, the interactions of the structural components of super-tall buildings are much more complicated than those of multi-story buildings. Therefore, no research currently exists regarding the simulation of the progressive collapse of super-tall buildings.

Following the previous work of Li *et al*. (2015), a multi-layer shell element model is proposed in this study to simulate floor slabs and shear walls during fire. The FE model of a typical super-tall RC frame-core tube building is established using the proposed fiber beam element model and the multi-layer shell element model. The fire-induced progressive collapse of a typical RC super-tall building is simulated. The simulation results show that the thermal expansion and fire-induced failure of the floor system critically influence the failure of peripheral columns when multiple stories of a super-tall RC building are exposed to fire. Specifically, the progressive collapse of the building is triggered by the flexural failure of the peripheral columns due to the thermal expansion of floor slabs and beams. This work reveals the mechanisms of fire-induced progressive collapse in typical tall RC buildings and provides a method for studying the fire safety of tall RC buildings.

NUMERICAL ANALYSIS METHOD

Analysis process

The framework used to simulate the fire-induced progressive collapse of super-tall RC buildings is shown in Figure 1. An FE model of the overall structural system is established first. The numerical analysis is divided into the following three steps. (1) In the first step, gravity loads are applied to the structure at room temperature to generate the initial internal force in the structure. (2) In the second step, a selected fire scenario is applied to the structure to generate the temperature distribution field. (3) Finally, in the last step, the simulated temperature fields of the components are assigned to the structure as boundary conditions to perform the fire-induced progressive collapse analysis.

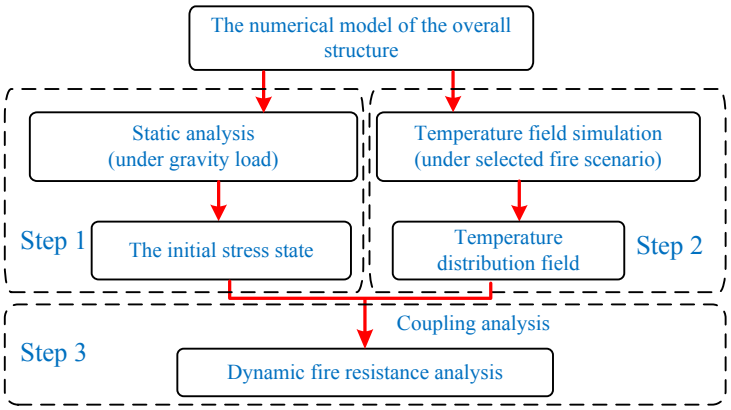

Figure 1 Framework for simulating the fire-induced progressive collapse of super-tall RC buildings

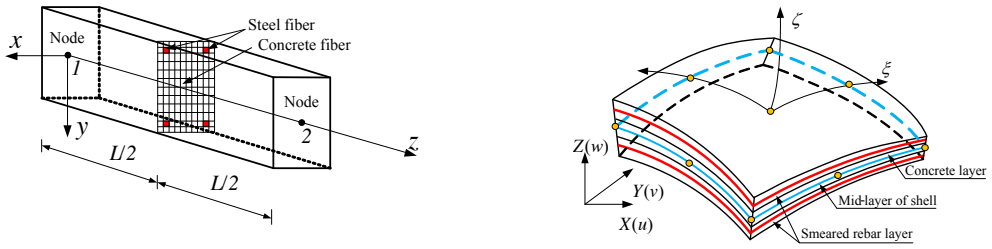
Numerical model

An accurate and efficient numerical model considering high temperature effects is critical for analyzing the fire-induced collapse of overall structures. The models for heated structural components and unheated structural components are introduced respectively as follows:

The unheated columns and beams are simulated using conventional fiber beam elements (Lu *et al*. 2013). The unheated shear walls, coupling beams and floor slabs are simulated using conventional multi-layer shell elements (Miao *et al*. 2011), as shown in Figure 2. Previous studies (Lu *et al*. 2013; Miao *et al*. 2011) have indicated that these models have satisfactory accuracy and efficiency for predicting the dynamic collapse of RC structures.

The temperature fields of RC components subjected to fire vary significantly inside the cross section and along the longitude axis. Therefore, based on conventional fiber beam elements and multi-layer shell elements, corresponding fiber beam elements and multi-layer shell elements are proposed for heated RC components. Different temperatures are assigned to different fibers or layers to account for the non-uniform temperature distribution within the cross-sections of the beams, columns, walls and slabs. The constitutive laws of the materials (Shi *et al*. 2002; Guo *et al*. 2003) that account for high-temperature effects are used to simulate the material behaviors subjected to evaluated temperature. A detailed introduction of the constitutive laws and element failure criteria is introduced by Li *et al*. (2015). The non-uniform temperature field along the longitudinal axis of the components can be considered by subdividing the component into many individual elements. The fiber beam elements and multi-layer shell elements are embedded into the general purpose FE code of MSC.Marc as user defined subroutines.



(a) Fiber beam elements (b) Multi-layer shell elements

Figure 2 Fiber beam elements and multi-layer shell elements

By comparing with the fire experiment results of different types of typical components, the proposed model can accurately predict the behavior of RC components under high temperatures. Furthermore, the computational efficient is high enough to satisfy the demands of overall structural collapse analysis. The validations of the numerical model are introduced in previous studies (Li *et al*. 2015; Li *et al*. 2011).

INTRODUCTION TO THE CASE STUDY

General building information

The studied case is a typical super-tall RC frame-core tube building which was designed by Lu *et al*. (2015) in accordance with JGJ3-2010 (2010). The building has 42 stories and a 6.1-m high penthouse on the top, with a total height of 141.8 m. Note that this building is also very similar to the typical super-tall RC frame-core tube building proposed by the Tall Buildings Initiative (TBI) project of the Pacific Earthquake Engineering Research Center (PEER) (Moehle *et al*. 2011). The three-dimensional model and planar layout of the structure are shown in Figure 3. The FE model of the building is established using the method proposed in Section 2.2, which contains 25,476 fiber beam elements and 17,352 multi-layer shell elements.

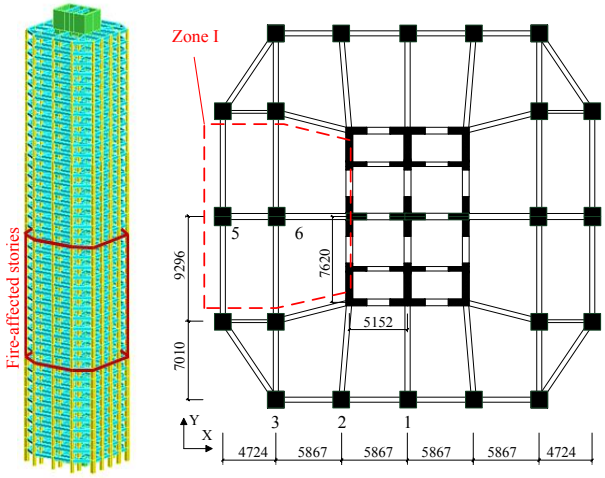


Figure 3 Structural arrangement and position of the fire-affected area (Unit: mm)

Fire scenario

Because no related reports are available regarding the fire-induced collapse of tall RC buildings, the most widely used International Standard ISO 834 (ISO 1999) standard temperature curve is used in this work to apply the thermal boundary condition, which refers to the fire resistance research (Frangi *et al*. 2004; Han *et al*. 2003) at the component level.

Because all of the tall buildings passed the conventional fire resistance requirement during the design procedure, only extreme fire loads can result in progressive collapse, which are much more serious than conventional fire loads. However, there is no related specification on such extreme fire in existing fire design codes (GB50016-2006 2006; National Fire Protection Association 2008) or progressive design codes (GSA 2008). Consequently, the fire scenarios in the collapse accidents of WTC and Windsor Tower will be used as important references. By considering the actual fire-induced collapse accidents of tall buildings, this study adopted a simplified extreme fire scenario in which a 10-hour ISO standard heating process is applied to multiple stories of a building. The fire spreading process is ignored due to the rapid vertical flame spreading speed in tall buildings (e.g., the speed of upward flame spreading in the Windsor tower was 6.5 min for each story). Of course, such a simplified extreme fire scenario cannot fully represent the complicated fire action of an extreme fire. However, note that this work is the first trial to implement the fire-induced progressive collapse simulation of tall RC buildings, and there are no previous widely accepted specifications on the fire action of extreme fire. Note also that the proposed simplified extreme fire scenario is convenient for other researchers to repeat the simulation in this work. Therefore, this simplified extreme fire scenario is adopted. Zone I is selected by considering the fire compartments in the building as typical fire-affected area (Figure 3).

The simulation of the temperature field

The thermal analysis module of MSC.Marc is used to predict the internal temperature field of the fire-affected components. The material thermal parameters, thermal radiation and convection parameters, which are required

for temperature field analysis, are determined according to Eurocode 2 (British Standards Institution 2004). Subsequently, the calculated temperature field is transferred to the structural analysis module.

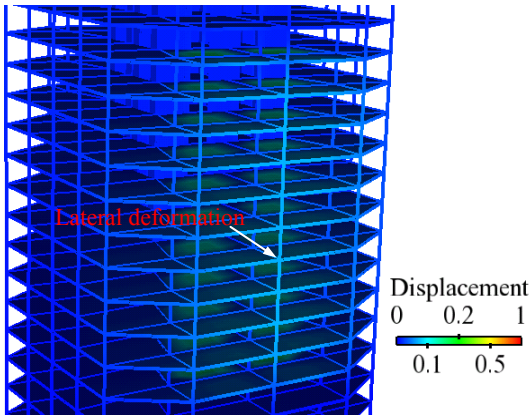
ANALYSIS OF FIRE-INDUCED PROGRESSIVE COLLAPSE

Fire resistance analysis is conducted for the case introduced above. The total computational time is approximately 60 hours on a computer with an Intel E5-2620 CPU and 64-GB of memory, which proves the computational efficiency mentioned above. After about 10 hours of fire exposure, progressive collapses occur in the case where most of the slabs, beams and columns in the fire-affected area collapsed.

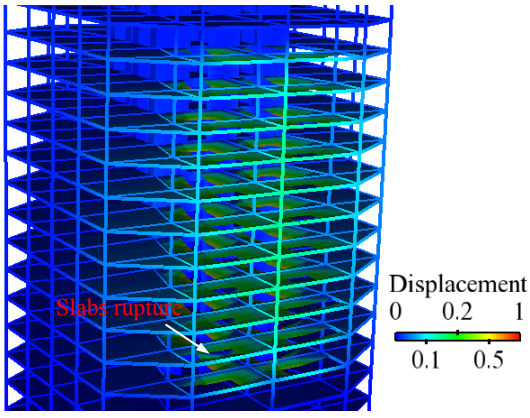
Collapse process

The case is discussed in detail in this section to illustrate the collapse process, failure mechanisms and interactions of different components in the building. For the convenience of the following discussion, the components in the building are named as "Column/Beam story number-component number". The planar layout of the components is shown in Figures 3. For example, "Column 11-5" represents Column 5 (in Figure 3) on the 11th story.

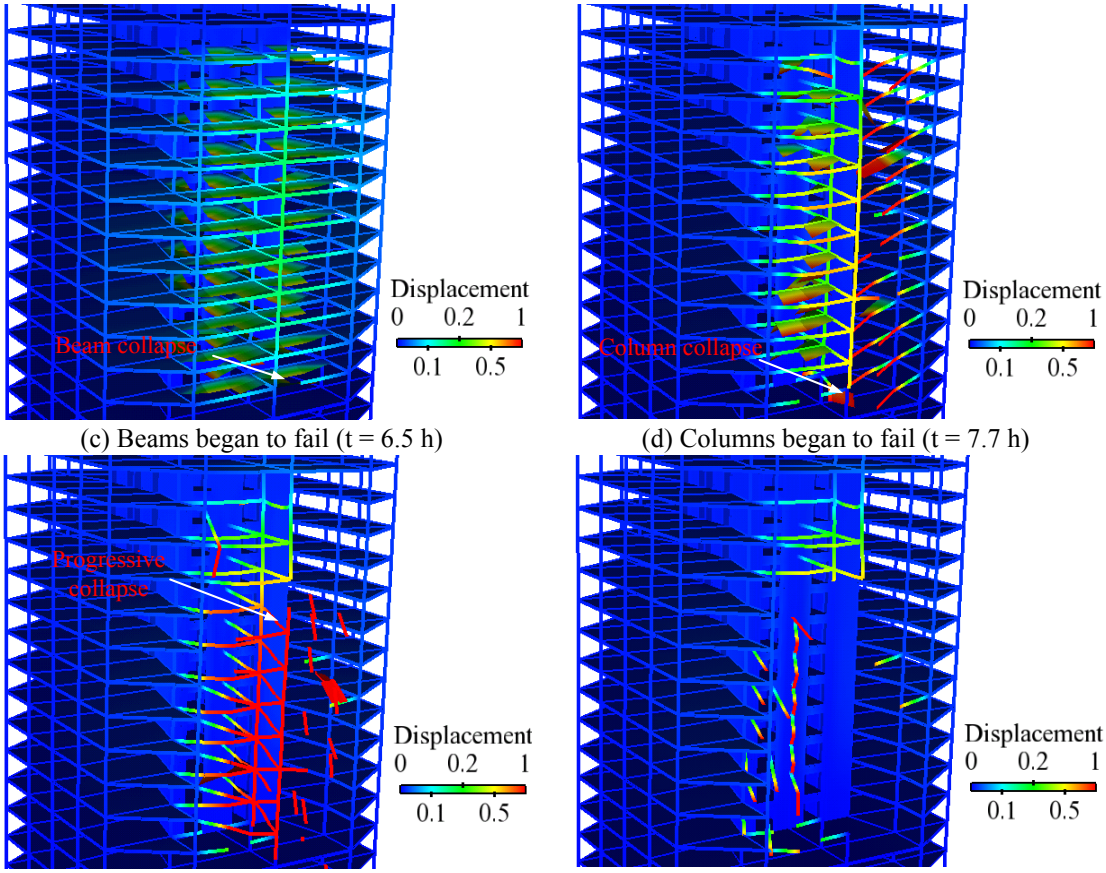
The progressive collapse process is shown in Figure 6. As the temperature increases, the heated slabs are vertically deformed due to the combined effects of temperature and gravity loads. Simultaneously, because of thermal expansion, the slabs and beams push the peripheral columns outward. When t = 1.5 h, the peripheral columns laterally deform up to 5 cm (Figure 4a). When t = 3.3 h, the vertical deflection of the slabs reaches 50 cm. Meanwhile, the tensile strain of steel in the middle span of the slabs exceeds the ultimate strain and ruptures. However, such a local collapse of the slabs does not affect the stability of the entire structure (Figure 4b). When t = 6.5 h, most of the slabs in the fire-affected area collapse. In addition, the peripheral beams located on the lower stories of the fire-affect areas collapse. When t = 7.3 h, Column 11-5 collapses due to large lateral deformation (Figure 4d). The detailed failure mechanism of Column 11-5 will be discussed in a later portion of this work. Two seconds after the collapse of Column 11-5, Column 11-6 collapses, which triggers a progressive collapse (Figure 4e). Ten seconds after the collapse of Column 11-5, the fire-affected structure collapses completely (Figure 4f). Due to the large redundancy of the tall building, the collapse in the fire-affected areas does not cause further collapse in the residual structure.



(a) Lateral deformation of peripheral columns (t = 1.3 h)



(b) Slabs began to fail (t = 3.3 h)



(c) Beams began to fail (t = 6.5 h)

(d) Columns began to fail (t = 7.7 h)

(e) Progressive collapse of structure (2 seconds after the columns failed)

(f) Final failure mode (10 seconds after the columns failed)

Figure 4 Simulated progressive collapse process (unit: m)

Analysis of the collapse mechanism

The numerical simulation introduced above shows that the failure of Column 11-5 triggers the progressive collapse of the entire structure. Figures 5a and 5b show the time histories of axial forces and bending moments in Columns 11-5 and 11-6. Before the progressive collapse (i.e., $t \leq 7.7$ h), the axial forces of the columns change significantly (up to 26.8%). The axial compressive forces increase firstly and then decrease when approaching to progressive collapse. In addition, the bending moments of the columns significantly change and the bending moments become reversed during the heating process due to the thermal expansion of the fire-affected floor slabs and beams.

The detailed collapse mechanisms are explained in Figure 6. During the initial phase of heating, the fire-affected stories pushed the column laterally outward due to thermal expansion. Figure 6a shows the lateral deformation of the column when $t = 3.3$ h. Subsequently, the fire-affected slabs and beams on the 11th through 13th stories fail one-by-one (Figures 4b). The push forces from the failed beams and slabs disappear, which results in the inward movement of Point a on the column due to the recovery of elastic deformation. Meanwhile, Point b on the column is continuously pushed outward by the thermal expansion of slabs and beams on the 14th to 20th stories. Such deformation results in a significant increase of curvature at Point a (Figure 7). Finally, Column 11-5 fails at Point a when $t = 7.7$ h due to extreme flexural deformation.

CONCLUSION

In this work, the progressive collapse of a typical super-tall RC frame-core tube building exposed to extreme fires is simulated using the proposed numerical model. The primary conclusions are as follows:

(1) When subjected to extreme fire loads, progressive collapse may occur inside the fire-affected area. However, because of the large redundancy of a super-tall RC frame-core tube building, the structures outside of fire-affected areas can avoid progressive collapse via alternative load paths.

(2) The progressive collapse of a super-tall RC frame-core tube building is triggered by the flexural failure of the peripheral columns, which are pushed outward by the thermal expansion of the floor system.

BEHAVIOUR OF PRE-STRESSED HIGH STRENGTH CONCRETE SLEEPERS SUBJECTED TO DYNAMIC LOADS

Taherinezhad Javad [1,*], Priyan Mendis [1], Tuan Ngo [1] and Massoud Sofi [1]
[1]Department of Infrastructure Engineering, the University of Melbourne, Parkville, VIC, Australia, 3010.

ABSTRACT

As part of ballasted railway track, pre-stressed concrete sleepers (PCSs) play an essential role in track response, performance and safety. PCSs are subjected to dynamic loads which are often high magnitude and low duration. The characteristics of dynamic loads, the interactions between track components and the dynamic responses of PCSs under dynamic loads have been vastly investigated throughout past decades and continue to be a subject of interest to the railway industry.. Mechanical behaviours of PCSs such as dynamic response and failure mechanisms are important to meet the structural and durability requirements of railway sleepers. However, the influence of high performance concrete (HPC) mechanical properties on behaviour of PCSs is currently lacking. This paper presents a finite element model developed as a part of a broader investigation undertaken at the University of Melbourne. Finite element modelling package LS-DYNA has been used to represent a sleeper in a simulated track condition. The model is validated based on published experimental information. Different grades of high strength concrete (HSC) have been investigated. Mechanical properties such as compressive strength, tensile strengths, fracture energy and elastic modulus are considered.. The results show that the using higher concrete grade in sleeper leads to a larger bending moment under the same dynamic load. This confirms the inadequacy of current design approach for PCSs.

INTRODUCTION

Railway is known as the best and the safest transportation mode for both passengers and merchandise across the world. Conventional track or ballasted track is still used in a large number of new tracks, even those made for high speed trains or heavy-haul trains. Ballasted tracks consist of two main parts, substructure (including ballast, sub-ballast and formation layer) and superstructure (including rail, fastening system and sleeper), as shown in Figure 1. As an essential member of ballasted track, sleepers play a major role in track performance and safety. Their main duty is support the rails, distribute the loads from the rails to the ballast, maintain the track gauge and tolerate the movements of the rails. Although, a few types of sleepers, such as timber and steel, have been utilised since establishment of the railways, pre-stressed concrete sleepers (PCSs) are the most popular type at the present time.

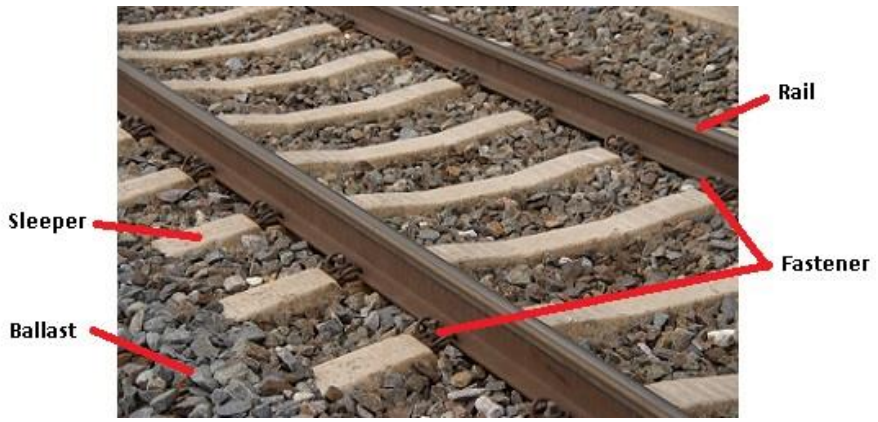

Figure 1 Main components of ballasted track

While the static wheel load of trains varies between 25 kN to 200 kN depending on the train type and function, the dynamic contact force between wheel and rail-head can reach over 750 kN. These high magnitude dynamic

loads have duration in the range of 1 to 12 ms and are generated due to irregularities at the wheel surface, abnormalities at the head of rail or even discontinuity in the support layer (Remennikov and Kaewunruen, 2008). The shape of the dynamic loads in time domain and their magnitude mostly depends on the kind of causes and rolling speed. These loads transfer to the sleeper via the fastening systems.

PCSs are expected to withstand the high magnitude loads and harsh environments. These loads can cause premature damages in PCSs mostly in the form of cracks (Van Dyk et al., 2012) which, in turn, facilitate penetration of water and corrosive ions, particularly chloride ions. Corrosion of the strands under the influence of chloride ions is known as a significant factor that leads to deterioration of sleepers and shortens their lifespan (Mohammadzadeh and Vahabi, 2011). In spite of the premature damage, researchers believe that there is a huge amount of untapped strength in PCSs (Remennikov et al., et al., 2007 and Leong and Murray, 2008). A controversial issue of premature damage and untapped strength is often attributed to conservativeness of static analysis and an allowable-stress design approach of PCSs which is prescribed by standard codes (Remennikov et al., 2007, Nairn and Stevens, 2010 and Murray and Bian, 2012).

For better understanding the behaviour of PCSs and address the unresolved problems which considerably shorten their service life, extensive research has been undertaken. Reviewing the literature, Taherinezhad et al, (2013) has indicated that the research works have shed some lights on the behaviour of PCSs and their interactions with other components of the track. Nevertheless, the material performance is still a subject of interest to the railway industry. High performance concrete (HPC) is believed as an appropriate solution to the issue. Very recently, some aspects of a few high performance concrete sleepers have been investigated (Hwang et al., 2011, Li et al., 2012 and Ramezanianpour et al.,2013). However, investigating the behaviour of HPC sleepers under the dynamic loads is still lacking.

The main purpose of this article is to report on the mechanical behaviour of high strength concrete (HSC) sleepers subjected to dynamic loads, as a part of a broader investigation undertaken at the University of Melbourne. The aim of the investigation is to establish the material necessities of the concrete sleepers in order to satisfy the structural and durability requirements. In the following sections, the methodology including available experimental study and the modelling approach for finite element analysis is reported.

METHODOLOGY

To investigate the mechanical behaviour of high performance concrete sleepers a finite element model has been developed using ANSYS LS-DYNA. The model has been calibrated based on available results of a comprehensive experimental work that had been conducted at the University of Wollongong Australia by Kaewunruen (2007) and colleague. A parametric study has been conducted to analyse the influence of concrete mechanical properties on the behaviour of pre-stressed concrete sleeper subjected to dynamic loads. This section is divided into two sub-sections. The first sub-section will introduce the experiments. The model and validation is reported it he second sub-section.

Experimental Overview

To study some aspects of mechanical behaviour of PCSs, Kaewunruen and Remennikov (2009, 2010 and 2011) utilised a high capacity impact test apparatus. The core of the test rig is a falling mass with a maximum drop height of 6 m. The weight of projectile was set as 5.81 kN (592 kg), and the drop heights varies to generate different magnitude of impact load at rail head. The impact loads were recorded by the dynamic load cell which installed at the rail head and connected to a computer. A high speed camera has been used to obtain the efficiency of drop weight through the calibration tests. Using the test rig the mechanical responses such as impact behaviour, impact capacity, impact fatigue, progressive failure and crack propagation of few PCSs, which are widely used in Australia, have been studied.

Using the actual ballast bed in the experimental work can cause difficulties in controlling boundary conditions and rearranging the test setup after multiple high magnitude impact loads. On the other hand, Australian Standard AS-1085.19 has adopted the alternative ballast for a specific use (AS-1085.19-2013, 2003). It states “the support shall permit a vertical deflection in the range of 0.1 mm 0.5 mm (inclusive) when a sleeper supported on it is subjected to an increase in static load from 50 kN to 60 kN at one rail seat”. Kaewunruen and Remennikov (2008) tested a variety of rubber material to simulate the ballast layer. Finally, they found that a combination of six layers of conveying belt provides satisfactory results and meets the stiffness requirement of alternative support prescribed in the Australian Standard.

To ensure realistic simulation of an actual track conditions using this approach, the relationship between impact load and dynamic bending moment at the rail seat has been investigated experimentally and compared with those of D-TRACK finite element model which was developed by Cai (1992) (as cited by Kaewunruen, 2007). The validity and capability of D-TRACK for simulation of track behaviour were investigated through 2 benchmark programs by Steffens (2005) and Leong (2007). A comparison of the results confirms the suitability of experimental test approach to model the actual impact loading of sleepers.

Although Kaewunruen and Remennikov (2009, 2010 and 2011) have examined sleepers with different lengths, cross sections and material properties in their study through the last decade, their final work has been considered for the current study. The selected sleeper represents a heavy-duty sleeper with total length of 2.80 m and gauge length of 1.60 m. The unconfined compression strength and mass density of concrete were 55 MPa and 2350 kg/m , respectively. 22 pre-tensioning strands were the high strength with rupture strength of 1860 MPa and diameter of 5.03 mm. The initial strain of strands due to pre-tensioning was about 6.70 mm/m. Figure 2 depicts the dimensions of the sleeper cross section at the rail seat and midspan plus locations of 22 pre-stressing tendons.

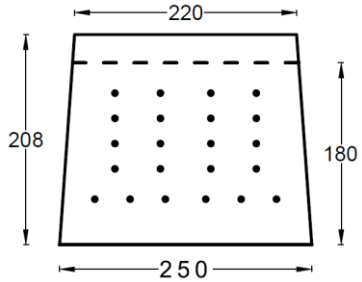

Figure 2 Dimensions of sleeper cross section at the rail seat and midspan, mm (Kaewunruen and Remennikov, 2011)

The Finite Element Modelling Approach

LS-DYNA has been used to develop a finite element model for better understanding of mechanical and cracking behaviour of PCSs and investigating the influence of concrete properties on sleeper behaviour such as stress distribution, cracking and bending moment. LS-DYNA is an advanced non-linear multi-physics simulation package to solve many complex and real world problems by using a time step history of explicit scheme. It has significant capability in simulating dynamic and high-rate loading such as falling-mass impact and blast shock. Although LS-DYNA is basically developed to analyse various types of structures and members subjected to dynamic loads, it provides three different methods to include static preloading: (a) explicit dynamic relaxation; (b) quasi-static transient analysis with mass damping; and c) implicit static analysis. Besides, LS-DYNA has a comprehensive library of material models which are capable of capturing the most key aspects of material behaviour (Hallquist, 2006).

There are about 30 material models available in LS-DYNA to represent geo-materials, such as soil, rock and concrete. However, for realistic predicting of concrete behaviour subjected to a triaxial state of stress, the constitutive model needs to simulate main features of material such as pressure-hardening, strain-softening, strain rate enhancement and crack propagation. Six constitutive models have been developed specifically for concrete material and implemented in LS-DYNA, including MAT072, MAT084-85, MAT111, MAT159, MAT172 and MAT272 (LSTC, 2009). While all of these models need more than 20 input parameters to capture key features of concrete, four models including MAT072R3, MAT084, MAT159 and MAT272 exhibit an automatic input capability to generate the data for model parameters (Brannon and Leelavanichkul, 2009). The first three models have been well documented and validated by a large number of research works since implemented in LS-DYNA. The suitability of these three models for analyzing PCSs under dynamic loading was investigated (Taherinezhad and et al., 2015). It has been demonstrated that MAT084 (Winfrith concrete model) simulates the behaviour of PCSs more suitable than those anticipated by the others in this case.

MAT084, the Winfrith concrete model, was implemented into LS-DYNA in 1991. The model was developed in 1980s, intended in analysing reinforced concrete structures under impact loading. The model provides a basic plasticity model includes strain softening in tension, omission of material dilation, optional strain rate enhancement and optional inclusion of smeared reinforcement. Furthermore, the model allows up to three orthogonal crack planes per element and cracks can be visualized via a post-processing interface such as LS-PREPOST (Schwer, 2011). In the case of automatic parameter generation, this model needs 7 mechanical

properties including density tangent modulus of elasticity, Poisson's ratio, uniaxial compressive strength, uniaxial tensile strength, fracture energy and maximum size of the aggregate.

An elaborated finite element model of the test as introduced in previous section has been developed. The model consists of a full scale concrete sleeper, pre-stressing tendons, two segments of rails, fastening system, simulated supporting environment, falling-mass and supporting base. Figure 3 indicates the complete finite element model. As the stress distribution in fastening system and its interactions with other parts are not the aim of this study, it has been simplified in geometry. However, the pre-loading to fix the rail to the sleeper has been simulated. The model considers all tendons as TRUSS elements and the fastening bolts and the fixing bolts (bolts used to fix the sleeper to the test rig) as BEAM elements. Further, all other parts are made of hexahedral SOLID elements. It contains 44 parts, 3'098 Truss elements, 54 BEAM elements, 141'474 SOLID elements and 180'088 nodes.

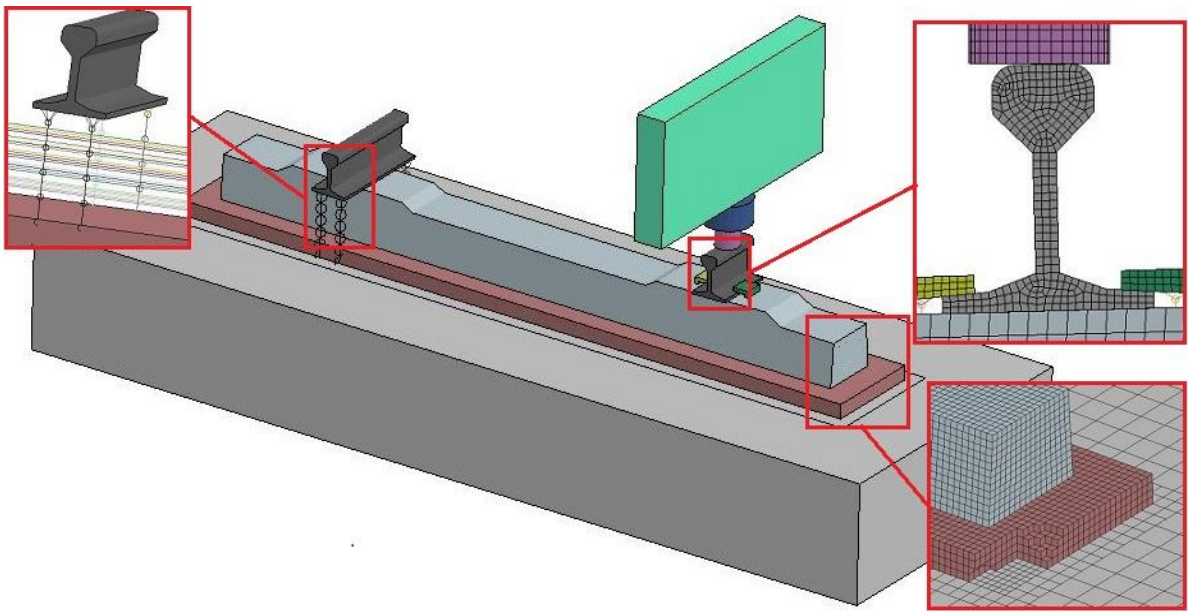

Figure 3 Schematic view of entire finite element model and few details of meshed parts

The analysis in this study is divided into two phases. In the first phase, dynamic relaxation is utilised to apply pre-loads including tendons pre-tensioning, the fasteners preload to connect the rail to the sleeper and pre-tensioning of bolts that used to fix the sleeper to the supporting environment. After completion of dynamic relaxation phase, the transient phase starts to generate the dynamic load by defining an initial velocity for the falling mass. The dynamic load is generated at contact between the nose of impactor and the head of rail then transfers to the sleeper through the rail.

Model Validation

Validation of the model is an important consideration in a finite element model to ensure a satisfactory representation of the reality. Thus, the newly developed finite element model in this study was calibrated and validated based on aforesaid experimental works. The contact force between the impactor and rail was used to calibrate the model. Figure 4 shows two samples of calibration of the model based on contact force due to 600 mm and 400 mm drop heights. To validate the model in the preloading phase, a computer program has been developed based on design approach of Australian Standard. The program calculates the stresses at the critical locations of sleeper including top and bottom of the rail seat and midspan. The stresses at these locations were also extracted from the finite element model. The results show good agreement between the analytical model and numerical model, see Table 1. To validate the model in the transient phase, the maximum bending moment at the rail seat has been compared by that measured during the experiments by Kaewunruen and Remennikov (2009). Figure 5 indicates relationship between dynamic force generated at the rail head and the bending moment of sleeper at the rail seat. The results show good correlation with a trend line which is suggested based on the test results, especially, those due to drop height of 600 mm which is used for the rest of analysis in this paper. This drop height corresponds with velocity of 3.43 m/s at the moment of contact. In this case the dynamic load at the contact between the impactor nose and rail head can reach 880 kN, see Figure 4.

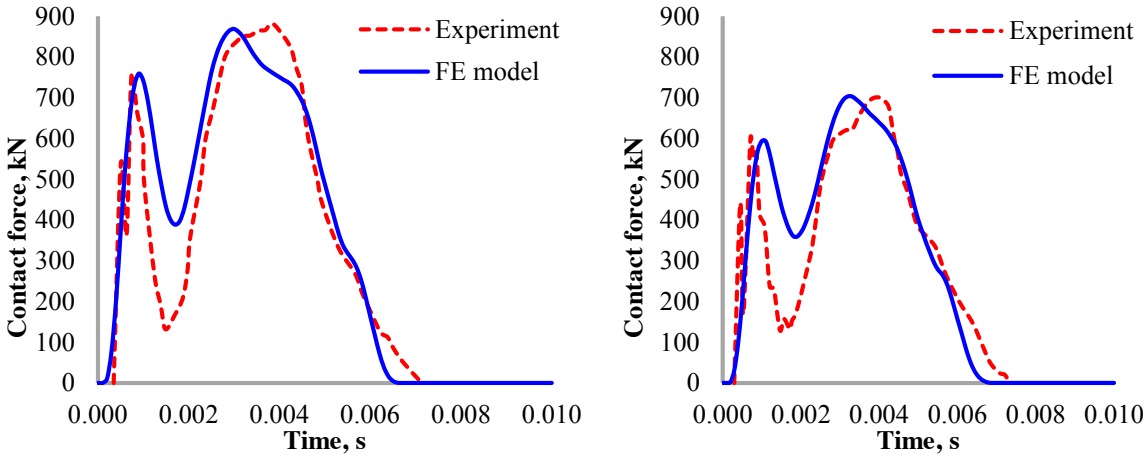

Figure 4 Time history of contact force between impactor and rail head due to drop heights of 600 mm (left) and 400 mm (right), the experimental results adapted from (Kaewunruen and Remennikov, 2009)

Table 1 Comparison of pre-tensioning stress at critical zones of the sleeper

Location	Midspan			Rail seat		
	Analytical (MPa)	FEM (MPa)	Difference (%)	Analytical (MPa)	FEM (MPa)	Difference (%)
Top	15.07	14.31	-5.0	8.40	7.65	-8.93
Bottom	11.03	11.74	+6.4	14.16	14.32	+1.1

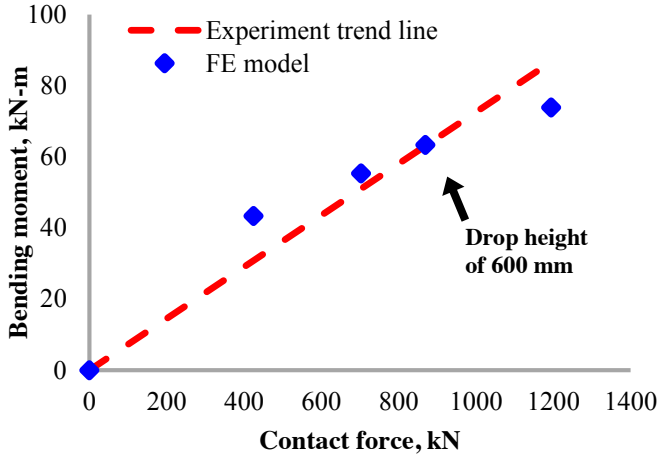

Figure 5 Ralationship between bending moment at the rail seat and contact load at the rail head, the experimental results adapted from (Kaewunruen and Remennikov, 2009)

In order to investigate the effects of concrete strength on sleeper behaviour, a few grades of high strength concretes (HSC) including C70, C85 and C99, have been investigated under dynamic load. The mechanical properties of each grade have been estimated based on standard codes and available literature. The contact force, bending moment at the rail seat and midspan, stresses at rail seat and concrete cracking are studied.

The relationship between characteristic compressive strength (f_c') and the other mechanical properties of concrete have been empirically formulated and published in Standard Guidelines and in the literature (AS3600, 2009; CEP-FIP, 1993; Mendis et al., 1997; Mendis, 2001 and Keru, 2001). CEB-FIP Model Code 1990 (1993) recommended equations for all mechanical properties including uniaxial tensile strength (f_{ct}'), fracture energy (G_F) and modulus of elasticity (E_c), that we need in this study:

$$f_{ct}' = 0.30\, f_c'^{2/3} \quad (1)$$

$$E_c = 10^4\, f_c'^{1/3} \quad (2)$$

$$G_F = a_d\, (f_c' + 8)^{0.7} \quad (3)$$

Where f_c': the characteristic compressive strength, f_{ct}': characteristic tensile strength, E_c: modulus of elasticity, G_F: fracture energy and a_d: index for the influence of maximum diameter (d_{max}) of aggregates and a_d is 6 for d_{max} of 16 mm, 10 for d_{max} of 32 mm. In this article, d_{max} is 19 mm, so a_d is given the value of 6.75. The predicted values of E_c using equation (2) are in very good agreement with those predicted by an equation recommended by Mendis et al., (1997) for HSC. However, estimation of f_{ct}' using equation (1) is slightly larger than that estimated using the equation suggested by Australian Standard (AS-3600, 2009). It is worth noting that the value of Poisson's ratio (υ) has been set to 0.2 according to CEB-FIP (1993) and AS-3600 (2009). Equation (3) overestimates the fracture energy of HSC as Dong and Keru (2001) has demonstrated based on a series of test results. Therefore, 85 percent of those predicted by equation (3) is used in this study. Based on above discussion, the properties of concrete are presented in Table 2.

Table 2 Values of concrete mechanical properties

Concrete grade	ρ (kg/m^3)	d_{max} (mm)	f_c' (MPa)	f_{ct}' (MPa)	υ	E_c (GPa)	G_{Fc} (N/m)
C55	2350	19	55	4.4	0.2	39.7	99
C70	2370	19	70	5.1	0.2	42.6	117
C85	2410	19	85	5.8	0.2	45.2	134
C99	2450	19	99	6.5	0.2	47.4	149

RESULTS AND DISCUSSIONS

This section presents the results of the finite element model which has been developed using LS-DYNA. The model simulates PCSs made of different grades of concrete that subjected to dynamic loads. The load can exceed 880 kN. LS-PREPOST interface has been employed to extract the results including contact force, bending moment, stress and cracking behaviour. Table 3 indicates the results for different grades of concrete materials. The results show that the maximum value of contact force at the rail head does not depended on concrete grade.

Table 3 Bending moments and stress due to drop height of 600 mm for different concrete grades (parentheses show the ratio to the results of grade C55)

Concrete grade	Maximum contact force, *(kN)*	Maximum bending moment, *(kN-m)*		Maximum stress at the rail seat in longitudinal direction, *(MPa)*	
		Rail Seat	Midspan	Top	Bottom
C55	884	66.3 (1.00)	-36.0 (1.00)	-94.0 (1.00)	5.9 (1.00)
C70	888	69.6 (1.05)	-36.5 (1.01)	-107.5 (1.14)	6.4 (1.08)
C85	889	70.9 (1.07)	-37.0 (1.03)	-111.4 (1.18)	7.1 (1.20)
C99	885	71.6 (1.08)	-37.9 (1.05)	-115.2 (1.22)	7.8 (1.32)

While the dynamic load at the rail head is almost constant for different grades of concrete, the bending moment at the rail seat and midspan of the sleeper increase 8 and 5 percent respectively. This increase can be attributed to the more uniformly distribution of loads on the alternative ballast due to larger stiffness of sleeper. Two factors participate in larger stiffness of sleeper made of HSC; (a) the elastic modulus of concrete increases with increasing the compressive strength, and (b) less cracks of concrete at the rail seat. Figure 6 indicates the visible cracks (with minimum crack width of 50 micrometers) at the bottom of rail seat.

A comparison of the maximum stress values (in Table 3) with the tensile and compressive strength values of concrete presented in Table 2 indicates that the maximum stresses are larger than the strength of concrete. It should be noted that only a limited number of concrete elements experience such large compressive stresses, see Figure 7. These elements located just underneath and are confined by the rail. The increase of compressive strength can be ascribed to strain rate enhancement and confinement effects. MAT084 material model considers the enhancement of concrete compressive strength due to both strain rate effects and confinement effects. In case of tensile stress, strain rate enhancement is the only factor which participates to the higher tensile strength.

Tensile softening is another key feature of concrete which plays a significant role in cracking behaviour of the PCSs. Study of tensile strain and stress variation at the bottom of rail seat indicates that the model properly simulates this behaviour. Figure 8 shows time history of tensile strain and stress at the bottom of rail seat of the sleeper (point B, Figure 7) made up of concrete grade C99 under drop height of 600 mm. At the beginning of analysis both strain and stress start to increase proportionally. At time around 0.0007 sec stress reaches its

maximum value and suddenly drops to about zero but, strain keeps its upward trend till exceeds strain of 4 mm/m. However, it should be noted that the curve shape of compressive stress and strain in time domain are similar and the compressive strain fluctuates between -0.15 mm/m and -1.9 mm/m.

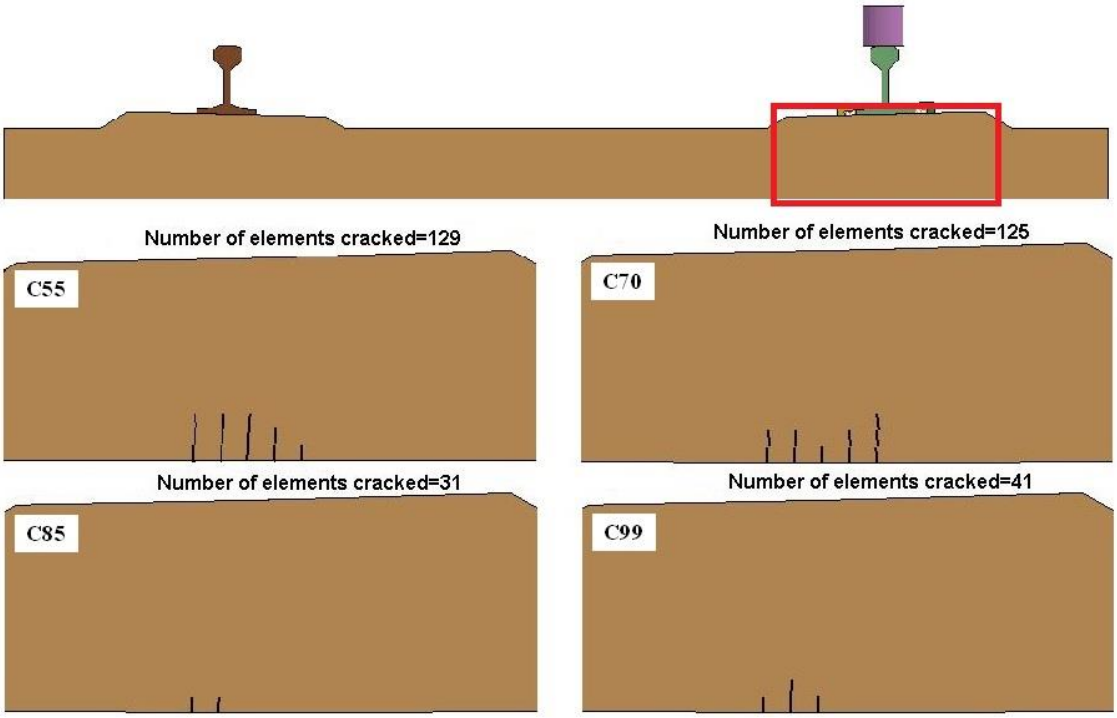

Figure 6 Visible cracks at the bottom of right rail seat due to drop height of 600 mm

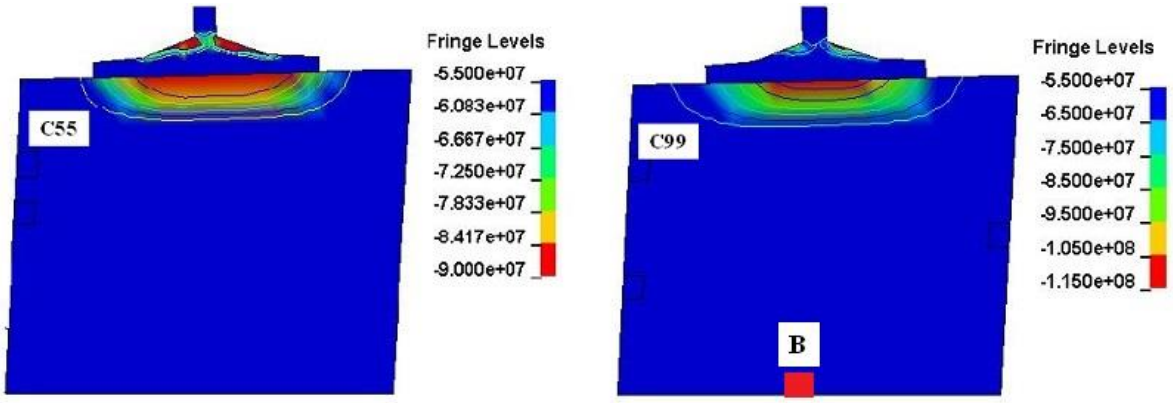

Figure 7 Area of the sleeper compressive stress (Pa) due to drop height of 600 mm

The above results show that using higher grade of concrete as material for PCSs does not necessarily results in a proportional increase of the sleeper load-carrying capacity. The results indicate that using a larger grade of concrete material leads to an increase of bending moment and bending stresses for the same dynamic load generated at the rail head. For example by replacing concrete grade C55 with concrete grade C70 the bending moment, compressive stress and tensile stress increase about 5, 14 and 8 percent, respectively, see Table 3. This confirms the inadequacy of current static analysis and allowable-stress design approaches which are accepted by standard codes such as AS-1085.14 (2012).

The next step of the investigation is examining the influence of each key mechanical properties of concrete on behaviour of sleeper. This constitutes work in progress at the University of Melbourne. The Study will provide a deeper insight into the behaviour of high performance concrete sleepers and will support designers to choose the most suitable material properties for PCSs. It is also expected that the investigation contributes to the establishment of a new design approach of PCSs.

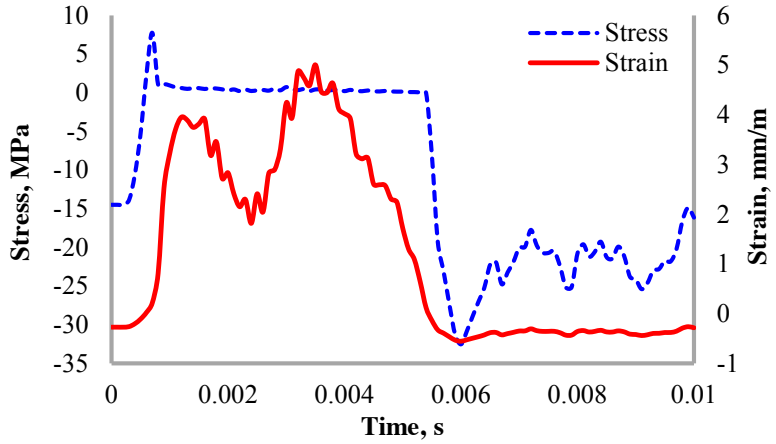

Figure 8 Time history of tensile stress and strain at the bottom of rail seat, concrete grade C99, drop height of 600 mm

CONCLUDING REMARKS

Using ANSYS LS-DYNA package, a finite element model has been developed to investigate the behaviour of high performance concrete sleeper under dynamic loads. The model has been validated based on results of experimental investigation published in the literature. At first step the behaviour of a sleeper made of different grades of high strength concrete has been studied under a dynamic load of 885 kN.

The results shows that using larger grade of HSC does not lead to a proportional increase of sleeper load-carrying capacity as a result of larger bending moment generated under same dynamic load. This confirms the inadequacy of the current approach of analysis and design of pre-stressed concrete sleepers.

The findings also indicate that the capability of developed finite element model in simulating concrete sleeper subjected to dynamic loads. So, the next step is using the model to investigate the behaviour of high performance concrete sleepers subjected to dynamic loads. It is expected that the investigation provides a deep insight into the behaviour of pre-stressed concrete sleepers which, in turn, can be associated with establishing a new design approach.

ABSTRACT

In Japan, there has existed a serious problem on seismic retrofit for a lot of one-story wooden structures such as temples and shrines in famous tourist resort areas, which were built by a Japanese traditional framed-construction method and have some types of thatched roof instead of tiles. In order to investigate the seismic behaviour of an old one-story thatched roof wooden structure, "Yakushi-doh", 3-D non-linear collapsing process analysis of Yakushi-doh structure was conducted against a strong earthquake ground motion with the Japan Meteorological Agency seismic intensity of "6 upper" level. A non-linear behaviour of timber elements in the wooden structure during a strong earthquake ground motion can be simulated by this 3-D non-linear collapsing process analysis based on the Distinct Element Method. The effect of the post fixing condition under wooden structure floor on seismic response of Yakushi-doh structure was numerically investigated in this paper.

KEYWORDS

One-story wooden structure with thatched roof, 3-D non-linear collapsing process analysis, seismic response.

INTRODUCTION

It is well known that a great number of wooden houses collapsed in the 1995 Hyogo-ken Nanbu Earthquake. In order to investigate seismic performance of wooden house against a strong earthquake ground motion, seismic collapsing analyses (Nakagawa and Ohta 2010; Takatani 2013, 2014; Takatani and Nishikawa 2012, 2014) for many Japanese old wooden houses built by a Japanese traditional framed-construction method have been conducted by 3-D non-linear collapsing process analysis based on the Distinct Element Method (Cundall and Strack 1979). In Japan, there has existed a serious problem on seismic retrofit for a lot of one-story wooden structures such as temples and shrines in famous tourist resort areas, which were built by a Japanese traditional framed-construction method and have some types of thatched roof instead of tiles. Because they are important cultural assets in Japan, it may be so difficult and not a good plan from a view point of scenery preservation to reconstruct these thatched roof wooden structures to conduct their seismic retrofits. It is, therefore, very important for structural engineers to perform seismic retrofit for one-story thatched roof wooden structure without reconstruction. In order to investigate the seismic behaviour of an old one-story thatched roof wooden structure, "Yakushi-doh", 3-D non-linear collapsing process analysis of Yakushi-doh structure was conducted against a strong earthquake ground motion with the Japan Meteorological Agency (JMA) seismic intensity of "6 upper" level. In general, the posts under an old wooden structure floor of Yakushi-doh structure are erected on their foundation stones and are not fixed. In this paper, the effect of the post fixing condition under wooden structure floor on seismic response of Yakushi-doh structure was numerically investigated by using two earthquake ground motions measured in 1995 in the seismic collapsing analysis.

OUTLINE OF YAKUSHI-DOH STRUCTURE

Photo 1 shows one-story wooden structure with thatched roof, Yakushi-doh structure, which was built an old Japanese traditional framed-construction method and have a thatched roof instead of tile. Yakushi-doh structure was dedicated in 1617 to deify "Bhaisajyaguru", who has been believed in a Buddha able to cure all ills, and has been an important cultural asset. Figure 1 indicates floor plan, elevation one, and cross section ones of Yakushi-doh structure. The width, depth, and height of Yakushi-doh structure are 13.211m, 11.756m and 10.254m, respectively. Photo 2 shows a post erected on a foundation stone under Yakushi-doh structure floor. There are many posts erected on their foundation stones with flat plane under Yakushi-doh structure floor, and they are not fixed on their foundation stones. Consequently, this system is likely to be a seismic base isolation. In this paper, the effect of the post fixing condition under wooden structure floor on seismic response of Yakushi-doh

structure is numerically investigated through the seismic response behaviours at Nos.1 to 3, which are illustrated in Figure 1 and are three measuring points in the collapsing process analysis described below.

OUTLINE OF COLLAPSING ANALSYS

Seismic Collapsing Analysis

In this paper, a structural analysis software of "Wallstat" is employed in order to investigate seismic response behaviour and collapsing process of Yakushi-doh structure during a strong earthquake ground motion. This software has an original analysis technique (Nakagawa and Ohta 2010) using the basic theory of the Distinct Element Method (Cundall and Strack 1979), and can be taken into consideration the extremely non-linear properties of timber members breaking or being dispersed. In the collapsing process analytical calculation, Yakushi-doh structure can be modelled by a lot of timber elements such as beam and pillar connected with non-linear spring as shown in Figure 2, and also can be modelled by lumped mass and the weight of each floor in Yakushi-doh structure model can be obtained from each structural element as illustrated in Figure 3. Timber characteristics of the compression and tensile elasto-plastic springs consist of an elastic part and slip-type part.

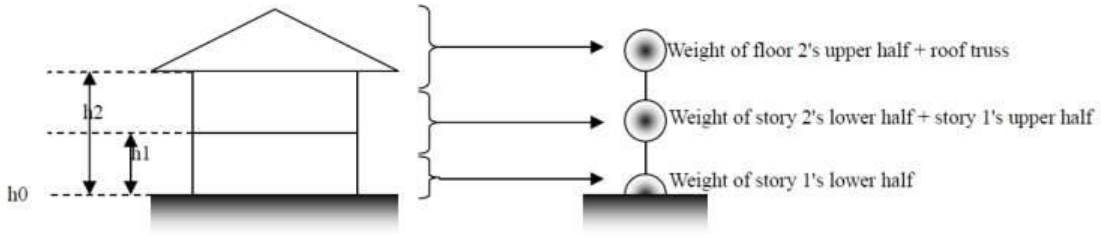

Figure 3 Weight of floor in the analytical model of wooden house (Nakagawa 2011)

Modelling of Structure Element

- Modelling of Frame

Timber frame is modelled by two elasto-plastic rotational springs (plastic hinge) and an elastic beam component as shown in the left-hand side of Figure 4. The spring can be defined by a relationship between bending moment M and angle of rotation θ with the skeleton curve indicated in the right-hand side of Figure 4. The bending moment starts to fall once if it is over the maximum bending moment, and the rotating spring changes to a pinned joint state at the point if the bending moment reaches 0, and then the beam component can be judged to have been broken.

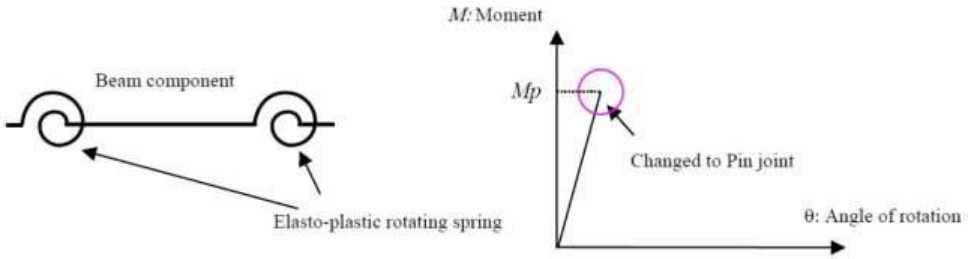

Figure 4 Schematic diagram and skeleton curve of frame spring (Nakagawa 2011)

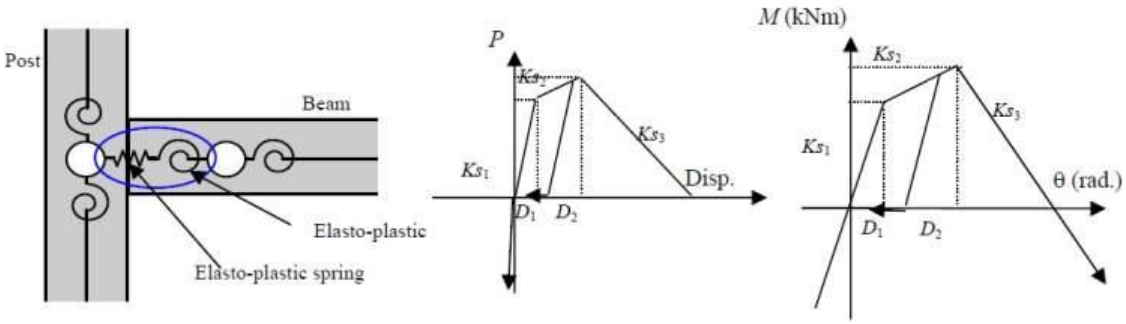

(a) Schematic diagram of joint element (b) Characteristic of elasto-plastic spring (c) Characteristic of rotational spring

Figure 5 Outline of joint modelling (Nakagawa 2011)

- *Modelling of Joint Spring*

Joint spring can be modelled by both an elasto-plastic spring and a rotational spring as shown in Figure 5(a). Timber characteristic of the compression and tensile elasto-plastic spring consist of an elastic part and slip-type part indicated in Figure 5(b), and also timber characteristics of the rotational spring is assumed to be a slip-type relationship between ending moment M and angle of rotation θ shown in Figure 5 (c). When the elasto-plastic spring or the rotational spring of the joint exceeds the maximum structural strength or moment and their strength values becomes 0, the joint will be adjudged to have been broken and then the spring will be annihilated.

- *Modelling of Shear wall and Bracing*

Vertical shear wall indicated in Figure 6 can be modelled by the replacement of truss component with a load-displacement non-linear relationship shown in Figure 8. Also, bracing shear wall illustrated in Figure 7 can be modelled by the replacement of compression and tensile truss components defined by a set of bi-linear and slip skeleton curve shown in Figure 8, too.

- *Parameters of Structural Element*

In general, Young's modulus and the maximum bending moment of timber component are assumed to be 2,000MN/m^2 and 10kNm, respectively. External and internal walls in a typical Japanese wooden house can be assumed to be lath mortal wall and clay wall, respectively. For seismic retrofit countermeasure for a wooden

Input Earthquake Motion in Seismic Collapsing Analysis

Seismic collapsing process analysis of Yakushi-doh structure is carried out in this paper. Two earthquake ground motion wave records with the JMA seismic intensity of "6 upper" level are employed as an input earthquake ground motion data in the collapsing analysis. The effect of the earthquake motion spectrum on the difference of seismic response can be investigated by using two earthquake wave records with the same level intensity which has a different peak frequency in Fourier acceleration spectra. Table 4 shows some parameters of two earthquake ground motion wave records used as an input excitation of the collapsing process analysis.
Figures 9 and 10 indicate two displacement wave data and their Fourier acceleration spectra for both NS and EW components in each earthquake ground motion record shown in Table 4. In the JMA Kobe wave record indicated in Figure 9, a peak frequency in each wave component is from 1Hz to 1.5Hz, and also a peak in each wave component of the JR Takatori wave record illustrated in Figure 10 exists about 0.8Hz. Because there are peak frequencies in both the JMA Kobe and the JR Takatori wave records in the frequency range of 0.5 to 1.5Hz, their wave records seem to cause severe damage in the collapsing analysis of an old wooden structure against a strong earthquake ground motion as reported by Sakai *et al*. (2002).

RESULTS AND DISCUSSIONS

Seismic Collapsing Behaviour

Figure 11 shows the seismic collapsing behaviour of Yakushi-doh structure under post fixed condition during the JMA Kobe earthquake ground motion wave shown in Figure 9. In seismic collapsing result of Yakushi-doh structure, the plastic deformation at the connection part between pillar and beam elements gradually increases during earthquake ground motion by means of the non-linearity characteristics. Yakushi-doh structure collapses after 16 seconds in the JMA Kobe wave record with a frequency range close to 0.5 to 1.0Hz. Figure 12 indicates the seismic collapsing behaviours of Yakushi-doh structure under post unfixed conditions of μ=0.2 and

Table 4 Earthquake ground motion wave records (the 1995 Hyogo-ken Nanbu Earthquake)

Record Name	I_{JMA}	Peak Ground Acceleration (cm/s^2)	Peak Ground Velocity (cm/s)	f_p (Hz)	Duration (s)
JMA Kobe	6.4	818	91	1.43	30
JR Takatori	6.4	657	126	0.81	30

0.4 during the JMA Kobe earthquake ground motion wave. The sign μ in this figure means a dynamic friction coefficient between a post element and its foundation stone under the floor of Yakushi-doh structure. It is found from Figure 12 that the collapsing elements of Yakushi-doh structure trends to increase with the friction coefficient μ, because the decrease of friction coefficient μ means to become a seismic base isolation.

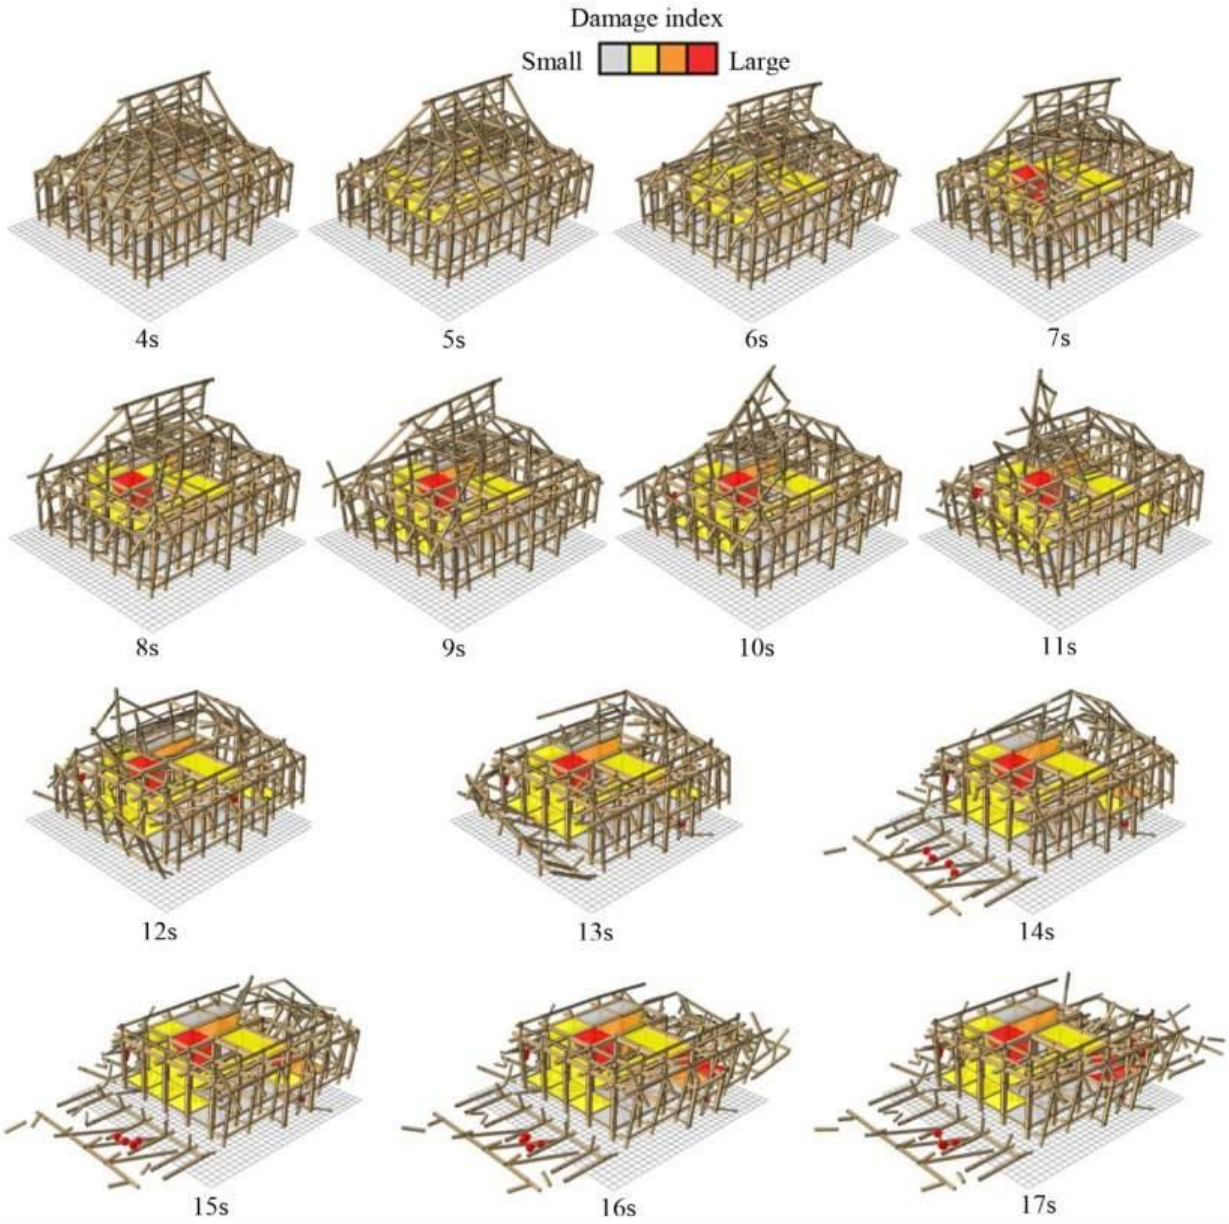

Figure 11 Seismic collapsing behaviour during the JMA Kobe wave under fixed post condition

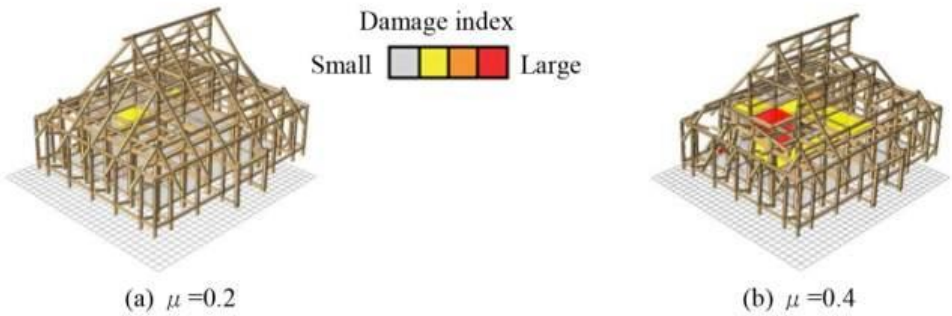

Figure 12 Seismic collapsing state after the JMA Kobe wave under unfixed post condition

Figure 13 shows the seismic collapsing behaviour of Yakushi-doh structure under post fixed condition during the JR Takatori earthquake ground motion wave shown in Figure 10. In particular, Yakushi-doh structure collapses after 10 seconds in the JR Takatori wave record with a frequency range of 0.5 to 1.0Hz, and the frequency range has a significant relationship with an old wooden structure collapsing rate against a strong earthquake

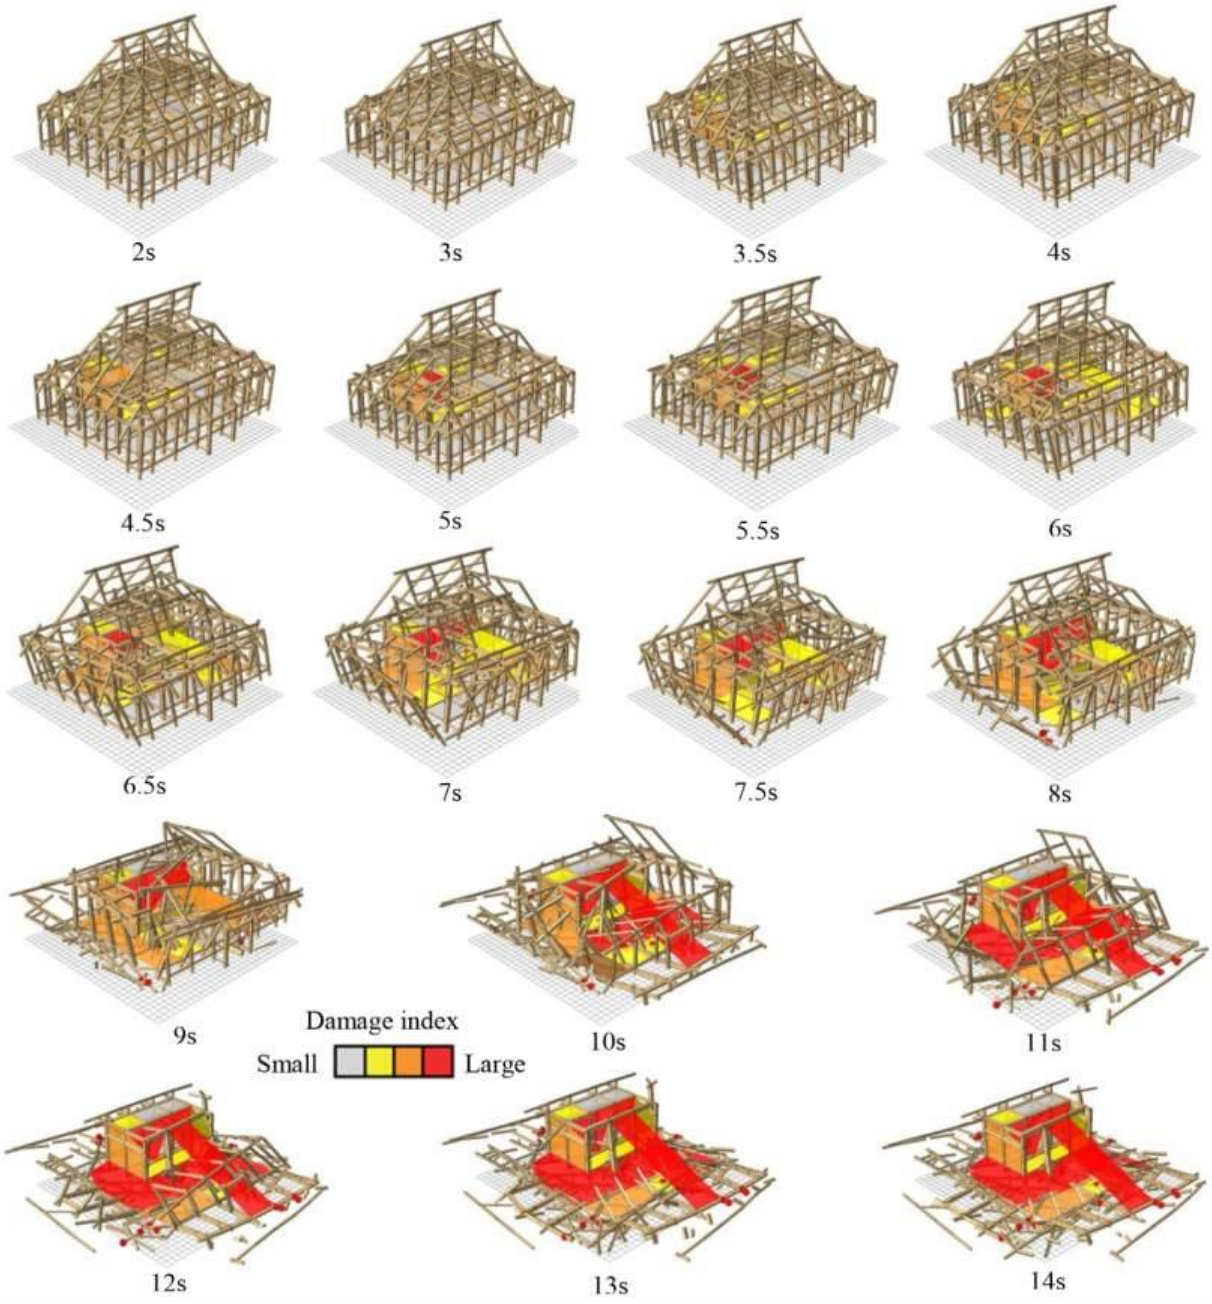

Figure 13 Seismic collapsing behaviour during the JR Takatori wave under fixed post condition

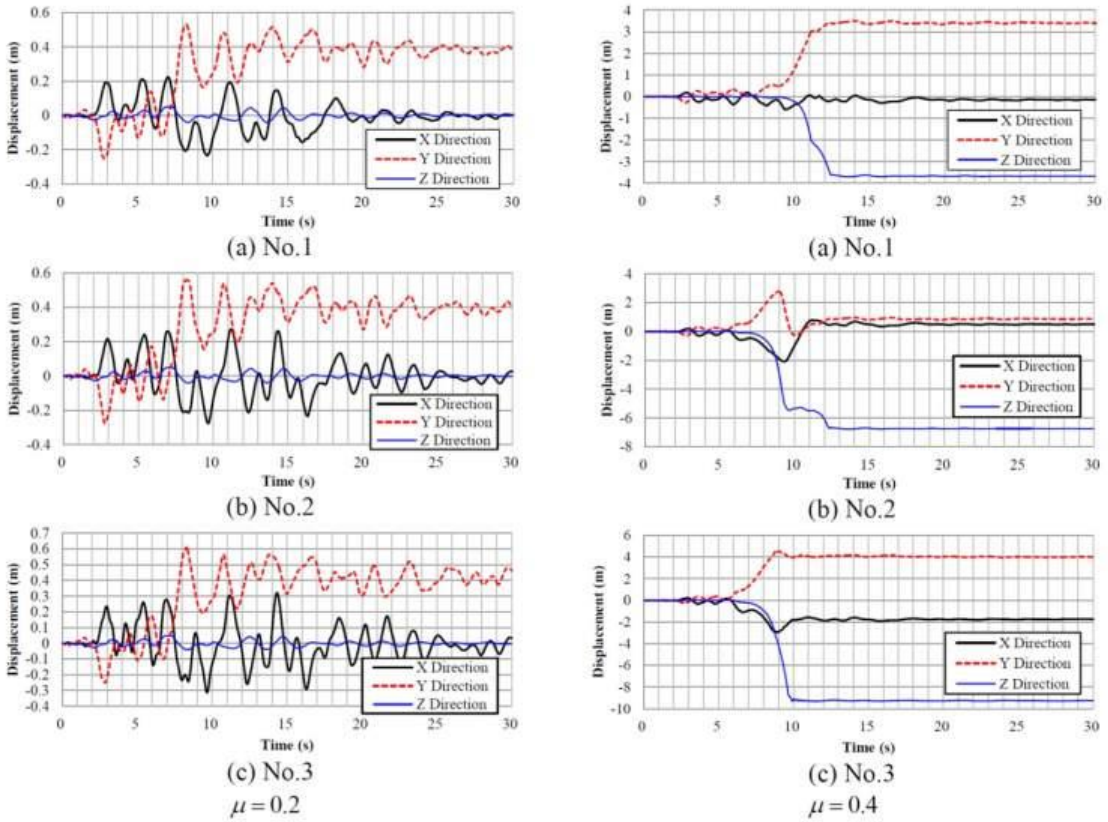

Figure 17 Displacement responses at Nos.1 to 3, the JR Takatori wave

motion. Moreover, the maximum velocity of the JR Takatori wave record is 126cm/s, and the wooden structure collapsing rate greatly depends on the maximum velocity. Yakushi-doh structure collapses after 10 seconds in the JR Takatori wave record with the frequency range close to 0.5 to 1.0Hz. Figure 14 indicates the seismic collapsing behaviours of Yakushi-doh structure under post unfixed conditions of μ=0.2 and 0.4 during the JR Takatori earthquake ground motion wave. Yakushi-doh structure does not collapse under post unfixed condition of μ=0.2, while it collapses after 10 seconds under post unfixed conditions of μ=0.4. There exists a significant difference between μ=0.2 and 0.4 in seismic collapsing response. It is, also, found from these figures that the collapsing elements of Yakushi-doh structure trends to increase with the dynamic friction coefficient μ, because the decrease of friction coefficient μ means to become a seismic base isolation.

Seismic Collapsing Response

Figure 15 shows seismic collapsing responses at Nos.1 to 3 under post fixed condition during the JMA Kobe and the JR Takatori waves. The heights of three measuring points of Nos.1 to 3 indicated in Figure 1 are 3.8m,6.2m, and 9.3m, respectively. Although the timber element of No.1 does not fall down for each earthquake ground motion, the timber elements of Nos.2 and 3 falls down after 13 seconds for the JMA Kobe wave and they does after 10 seconds for the JR Takatori wave. On the other hands, seismic collapsing responses at Nos.1 to 3 under post unfixed conditions of μ=0.2 and 0.4 during the JMA Kobe wave are indicated in Figure 16. It is found from Figure 12 that three timber elements of Nos.1 to 3 have slightly horizontal deformation after earthquake wave and does not fall down because of post unfixed condition. Figure 17 shows seismic collapsing responses at Nos.1 to 3 under post unfixed conditions of μ=0.2 and 0.4 during JR Takatori wave. Three timber elements of Nos.1 to 3 under post unfixed condition of μ=0.2 have some horizontal deformation of Y direction after earthquake wave and does not fall down because of post unfixed condition. While, three timber elements of Nos.1 to 3 under post unfixed condition of μ=0.4 fall down after 10 seconds.

CONCLUSIONS

In order to investigate the seismic behaviour of an old one-story thatched roof wooden structure, “Yakushi-doh”, 3-D non-linear collapsing process analysis of Yakushi-doh structure was conducted against two strong earth-

quake ground motions with the Japan Meteorological Agency (JMA) seismic intensity of "6 upper" level. The posts under Yakushi-doh structure floor are erected on their foundation stones and are not fixed. The effect of the post fixing condition under Yakushi-doh structure floor on seismic response was numerically investigated in this paper.

The summary obtained in this paper is as follows.

(1) Seismic collapsing behaviour of a one-story thatched roof wooden structure depends on the seismic intensity of the input earthquake motion in the collapsing analysis.
(2) A one-story thatched roof wooden structure may be collapsed by a strong earthquake ground motion with the JMA seismic intensity of "6 upper" level.
(3) Seismic collapsing behaviour of wooden structure strongly depends on the post fixing condition under the floor of one-story thatched roof wooden structure.
(4) The collapsing elements of Yakushi-doh structure trends to increase with the dynamic friction coefficient μ, because the decrease of dynamic friction coefficient μ means to become a seismic base isolation.

In this paper, two earthquake ground motions measured in the 1995 Hyogo-ken Nanbu Earthquake are employed in this collapsing analysis of Yakushi-doh structure as a strong earthquake ground motions with the JMA seismic intensity of "6 upper" level, because these earthquake ground motions have been used in a lot of seismic collapsing analyses of various structures to investigate the seismic behaviour during a strong earthquake ground motion. If a wooden structure does not collapse against these earthquake ground motions, it may have a high seismic performance against a strong earthquake ground motions with the JMA seismic intensity of "6 upper" level.

3-D non-linear collapsing process analysis may be an effective tool to evaluate a seismic performance of wooden structure. Also, this collapsing process analysis has a significant potential to find when and where begin to break first in an old one-story thatched roof wooden structure during a strong earthquake ground motion. An optimum seismic retrofit of the one-story thatched roof wooden structure can be made by using the collapsing analysis. In addition, further investigation may be needed to simulate the collapsing process phenomenon of a one-story thatched roof wooden structure with or without seismic retrofit and make some concrete conclusions.

ABSTRACT

The Saint Peter Apostle church of Andahuaylillas was built at the early 17th Century and is a representative example of colonial adobe churches in the Andes. Although it has been subjected to constant aesthetic restoration in the recent years, a complete study of its seismic behavior is needed due to the brittle condition of its structural system (composed by a unfired-clay-bricks and earthen mortar known as adobe masonry) and its location in a region with high seismic hazard. This work is part of the integral seismic assessment of the building and focuses on the seismic evaluation of the triumphal arch by means of a static nonlinear analysis. For this purpose, nonlinear finite element (FE) models of the arch were implemented in Abaqus/CAE Explicit and TNO Diana considering a damage-plasticity formulation and a total-strain crack constitutive relationship, respectively, for representing the adobe quasi-brittle behavior. Following an analysis approach simulating up to complete structural collapse, the FE models were used to identify the critical accelerations leading to collapse and the damage patterns. A sensitivity analysis was also carried out considering different material properties for determining the influence of these parameters in the lateral capacity of the studied sub-structure. In addition, different geometrical conditions were considered to increase the capacity of the triumphal arch. Removing the window openings from sidewalls provided more capacity and different crack patterns. Heightening the sidewalls also had a significant influence on capacity.

Triumphal arch, pushover analysis, adobe masonry, FEM nonlinear explicit analysis.

INTRODUCTION

Adobe has been employed as a construction material around the world since remote times (Houben *et al*. 1994). In Peru, adobe bricks have been frequently used for the construction of churches, mainly during the baroque period in the Andean region. In the region of Cusco, along the so-called Andean baroque route – Figure 1(a), there are several adobe churches belonging to the baroque artistic movement. St. Peter Apostle of Andahuaylillas is the most important monument in this route. Figure 1(b) offers a view of the façade of the monument.

Over the last sixty years, the interest on the preservation of historic masonry buildings has been steadily increasing (Giuffrè and Carocci 1996). Numerous studies and interventions have substantially increased our knowledge of materials and construction processes. In particular, non-destructive diagnostic techniques have been developed in order to determine the current state of a structure of high cultural and architectural value without affecting its integrity. This diagnostic step is necessary prior to any intervention, because the effects of the intervention itself are difficult to predict and could negatively impact the stability of the structure.

Modeling and analyzing masonry structures are inherently difficult tasks and their complexity increases in the particular case of historical constructions. In order to carry out a structural evaluation, detailed information related to the construction history and architectural evolution must be acquired together with the geometry, fracture patterns and any other anomalies present in the structure. In addition, detailed knowledge of the building materials and their mechanical properties are essential for a proper execution of the evaluation (Binda and Saisi 2001). The necessary information is acquired through qualitative and quantitative research procedures involving the collection of data from preliminary studies in-situ and laboratory tests. These data will determine the type of structural analysis that needs to be applied to evaluate the monument.

(a)

(b)

Figure 1. St. Peter Apostle Church of Andahuaylillas: (a) location on the Andean baroque route and (b) façade (looking east)

In the case of masonry churches, several studies have focused on the assessment of the triumphal arch considered as a separate substructure. Mele *et al*. (2003) analyzed the Saint Ippolisto Martire church located in Southern Italy by means of kinematic limit and pushover analysis, aiming to assess the structural behavior and the seismic vulnerability. Since this construction consists of well-defined structural elements - such as the façade, triumphal arch, lateral walls, etc.- the separate study of individual elements provides information on the global structural performance as well as useful indications of the effectiveness of specific intervention measures on the element in question. Three specific elements of the church were studied carrying out a simplified assessment of the seismic behavior: chancel end wall, triumphal arch and a longitudinal section of the nave arcade. In the case of the triumphal arch, a high correlation was obtained between limit and pushover FEM analysis results, indicating a maximum capacity of 0.283g. Additionally, several analyses were performed on the arch to evaluate the effect of different values of the compressive and tensile strength.

Similarly, a simplified procedure for assessing the seismic capacity of masonry arches is proposed in De Luca *et al*. (2004). This involves kinematic limit analysis and linear static FEM analysis, the former aiming to determine the acceleration that promotes instability – and thus failure - of the assumed kinematic mechanism, the latter aiming to detect tensile and compressive stress zones which may produce the fractures and thus the mechanism. Nonlinear FEM analysis was used in order to verify the results of the limit analysis. Two triumphal arches from different churches were selected as case studies: the church of San Giovanni a Mare and the church of San Giovanni Maggiore both in Southern Italy. Each case presents particular architectural characters. The first triumphal arch has non-symmetrical shape, with a main semi-circular arch, flanked by two lower and narrower pointed arches. The second is a large semi-circular arch with very wide and stocky lateral walls.

The critical zones, and consequently the potential hinges, were determined due to these stress distributions computed via linear FEM analysis. As in the previous case, the critical collapse multiplier was defined by varying the position of the hinges. In both cases, as shown in Figure 3, a good correlation between the limit and nonlinear FEM results is obtained. The collapse multipliers from limit analysis were 0.224 and 0.4, and the maximum load capacities from nonlinear FEM were 0.20 and 0.31 for San Giovanni a Mare and San Giovanni Maggiore, respectively. Note that, despite the marked geometrical differences, a similar ‘global-type’ kinematic mechanism was assumed for both arches

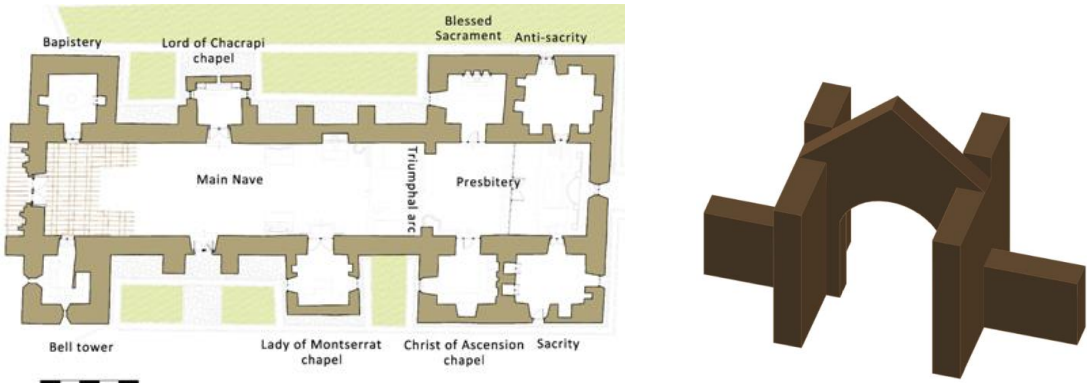
Our paper presents a portion of a preliminary study of the seismic behavior of St. Peter Apostle Church of Andahuaylillas. The building, constructed almost entirely with adobe bricks and located in a region with major seismic activity, is in constant risk. Because the church is actively used, the people of the local parish are also at risk. In the following, the historical, architectural and structural aspects together with a detailed description of the triumphal arch of the church are provided. We then report the details of the dynamic tests carried out on the bell tower and of the subsequent FEM model calibration procedure followed to determine the elastic properties of the adobe bricks. Finally we discuss the pushover analysis performed to evaluate the influence of different structural elements on the capacity of the arch under in plane accelerations. To this aim, we use nonlinear FEM models developed in Abaqus/CAE Explicit and Diana.

SAINT PETER APOSTLE CHURCH OF ANDAHUAYLILLAS

St. Peter Apostle church is located in the main square of the village of Andahuaylillas. Although the main function of the church is religious, it also supports the village in economic and development programs (anadahuaylillas.com 2015). The church was built by Jesuits over a pre Columbian Huaca and, based on the

style of the paintings inside the church, its erection dates from the late 16th or early 17th century (Castillo *et al*. 2012). The building follows a west-east orientation and is composed of the nave, the presbytery, the bell tower and several side chapels, as shown in Figure 2(a). At the west front, the main nave connects to the baptistery, the bell tower, the choir loft, and two chapels. The presbytery is separated from the nave by the triumphal arch and opens on four side rooms. The second level of the church, which is accessed from the bell tower, consists of a choir loft and an open chapel.

The substructure under study is the triumphal arch, consisting of the arch proper with the tympanum and the lateral shear walls corresponding to the west walls of the side chapels. The 3D model in Figure 2(b) provides an architectural view of the substructure (in this case, including sections of the nave walls.) The triumphal arch is mainly composed by adobe and brick masonry, with an average thickness of 1.5m.



(a) (b)

Figure 2 Architectural representation: (a) Plan view of the church, and (b) 3D model of the triumphal arch

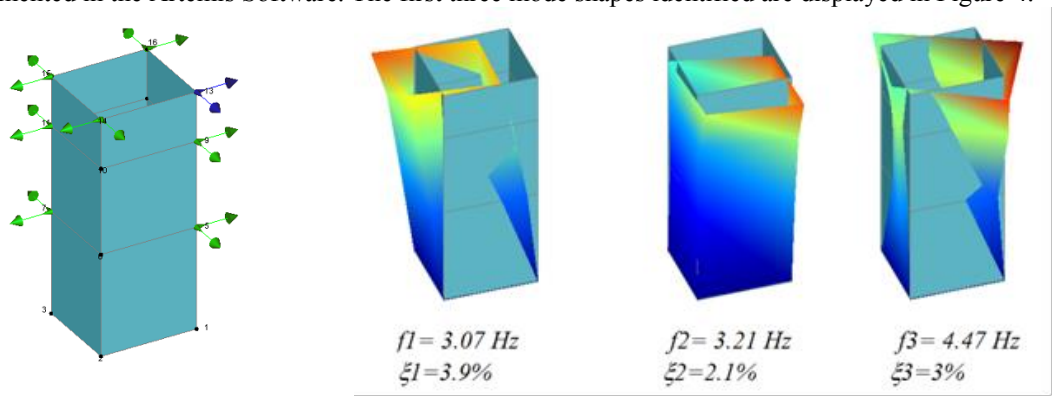
It is not possible to completely asses the deeper damage of the church accumulated over the years because the building has undergone conservation works in the last 50 years (Vargas *et al*. 2013). To complicate matters, the majority of the previous works were executed taking into account the aesthetic - and thus non-structural – aspects only. Deep fractures in the walls of the presbytery and the chapels, and in the triumphal arch have been identified. For example, a large fracture is observed in the south wall next to the triumphal arc and diagonal deep fissures are present in the tympanum above the triumphal arch, as shown in

Figure 3 Deep fissures on the triumphal arch of Andahuaylillas church

OPERATIONAL MODAL ANALYSIS AND DETERMINATION OF ELASTIC PROPERTIES

Ambient modal identification, also known as Operational Modal Analysis (OMA) (Aguilar *et al*. 2013 a), offers a useful approach to study earthen historical constructions through the identification of structural conditions, such as local damage (Fonseca and D'Ayala 2012, Aguilar et al 2013b). Being a non-destructive diagnosis technique, OMA is highly recommended for the application on historical constructions. As part of this preliminary study, OMA tests were carried out in the bell tower of the Andahuaylillas church in order to estimate the dynamic characteristics of the entire structure. Tests were performed in the tower in order to capture higher amplitude of the modal response. The resulting measurements were used to calibrate the accuracy of a global linear FEM model and thus determine the elastic properties of the adobe material, i.e., Young's modulus and Poisson ratio.

OMA tests in the bell tower were carried out by using the ambient noise as the excitation source. Eight measuring points according to a biaxial configuration were established in seven setups, considering two fixed and two routing sensors. The transducers used were four piezoelectric accelerometers with a sensitivity of 10 V/g and a dynamic range of ± 0.5 g together with an USB-powered 24 bits resolution data acquisition module. The data processing was carried out using the stochastic subspace identification method (SSI) implemented in the Artemis Software. The first three mode shapes identified are displayed in Figure 4.



(a) (b)

Figure 4. Modal identification tests in the bell tower: (a) general test setup and (b) first three mode shapes

For the church, the model calibration is based on a modal analysis approach, for which the structural response is considered to remain in the elastic range. Two FEM models were built in Diana (2013) and Abaqus/CAE (2013). In both cases, the adobe masonry was represented as a homogeneous linear elastic material. The models were calibrated via a sensitivity analysis of the material properties and boundary conditions, by comparing the results of FE modal eigenvalue analysis to those of the OMA experimental tests. Modal Assurance Criterion (MAC) (Allemang 2003) was used to compare the experimental and numerical mode shapes and frequencies. At the end of the calibration process, a high correlation is observed between the numerical model and experimental results from both models. The first three modes shapes have MAC values of 0.95, 0.97 and 0.75, respectively. The final elastic properties of materials were assumed based on the recommendations given in (Fonseca and D'Ayala 2012, NTE.010 2006). The elastic properties resulting from the calibration process are presented Table 1.

Table 1 Elastic properties of materials

Material	Specific weight, w (KN/m^3)	Young's modulus, E (MPa)	Poisson ratio, ν
Adobe masonry	15.1	350	0.25
Rubble stone masonry	24.0	800	0.20
Wooden elements	4.7	10,000	0.20

PUSHOVER ANALYSIS

Pushover analysis has been developed as an acceptable approach for assessing the damage sequence due to seismic action. The analysis is helpful to evaluate the performance of buildings through displacement verifications, to identify critical zones in order to proceed with local implicit safety verifications, and to analyze the effects of seismic retrofitting. In this study a series of geometrical models developed in Abaqus/CAE Explicit and Diana were used to evaluate the influence of structural elements on the lateral capacity and on the damage pattern of the triumphal arch.

In Abaqus/CAE Explicit adobe was modeled as a quasi-brittle material using the concrete damaged plasticity formulation. In order to evaluate the sensitivity of the structural response to the tensile and compressive fracture energy three nonlinear material models were constructed. All have the same tensile and compressive strength, but two different sets of fracture energies were used to represent the nonlinear softening behavior in tension and compression. The first set of nonlinear material properties was extrapolated from the experimental results given in the previous section following recommended procedures for masonry material given in the literature (Van der Pluijm 1999, Lourenço 2009). The compressive strength was taken as fm = E/400, where E is 350 MPa, and thus fm = 0.875 MPa. The tensile strength and the tensile fracture energy were estimated as $ft = fm/10$= 0.0875

MPa and Gf = 4 Nm^{-1}, respectively. Assuming a ductility factor of 1.6 mm (Lourenço 2009), the compressive fracture energy was estimated as Gm=1.6 x fm= 1,400 Nm^{-1}. Following the masonry models by Lourenço (2009) the compression curve is parabolic while the tension softening is represented by an exponential decay. Taking into account that the characteristic length of our FE models is h = 0.207 m, the compressive and tensile stress versus plastic strain curves shown in Figure 5 are generated.

For constructing the second set of nonlinear material properties we fitted to our case the tensile and compressive stress versus plastic strain curves adopted by Tarque et al. (2010) for an adobe Abaqus model. In this case, too, the compression curve is parabolic while the tension softening is represented by an exponential decay. We scaled these curves so that the strengths in tension and compression match 0.0875 MPa and 0.875 MPa, respectively. For h = 0.207 m the corresponding tensile fracture energy for this material model is Gf = 32 Nm^{-1} while the compressive fracture energy is Gm = 550 Nm^{-1}. The compressive and tensile stress versus plastic strain curves are shown in Figure 5.

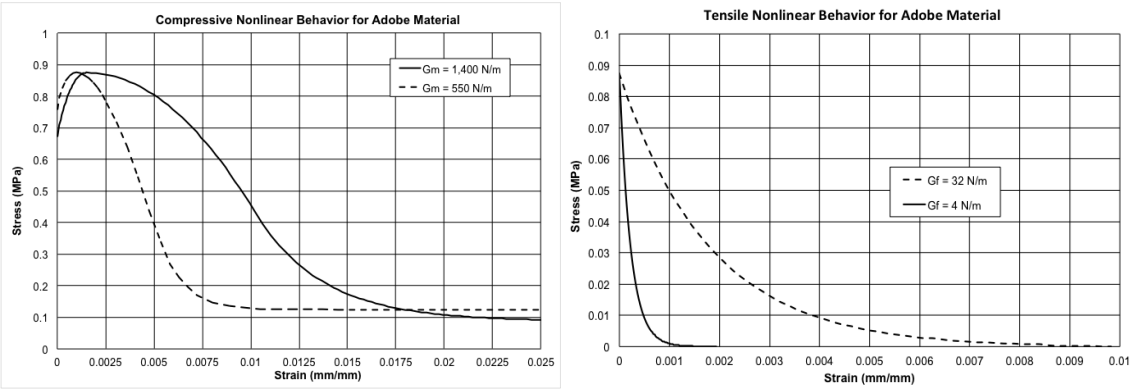


Figure 5. Constitutive laws for constructing the material models in Abaqus/CAE Explicit

The three material models used in Abaqus/CAE Explicit are given in Table 2. As noted earlier, all materials have the same tensile and compressive strengths, but Material 1 is characterized by high tensile fracture energy and low compressive fracture energy, while the opposite is true for Material 3. Material 2 combines low fracture energies for both tension and compression.

Table 2 Material models used in Abaqus/CAE Explicit

Material model	Compressive fracture energy Gm [N/m]	Tensile fracture energy Gf [N/m]
1	550	32
2	550	4
3	1,400	4

The elastic and the general plastic properties common to all three material models used in Abaqus/CAE Explicit are presented in Table 3 and 4, respectively.

Table 3 Elastic properties of adobe masonry in Abaqus/CAE Explicit and Diana

Specific weight (kN/m^3)	E (MPa)	ν
15.1	350	0.25

Table 4 Plastic properties of adobe masonry in Abaqus/CAE Explicit

1	0.1	1.16	0.6666	1E-8	0.875	0.0875

In Diana the non-linear behavior of the masonry was modeled by the adoption of a constitutive relationship based on the total strain crack model, which provides good stability in the opening crack control, as well as moderate computer cost. The material laws in compression and tension were assumed to follow parabolic and exponential laws, respectively (Lourenço 2009). Figure 6 shows the compressive and tensile curves used to

represent the adobe masonry. Post-cracked shear behavior was modeled using a shear retention factor of 0.01. Similarly to Abaqus/CAE models, the compressive and tensile strength were 0.875 MPa and 0.0875 MPa, respectively. The fracture energy was 1,400 Nm^{-1} in compression and 4 Nm^{-1}in tension. The elastic properties are identical to those adopted for the Abaqus/CAE models – see Table 3.

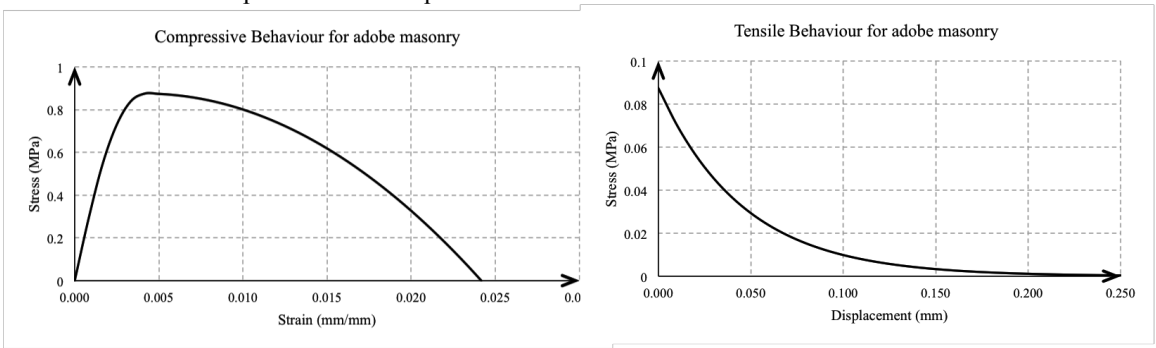

Figure 6. Nonlinear material behavior for Diana models

The Abaqus/CAE Explicit analysis was articulated in three loading steps. The kinematic boundary conditions were set in the initial step. To simulate a realistic situation, gravitational acceleration was applied first, followed by the horizontal acceleration load. Both accelerations were applied as uniform fields acting at each element integration point of the entire model. The intensity of each field was set to increase linearly with time. In order to force the explicit dynamic to simulate quasi-static conditions during loading, the maximum time increment for each step was set to $1.x10^{-6}$. In a similar fashion, constant gravity loads in Diana models were applied to each case under study. Subsequently, the structure was pushed laterally with a horizontal acceleration ramp loading applied uniformly over the entire mesh. The regular Newton–Raphson method combined with the arc-length procedure was adopted in order to determine the solution of the nonlinear problem.

The triumphal arch is composed of several sub-structural elements: the arch proper, the tympanum, and the sidewalls (here considered with and without window openings.) Each element contributes distinctively to modulating the capacity of the triumphal arch and therefore must be examined through a separate FEM model. Four structural models are reported in the present study: M1, the arch proper; M2, the arch with the tympanum only; M3, the arch including the tympanum and the lateral walls without windows, and M4, the same configuration as M3 but with the addition of window openings. Each model was analyzed in Abaqus/CAE Explicit and Diana using nearly identical 2D meshes of quadratic triangular plane stress elements - CPS6 and CT12M, respectively. All models were fully constrained on their bottom edge. Finally, we used Models 5 and 6 to explore how the height of the lateral walls affects the capacity of Models 3 and 4, respectively.

RESULTS

Model M1: the Arch

Figure 7 (a) shows the capacity curves for Model M1 calculated for the top left corner by Abaqus/CAE with Materials 1-3 and by Diana. Figure 7 (b) shows the damaged status of the model at the computed collapse conditions in Abaqus in terms of maximum principal plastic strains. A similar picture in terms of element damage status is computed in Diana. As expected, the damage originates at the center of the intrados at the end of gravity loading, indicating that a vertical crack begins forming in this zone. When horizontal acceleration is applied, the crack is deviated laterally and then downward. As shown in Figure 7 (b) two additional tensile fractures occur at the top right shoulder and at the bottom of the right pier. As a result, the right pier gradually separates from the arch and ultimately collapses through rotation, while the arch itself breaks into two separate parts. Immediately thereafter the left pier also collapses after developing a fissure at the springing of the arch. The damage at the right bottom corner of the right pier is due to the high compressive stresses produced at impending rotation. From a kinematic perspective, the location of the hinge about which the pier is rotating depends upon the compressive strength of the material.

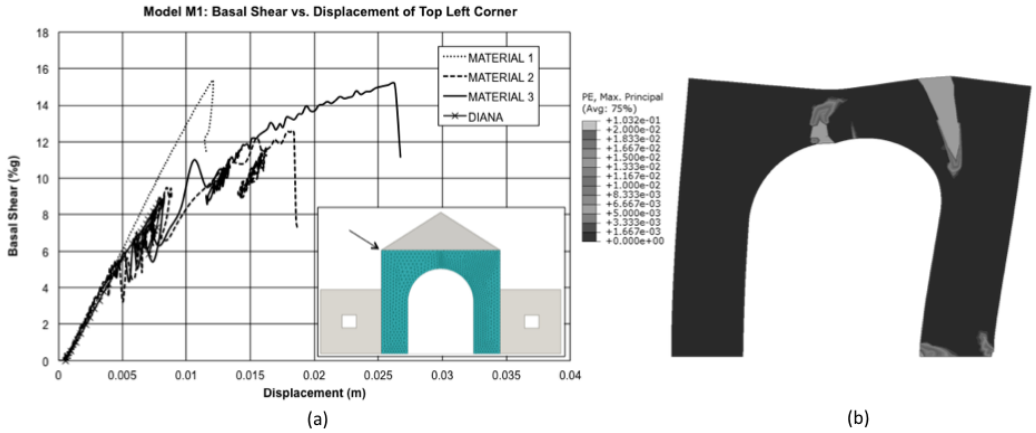

Figure 7 (a) Capacity curves for model M1, and (b) maximum plastic strains at collapse (Abaqus/CAE); displacements are computed at top left corner indicated by arrow in (a)

Material 1 produces a capacity of 15%g with a nearly linear response up to collapse. Reducing the tensile fracture energy – Material 2 – lowers the capacity to 12.3%g and results in a markedly nonlinear behavior, which could be attributed to the right pier separating more easily from the arch. With Material 3 the compressive fracture energy increases, thus increasing the resistance to damage at the right bottom corner of the critical right pier. The capacity grows back to almost 15%g but the ductility increases two and a half times with respect to Material 1. Diana produces similar results to Material 2 and 3, but terminates at approximately at 9%g.

Model M2: the Arch with Tympanum

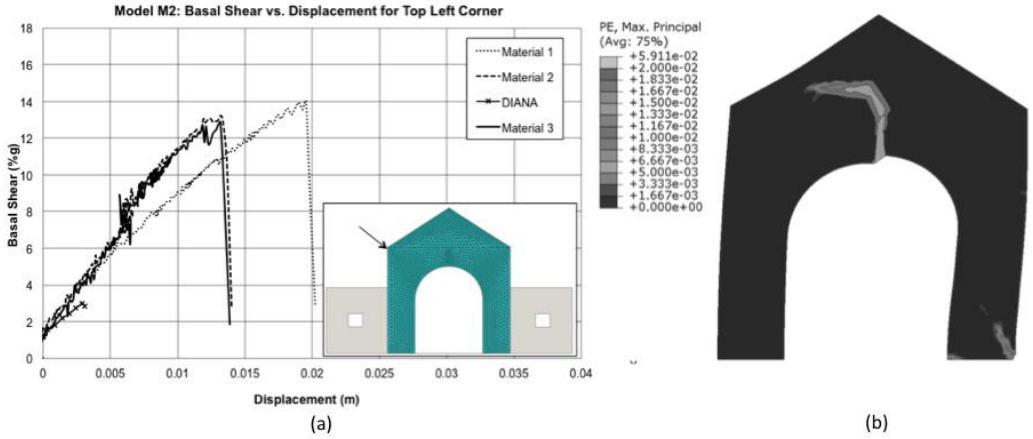

Figure 8 (a) Capacity curves for model M2, and (b) maximum plastic strains at collapse (Abaqus/CAE); displacements are computed at top left corner indicated by arrow in (a)

Figure 8 shows the capacity curves for Model M2 and the damage status of the model at the computed collapse conditions in terms of maximum principal plastic strains. As for M1, a vertical crack forms at the center of the intrados at the end of gravity loading, and then grows laterally with the horizontal acceleration being applied. However, there is no pier rotation in this case. Rather, collapse appears to be triggered by a shear fracture developing diagonally in the right pier before the center crack reaches the extrados. The reduction in tensile fracture energy in Material 2 and 3 compared to Material 1 affects the capacity only by 7%. Diana results stop at only 3%g.

Model M3: the Arch with Tympanum and Lateral Walls

The capacity curves for Model M3 and the damage status at collapse are illustrated in Figure 9. Contrary to the previous case, due to the constraining effect of the lateral walls on the downward deformations induced by gravity, gravitational loading produces no damage at the center of the intrados or elsewhere in the structure.

Under horizontal accelerations increasing linearly from 0 to 0.6 g an asymmetric crack starts from the intrados of the arch and proceeds laterally followed by a fissure separating the left wall from the left pier. For Material 1, the collapse is due to the separation of the left pier followed immediately by a shear fracture of the right wall - see Figure 9 (b). The capacity curve reaches 53%g – 3.5 times the capacity of Model 1.

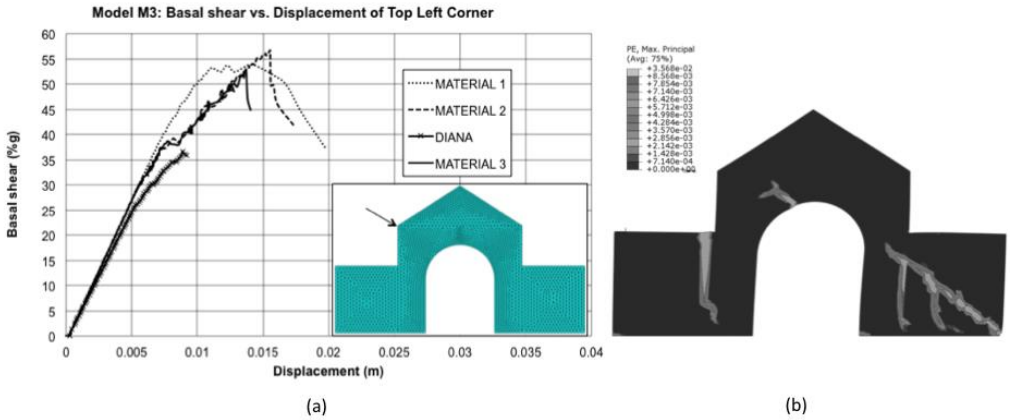

Figure 9 (a) Capacity curves for model M3, and (b) maximum plastic strains at collapse (Abaqus/CAE); displacements are computed at top left corner indicated by arrow in (a)

The failure picture for Materials 2 and 3 is more complex. The crack at the intrados of the arch turns downward and produces the detachment of a section of the arch at 45%g basal shear. This constitutes only a partial collapse and the structure continues to resist up to 56%g, for Material 2 and 53%g for Material 3. The increased compressive fracture energy in Material 3 appears to facilitate the formation of a shear fracture in the right lateral wall. Diana' s results show a good correlation in terms of stiffness, but the response terminates at 35%g, below the point of the capacity curve corresponding in Abaqus to the local collapse. In all the cases considered, the presence of the sidewalls is of great importance to improve the structure's stability under vertical and horizontal loading.

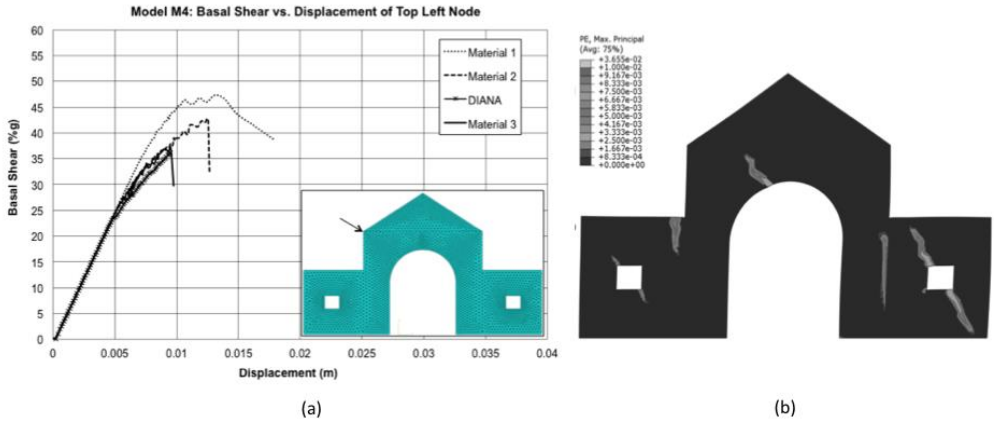

Figure 10 (a) Capacity curves for model M4, and (b) maximum plastic strains at collapse (Abaqus/CAE); displacements are computed at top left corner indicated by arrow in (a)

Model M4: the Arch with Tympanum and Lateral Walls with Window Openings

The capacity curves for Model M4 and the damage status at collapse are illustrated in Figure 10. As for M3, at the end of the gravitational loading no damage is present in the structure, confirming the stabilizing effect of the sidewalls. The similarity with the previous case continues during the initial stages of the horizontal acceleration, as an asymmetric crack develops at the intrados and then turns inward. Thereafter, the pattern changes. For all three materials in Abaqus as well as for Diana, shear fractures originating at the windows quickly develop together with fissures separating the walls from the piers – see Figures 10 (b). Finally, the shear fracture at the right window leads to total collapse of the structure. Materials 1 and 2 yield a capacity of 46%g and 42%g,

respectively, while Material 3 and Diana give the same value of 36%g. In this case too, the increase in compressive fracture energy appears to lower substantially the capacity of the structure.

Models M5 and M6: Variation in the Height of the Sidewalls

Finally, we consider how increasing the height of the lateral walls changes the capacity of the structure, modeled – in this case – with Material 3 only. M5 and M6 denote the wall configurations without and with window openings, respectively. Figure 11 (a) shows the capacity curve for three wall heights: TWH0 (the actual height, same geometry as Model 3), TWH2 (the height of the base of the tympanum), and TWH1 (intermediate between the other two.) As noted earlier in discussing Model 3, TWH0 exhibits a partial collapse at 45%g, due to the detachment of an arch section, followed by total collapse at 56%g. For TWH1 and TWH2 the detachment of the arch section corresponds to the final collapse at 52%g and 47%g, respectively. Therefore, extending the elevation of the lateral walls increases the structural capacity only if we assume the partial collapse of TWH0 as defining the total capacity of the structure in the actual wall configuration. Under the same assumption, extending the elevation increases does not affect the ductility of the structure, which remains at 11 mm.

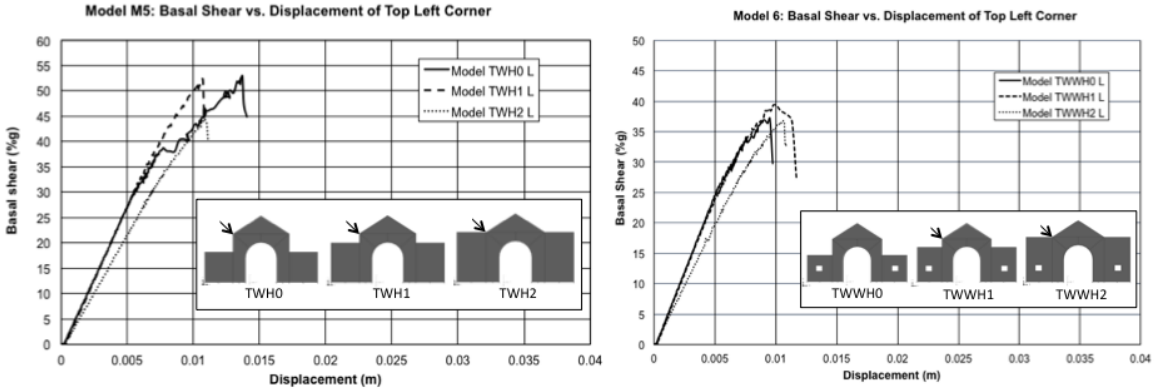

Figure 11 Capacity curves for (a) model M5 and (b) model M6; in each case, three wall heights are considered and the displacements are computed at top left corner indicated by arrow

As shown in Figure 11 (b), when the window openings are taken into account, increasing the wall height has only a marginal effect on the structural capacity – from 37%g to 39%g – as well as the ductility – from 9 mm to 10 mm.

CONCLUSIONS

St. Peter Apostle Church of Andahuaylillas is a representative structure of early colonial Peruvian religious buildings constructed in adobe. Given its remarkable historical, architectural and artistic features, it is considered a masterpiece of the Andean baroque architecture. The seismic assessment of this church requires the individual study of specific structural elements presenting a high damage concentration, as it is the case for the triumphal arch. This paper presents some preliminary results of the seismic evaluation of the arch subjected to in plane lateral accelerations. The study is conducted using similar 2D nonlinear FEM models developed in Abaqus/CAE Explicit and Diana. In order to better understand how each sub-structural element contributes to modulating the capacity of the complete triumphal arch, a sequence of models is constructed by adding to the arch proper first the tympanum and then the lateral walls (with and without window openings.)

The results indicate that the crack pattern and load capacity are substantially affected by the model geometry and by the tensile and compressive fracture energies associated with the material models used to represent the nonlinear behaviour of adobe masonry. The analyses confirm the weakness in tension at or near the centre of the intrados and at the connections with the sidewalls. In general, reducing the tensile fracture energy reduces the structural capacity. However, increasing the compressive fracture energy produces mixed effects: it increases the capacity for M1, but decreases it for all other cases. The latter effect appears to be correlated with the presence of major shear fractures at collapse. On the geometry side, the influence of the shear walls and window openings on the seismic capacity is evident. Shear walls increase considerably the load capacity by stabilizing the arch, but the inclusion of the window openings reduces markedly their effect. Considering the effect of increasing the height of the sidewalls, it appears that the current configurations provides a nearly optimum capacity under the conditions tested with the numerical models.

ABSTRACT

This paper presents the details of experimental and numerical studies on the web crippling behaviour of hollow flange channel beams, known as LiteSteel beams (LSB). The LSB has a unique shape of a channel beam with two rectangular hollow flanges, made using a unique manufacturing process. Experimental and numerical studies have been carried out to evaluate the behaviour and design of LSBs subject to pure bending actions, predominant shear actions and combined actions. To date, however, no investigation has been conducted into the web crippling behaviour and strength of LSB sections under ETF and ITF load conditions. Hence experimental studies consisting of 28 tests were first conducted in this research to assess the web crippling behaviour and strengths of LSBs under two flange load cases (ETF and ITF). Experimental web crippling capacity results were then compared with the predictions from AS/NZS 4600 and AISI S100 design rules, which showed that AS/NZS 4600 and AISI S100 design equations are very unconservative for LSBs under ETF and ITF load cases. Hence improved equations were proposed to determine the web crippling capacities of LSBs. Finite element models of the tested LSBs were then developed, and used to determine the elastic buckling loads of LSBs under ETF and ITF load cases. New equations were proposed to determine the corresponding elastic buckling coefficients of LSBs. Finally suitable design rules were also developed under the Direct Strength Method format using the test results and buckling analysis results from finite element analyses.

KEYWORDS

Cold-formed Steel, Web Crippling, ETF and ITF Load Cases, Hollow Flange Channel Beams.

INTRODUCTION

Cold-formed steel (CFS) structural members are widely used in modern construction due to the many advantages they offer in comparison with conventional hot-rolled steel sections. They are usually thin-walled members with large width-to-thickness ratios. Lightweight, high strength and stiffness, accurate section dimensions, easy prefabrication and mass production are some of the qualities of cold-formed steel members that create cost savings in construction.

Since early 1990s, Australian manufacturing companies (OATM, 2008) have introduced innovative cold-formed hollow flange sections, and one of them known as LiteSteel beams (LSB) is shown in Figure 1. The development of this hollow flange channel section was based on improving the structural efficiency by adopting torsionally rigid rectangular hollow flanges, minimising local buckling of plate elements by eliminating free edges, distributing material away from the neutral axis to afford greater bending stiffness than conventional cold-formed sections, and optimising manufacturing efficiency. The LSB sections were produced from a single steel strip using a combined dual electric resistance welding and automated continuous roll-forming process (OATM, 2008), primarily for use as floor joists and bearers in residential, industrial and commercial buildings.

The base steel used for LSB production has a yield strength of 380 MPa and a tensile strength of 490 MPa. However, due to cold-forming, the nominal yield strengths of the web and flange elements are 380 and 450 MPa, respectively (OATM, 2008). The manufacturing process also introduces residual stresses and initial geometric imperfections which differ from those of common cold-formed and hot-rolled steel sections. Due to the geometry of the LSB, as well as its unique residual stress characteristics and initial geometric imperfections resultant of manufacturing processes, much of the existing research for common cold-formed steel sections is not likely to be directly applicable to the LSB.

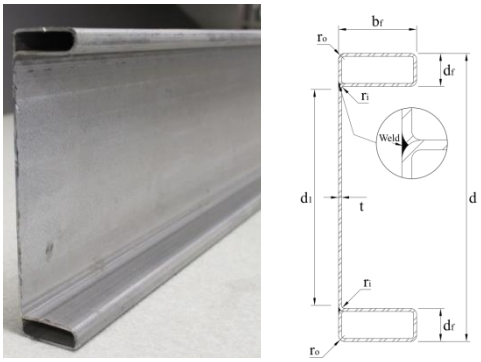

Figure 1 LiteSteel beams

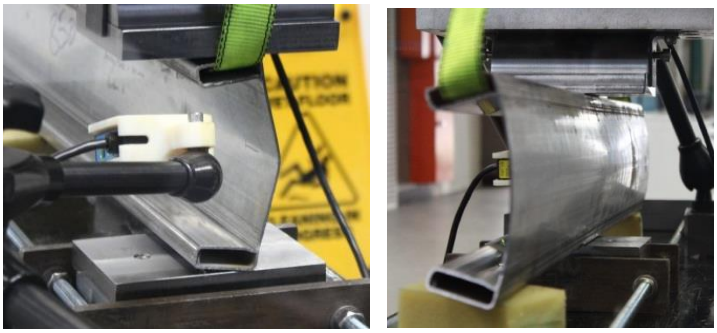

Figure 2 Web crippling failures of LSBs

Web bearing is a form of localized failure that occurs at points of transverse concentrated loading or supports of thin-walled steel beams (Rhodes et al., 1998). LSB joists and bearers that are unstiffened against this type of loading are also vulnerable to web bearing/crippling failures (see Figure 2). The computation of the web bearing strength by means of theoretical analysis is quite complex as it involves many factors such as local yielding in the loading region, instability of the web element, and many others. Hence the current design rules in most cold-formed steel structures codes are empirical in nature developed based on more than 1200 tests of conventional cold-formed steel sections such as C-, Z- and hat sections and built-up sections (Winter and Pian; 1946, Walker, 1972; Khan and Walker, 1975; Prabakaran, 1993; Young and Hancock, 1998 and Macdonald et al., 2011) for the four types of web crippling loading conditions shown in Figure 3: End-One-Flange Loading (EOF), End-Two-Flange Loading (ETF), Interior-One-Flange Loading (IOF) and Interior-Two-Flange Loading (ITF). Since 2005, unified web bearing capacity equations have been developed that define specific web crippling coefficients for the key parameters influencing the web bearing capacity of C-, Z-, Hat and built-up sections, namely, clear web height to thickness ratio (d_1/t_w), inside bent radius to thickness ratio (r_i/t_w), bearing length to thickness ratio (l_b/t_w), in addition to web thickness (t_w) and yield stress (f_y). However, these capacity equations are not applicable to the LiteSteel beams (LSB) due to the presence of two rectangular hollow flanges instead of the conventional flange plate elements. Effects of the presence of hollow flanges including the higher rotational restraint at the LSB web-flange juncture have been successfully included in the shear capacity design rules of LSBs (Keerthan and Mahendran, 2010 and 2011). However, such an approach has not been developed yet for the web crippling capacity of LSBs.

Hollow flange channel sections such as LSBs can be used as flexural members in steel building systems, for example, floor joists and bearers. For them to be used as flexural members, their flexural, shear and web crippling capacities must be known. Recent research studies have investigated the flexural (Anapayan and Mahendran, 2011 and 2012) and shear (Keerthan and Mahendran, 2010 and 2011) behaviour and capacities of LSBs. However, no investigation has been conducted into the web crippling behaviour and strength of LSB sections. In this research web crippling behaviour and strength of LSBs under ETF and ITF load cases was investigated using experimental and numerical studies. Experimental study was used to determine the ultimate web crippling capacities while finite element analyses were used to determine their elastic buckling loads for these two load cases. Using these results, improved design rules are proposed including the direct strength method based design rules. This paper presents the details of these studies, and the results.

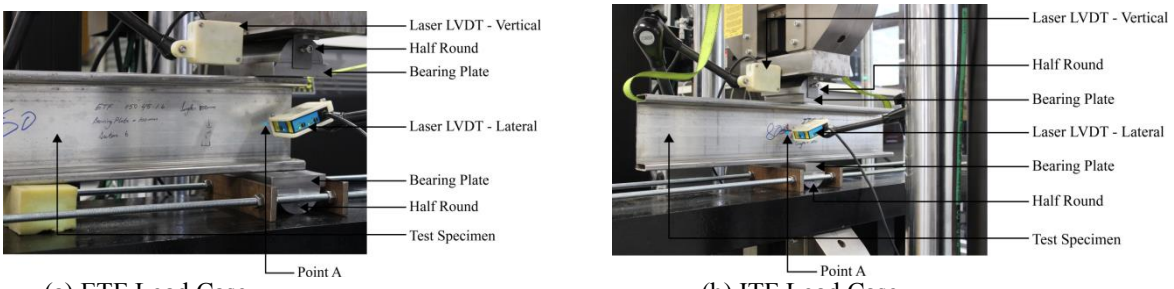
(c) End one flange (EOF) loading (d) Interior one flange (IOF) loading

Figure 3 Loading conditions for web crippling tests (AISI, 2008)

WEB CRIPPLING TESTS

Twenty eight tests were conducted to investigate the web crippling behaviour of LSBs under ETF and ITF load cases. Table 1 presents the details of the web crippling test specimens. It includes the measured web thicknesses (t_w), clear web heights (d_1), and yield stresses (f_y) of the web elements of tested LSBs. Since the outside of the inner bent corners (r_i) is filled with weld material unlike in open cold-formed channel sections, the inner bent radius (r_i) of LSB was considered as zero (see Figure 1). Figures 4 (a) and (b) show the test set-up used in the web crippling tests of this research for ETF and ITF load cases, respectively, built based on the recommended AISI standard test method shown in Figure 3 (a) and (b).

It is stated in the AISI S909 test method (AISI, 2008) that the specimen length should be at least equal to three times the flat portion of clear web height for the ETF load case while it should be at least equal to five times the flat portion of clear web height for the ITF load case. Hence five times the section depth was selected for both ETF and ITF load cases.



(a) ETF Load Case (b) ITF Load Case

Figure 4 Web crippling test set-up

All the LSB tests were conducted using an Instron testing machine**.** Three different sizes of bearing plates (50 mm, 100 mm and 150 mm) were used to attain three types of testing conditions for both ETF and ITF load cases. The support system was designed to ensure that the test beam had pinned supports at the top and bottom. The applied load is the important parameter. The measuring system was set-up to record the applied load and associated test beam displacements. The cross-head of the testing machine was moved at a constant rate of 0.7 mm/minute until the test beam failed. Figures 5 (a) and (b) show the web crippling failure modes of 200x45x1.6 LSBs under ETF load and ITF cases, respectively (bearing length = 100 mm). No flange crushing failures were observed in the tests.

Experimental ultimate web crippling capacities are compared with the predictions from the design equation (Equation 1) based on AS/NZS 4600 (SA, 2005) and AISI S100 (AISI, 2012) in Table 1. For the prediction of web crippling capacities, support and flange conditions were taken as Unfastened, Stiffened or partially

stiffened flanges and Two-flange loading or reaction and the corresponding web crippling coefficients are as follows.

$$R_b = Ct_w^2 f_y \sin\theta \left(1 - C_r\sqrt{\frac{r_i}{t_w}}\right)\left(1 + C_l\sqrt{\frac{l_b}{t_w}}\right)\left(1 - C_w\sqrt{\frac{d_1}{t_w}}\right) \quad (1)$$

Therefore C = 13, C_r = 0.32, C_l = 0.05, C_w = 0.04 for ETF load case
C = 24, C_r = 0.52, C_l = 0.15, C_w = 0.001 for ITF load case

Table 1 Web crippling capacities of tested LSBs and comparisons with AS/NZS 4600 design rules

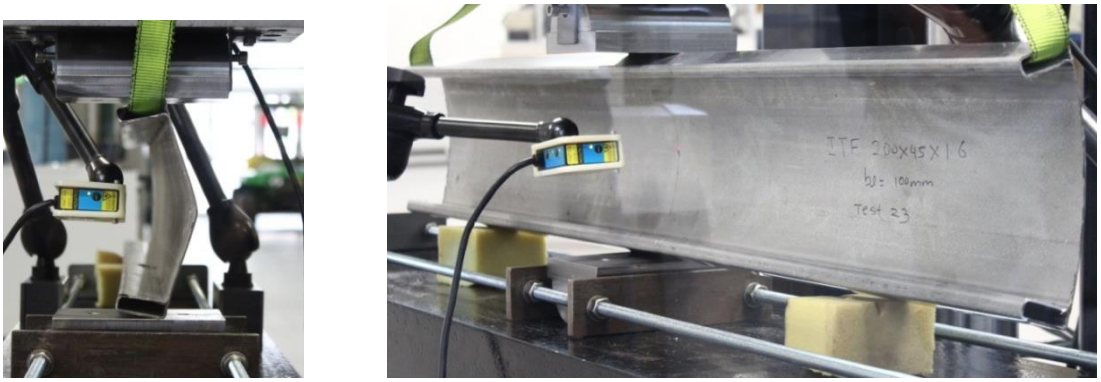
Note: AS/NZS 4600 and AISI S100 design rules are identical.

For ETF load case, the mean value of test to predicted web crippling capacity of LSB by AS/NZS 4600 is 0.76 while the corresponding coefficient of variation (COV) is 0.19. For ITF load case, the mean value of test to predicted web crippling capacity of LSB by AS/NZS 4600 is 0.31 while the corresponding COV is 0.21. Table 1 results show that AS/NZS 4600 (SA, 2005) and AISI S100 (AISI, 2012) design equations are considerably unconservative for LSB sections, in particular under ITF load case. Since AS/NZS 4600 (SA, 2005) and AISI S100 (AISI, 2012) design equations were developed for open cold-formed steel sections, new web crippling capacity equations should be developed for LiteSteel beams (LSBs) with rectangular hollow flanges. Details of the proposed web crippling capacity equations for LSBs are given in the next section.



(a) ETF load case (b) ITF load case

Figure 5 Web crippling failure modes of 200x45x1.6 LSBs under ETF and ITF load cases (Bearing Length = 100 mm)

Since the currently available web crippling capacity equations are unsafe for LSBs, new design equations are proposed to predict the web crippling capacities of LSBs based on experimental results. This approach is similar to that used in the current cold-formed steel design codes (SA, 2005 and AISI, 2012) in which Equation 1 is proposed with modified web crippling coefficients C, C_r, C_l and C_w. Since the inside bent radius (r_i) was considered as zero, C_r was taken as zero. Equations 2 and 3 show the proposed design equations for the web crippling capacities of LSBs (R_b) while Table 2 shows the associated, modified web crippling coefficients. Experimental ultimate web crippling capacities are compared with the predictions from the proposed Equations 2 and 3 in Table 1. For ETF load case, the mean value of test to predicted web crippling capacity ratio is 1.00 with a COV of 0.098. For ITF load case, these values are 1.00 and 0.135. It shows that the web crippling capacities predicted by Equations 2 and 3 agree well with the experimental web crippling capacities of LSBs under ETF and ITF load cases.

$$R_b = 12.5 t_w^2 f_y \left(1 + 0.12\sqrt{\frac{l_b}{t_w}}\right)\left(1 - 0.07\sqrt{\frac{d_1}{t_w}}\right) \quad (2)$$

$$R_b = 25.7 t_w^2 f_y \left(1 + 0.04\sqrt{\frac{l_b}{t_w}}\right)\left(1 - 0.06\sqrt{\frac{d_1}{t_w}}\right) \quad (3)$$

ELASTIC BUCKLING FINITE ELEMENT ANALYSES

Theoretical elastic buckling analysis approaches were attempted in the past to investigate the buckling behavior of steel sections under concentrated loads (Walker, 1975). They idealized the webs of cold-formed steel sections as simply supported rectangular thin plates along the edges and subjected to locally distributed in-plane edge compressive forces. However, some stiffened compression elements will not fail when the elastic buckling load is reached but will develop post-buckling strength by means of redistribution of stresses. The post-buckling strength computation is rather complex, especially with the interaction of web and flange elements. Most of the past theoretical studies simply ignored this and considered it as a plate element.

This section presents the development of finite element models to investigate the elastic buckling behaviour of LiteSteel beams under concentrated loads. Finite element modelling software ABAQUS was used to perform this task. ABAQUS has several element types to simulate the buckling behaviour of beams. But among them, S4R shell element was selected as it has the capability to simulate the linear buckling behaviour of LSBs. LSB sections were meshed in to 5 mm x 5 mm, except the section's corners. These corners were modelled with 1 mm x 5 mm mesh to accurately represent the influence of outside corner radius (r_o). Figure 6 shows the developed finite element model of LSB under ITF load case.

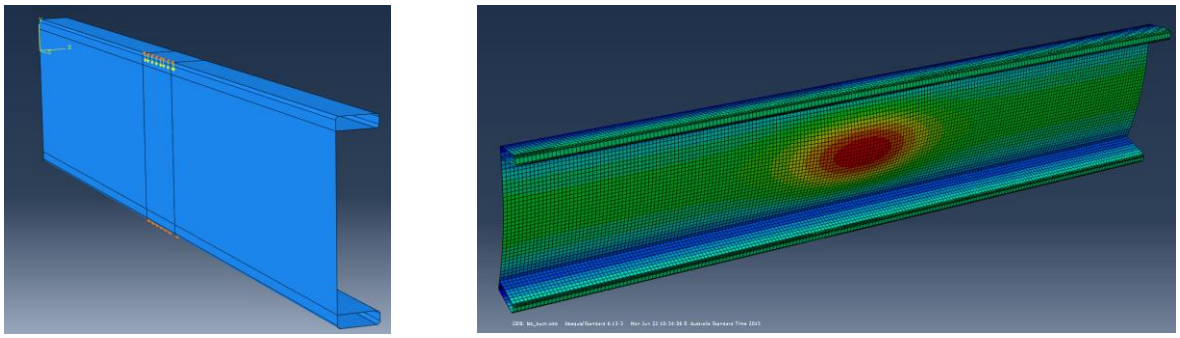
Loading was directly applied by means of nodal forces in the top web-flange junction to represent the load applied through loading plate. The top flange nodes with the applied equivalent nodal forces were prevented from moving along the transverse and longitudinal directions (axes 1 and 3). Every node on the bottom bearing length (end span section in ETF and mid-span section in ITF load cases) was prevented from moving along the transverse (axis 1), vertical (axis 2) and longitudinal (axis 3) directions.



(a) Load and Boundary Conditions (b) Buckling Mode

Figure 6 Finite element model of 200x45x1.6 LSB under ITF load case

Elastic critical buckling loads calculated from finite element analyses (FEA) were combined with the critical buckling load equation (Equation 4) to calculate the buckling coefficient (k) and the results are summarized in Table 3. These analyses show that the buckling loads of the sections vary with bearing length. Based on the elastic buckling analysis results, the following simple equation (Equation 5) was developed for the determination of the elastic buckling coefficients of LSBs under ETF and ITF load cases. Finite element analyses coefficients (k_{FEA}) and proposed buckling coefficient (K_{Prop}) were compared in Table 3. The mean values of FEA to proposed coefficients (k_{FEA}/k_{Prop}) for ETF and ITF load cases are 1.00 while the corresponding COVs are 0.03 and 0.02, respectively. It shows that the buckling coefficients predicted based on the proposed equation (Equation 5) agree well with FEA bucking coefficients for LSB sections under both load cases.

This buckling coefficient equation includes the effect of inside bent radius (r_i), web depth (d_1), bearing length (ℓ_b), flange width (b_f) and thickness (t_w) of the sections, which is in a similar form of AISI S100 (2012) and AS/NZS 4600 design rules for web crippling capacities. Coefficients for calculating the buckling coefficient (k) under ETF and ITF load cases can be obtained from Table 4.

$$P_{cr} = \frac{\pi^2 E k \, t_w^{\,3}}{12\left[1-\upsilon^2\right] d_1} \tag{4}$$

$$K_{Prop} = C_b\left(1 - C_{b,r}\sqrt{\frac{r_i}{t_w}}\right)\left(1 - C_{b,w}\sqrt{\frac{d_1}{t_w}}\right)\left(1 + C_{b,\ell}\sqrt{\frac{\ell_b}{t_w}}\right)\left(1 + C_{b,b}\sqrt{\frac{b_f}{t_w}}\right) \tag{5}$$

C_b = general coefficient, $C_{b,r}$ = coefficient of inside bent radius to thickness ratio, $C_{b,w}$ = coefficient of web slenderness ratio, $C_{b,\ell}$ = coefficient of bearing length to thickness ratio, $C_{b,b}$ = coefficient of flange width to thickness ratio

This proposed equation to calculate the buckling coefficient was used to derive the web crippling capacity equations of LSB sections under ETF and ITF load cases in the next section. This method to predict buckling coefficients under web crippling can be extended to other cold-formed steel sections such as lipped channels and channels with web ribs in the future.

DIRECT STRENGTH METHOD

The direct strength method (DSM) is an alternative to the traditional effective width method and has been adopted as an alternative design method in AS/NZS 4600 and AISI S100. However, no formal DSM provisions exist for web crippling of cold-formed steel beams. Hence suitable design rules were developed for the web crippling capacity of LSBs under the DSM format. They are proposed in a similar manner to those of the section capacity of columns in compression subject to local buckling (Equations 6 and 7) using test results. In these equations the DSM based nominal web crippling capacity (P_u) is proposed using the local buckling capacity equation (N_{cl}) where N_{cl}, N_{ol} and N_{ce} are replaced by P_u, P_{cr} (elastic buckling capacity in web crippling) and P_y (yield capacity in web crippling), respectively. In these equations, power coefficients of 0.78 and 0.75 are used instead of 0.4 based on the experimental results of LSBs for ETF and ITF load cases, respectively. Slenderness (λ) was calculated using Equation 8. Equations 6 and 7 show the proposed DSM based design equations for the web crippling capacity of LSBs under ETF and ITF load cases, respectively.

$$\frac{P_u}{P_y} = 0.50\left[1 - 0.05\left(\frac{P_{cr}}{P_y}\right)^{0.78}\right]\left(\frac{P_{cr}}{P_y}\right)^{0.78} \tag{6}$$

$$\frac{P_u}{P_y} = 0.56\left[1 - 0.05\left(\frac{P_{cr}}{P_y}\right)^{0.75}\right]\left(\frac{P_{cr}}{P_y}\right)^{0.75} \tag{7}$$

$$\lambda = \sqrt{\frac{P_y}{P_{cr}}} \tag{8}$$

$$P_y = f_y t_w \left(l_b + d_1\right) \tag{9}$$

$$P_y = f_y t_w \left(l_b + \frac{d_1}{2}\right) \tag{10}$$

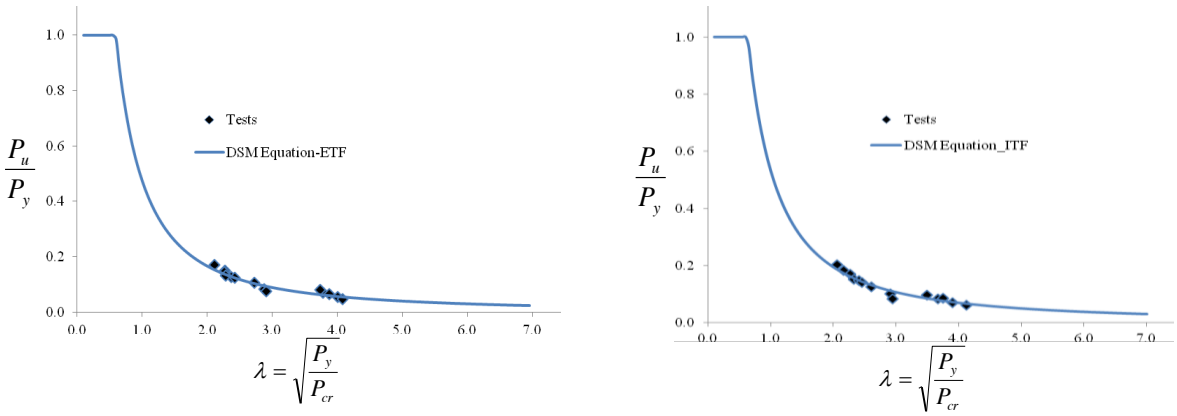


Figure 7 Comparison of web crippling capacities of LSBs from tests and DSM based design equations

Equations 9 and 10 above present the equivalent yield capacities in web crippling based on a 45° load distribution to the middle from the bearing plate edges for ETF and ITF load cases, respectively. These equivalent web yield capacity expressions also agree with the yield-line model of Young and Hancock (2001).

In order to investigate the accuracy of the proposed DSM based web crippling design equations for LSBs, experimental ultimate web crippling capacity results were processed within the DSM format and compared with the proposed design equations (6 to 10). They are shown in Figures 7 (a) and (b) for ETF and ITF load cases, respectively. These figures are in a non-dimensional format, ie. P_u/P_y versus $\lambda = (P_y/P_{cr})^{0.5}$. It can be seen that the proposed DSM equations are able to predict the web crippling capacities of LSBs accurately. Further FEA based research is continuing to improve the proposed DSM equations using more web crippling capacity data.

CONCLUSIONS

This paper has presented the details of 28 web crippling tests conducted to investigate the web crippling behaviour and capacities of hollow flange channel beams known as LiteSteel beams (LSB) under ETF and ITF load cases, and the corresponding finite element analyses to determine their elastic buckling loads. Comparison of the ultimate web crippling capacities from tests showed that AS/NZS 4600 (SA, 2005) and AISI S100 (AISI, 2012) design equations are unconservative for LSB sections under both ETF and ITF load cases. New equations were therefore proposed to accurately predict the web crippling capacities of LSBs based on the test results. New equations were also proposed to calculate the elastic buckling loads of LSBs under ETF and ITF load cases. Suitable DSM based design equations were then developed for the web crippling capacity of LSBs under ETF and ITF load cases. Further finite element analyses are continuing to improve the DSM equations. A similar approach can be used to develop DSM based design equations for conventional open cold-formed steel sections.

ABSTRACT

Failure in quasi-brittle materials usually appears in the form of narrow bands called fracture process zones, where all inelastic deformation takes place, while the surrounding bulk material outside those areas typically unloads elastically. This localised nature of failure is the main source of size effects in these materials, since the width of the fracture process zone is a material property that does not scale with the size of the material volume. An adequate description of localised failure and associated size effects requires both size and behaviour of the fracture process zone and neighbouring material to be properly taken into account. In this study, we present two alternative approaches for modelling localised failure and simulating fracture propagation using finite element methods. In the first approach, an embedded crack appears at a constitutive level by enriching the kinematics of constitutive models, while in the second one this is done at the finite element level using cohesive interface elements. The advantages and shortcomings of both are presented through one numerical example on the failure of fibre-reinforced composite materials.

KEYWORDS

Quasi-brittle, cohesive crack, constitutive modelling, finite elements, interface elements.

INTRODUCTION

Localised mode of failure is usually encountered in quasi-brittle materials such as concrete, rock and ceramics. The deformation in such cases usually localises on narrow bands where all inelastic deformation takes place and the surrounding bulk material outside those areas typically unloads elastically. Since the width and orientation of the localisation band are both material properties, taking them into account in constitutive modelling of quasi-brittle materials is critical for a correct description of their post-localisation behaviour. This behaviour in such cases, scales with the width of the localisation band and the size of the volume element that contains it. This is the well-known 'size effect' mentioned in the literature.

Localised failures have traditionally been modelled using two approaches - the continuous and the discontinuous approach. Notable models belong to the former class include nonlocal constitutive models (Bazant and and Pijaudier-Cabot 1988), gradient enhanced damage models (Peerlings *et al*. 1996), smeared crack models (Rashid 1968, Bazant and Oh 1983), and recently emerged phase field models (Miehe *et al*. 2010). The key characteristics of the continuous approach is that the failure process is modelled by the degradation of the material and therefore the incorporation of a length scale is done at the constitutive level, or alternatively at the integration point level in a numerical method framework, such as the finite element method (FEM). Its name reflects one of the drawbacks of the continuous approach - true separation cannot be captured since the continuum, even though cracked, is always simulated as continuous medium. This is due to the fact that cracks are not explicitly represented; only their effects are taken into account through the degradation of effective properties of the continuum. On the other hand, discontinuous approaches employ explicit crack representations and hence allow material separation to be accurately reproduced as a geometrical discontinuity. Some of the methods for localised failure include zero-thickness cohesive interface elements (Ngo and Scordelis 1968, Xu and Needleman 1994, Mergheim *et al*. 2004, Dias-da-Costa *et al*. 2009a, Nguyen 2014a), elements with embedded strong discontinuities (Dvorkin *et al*. 1990, Dias-da-Costa *et al*. 2009b, 2013) and extended finite elements (XFEM) (Moes *et al*. 1999, Wells and Sluys 2001). Cohesive zone models (Barenblatt 1962 and Dugdale 1960) are usually employed in discontinuous approaches.

In this paper a comparison of computational performances, particularly the efficiency and robustness, of the continuous approach and the discontinuous approach is established for the modelling of quasi-brittle failure. We use the kinematically enriched constitutive model developed recently by (Nguyen *et al*. 2012, 2014, 2015b) as a

continuous approach. For the discontinuous approach, the cohesive interface elements are used in the framework of discontinuous Galerkin approach recently employed by Nguyen (2015a). These two different approaches are used in the simulation of a fibre-reinforced composite material at the mesoscale, where both matrix and fibres are explicitly represented. All simulations are carried out on the same computer using the same FE solver facilitating the comparison of these approaches. In the next section, the kinematically enriched constitutive model approach is presented, followed by the formulation of a cohesive element in Section 3. In the last sections, the numerical example and findings are discussed and conclusions withdrawn.

KINEMATICALLY ENRICHED CONSTITUTIVE MODEL

General case

We consider a material volume Ω consisting of a localisation zone Ω_i of thickness h, surrounded by a bulk material Ω_O (Fig. 1). Subscripts "i" and "o" are used for quantities inside and outside the localisation band, respectively (Einstein summation convention does not apply here). Accordingly, the stresses and strains are denoted by $(\boldsymbol{\sigma_i}, \boldsymbol{\epsilon_i})$, $(\boldsymbol{\sigma_o}, \boldsymbol{\epsilon_o})$ for the material inside and outside the localisation band, the latter within the homogeneous bulk. Dissipative processes are assumed to take place exclusively inside the thin localisation band, while the outside bulk is undergoing elastic unloading. Note that this assumption belongs to a more general case of discontinuous bifurcation, and while it is valid for quasi-brittle materials such as concrete, it may not hold for other materials. Examples of these materials include the ones with inelastic unloading outside shear bands such as in granular materials. The point is to devise a model, in terms of the averaged (or macro) stress $\boldsymbol{\sigma}$ and averaged strain $\boldsymbol{\epsilon}$ defined over the domain Ω, by coupling the different responses of the material inside and outside the localised region i.e., in terms of $(\boldsymbol{\sigma_i}, \boldsymbol{\epsilon_i})$, $(\boldsymbol{\sigma_o}, \boldsymbol{\epsilon_o})$, η, h and H (definitions shown in Fig. 1).

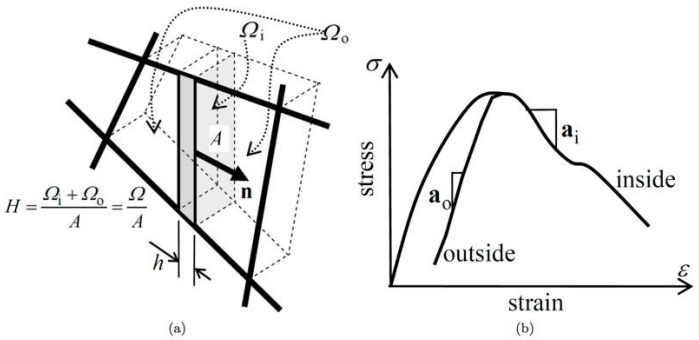

Figure 1: Numerical discretisation and a localisation zone (shadowed) (a) and corresponding material responses inside and outside the localisation zone (b) (after Nguyen et al., 2014).

Key-equations are presented here, while further details can be found in (Nguyen *et al*. 2012, 2014, 2015b). The macro strain rate is defined as the volume-averaged strain rates inside and outside the localisation band:

$$\dot{\boldsymbol{\epsilon}} = \eta\dot{\boldsymbol{\epsilon}}_i + (1-\eta)\dot{\boldsymbol{\epsilon}}_o \tag{1}$$

where η is the volume fraction of the localisation band, $\eta = \frac{h}{H}$ (Fig. 1). Given a very narrow localisation band, usually approximated by a zero thickness cohesive zone in quasi-brittle failure, the strain rate inside the localisation band can be approximated as

$$\boldsymbol{\epsilon}_i \approx \frac{1}{h}\,(\boldsymbol{n} \otimes [\![\dot{\boldsymbol{u}}]\!])^{sym} \tag{2}$$

where $\boldsymbol{n}$ denotes the outward unit vector normal to the localisation band and $[\![\dot{\boldsymbol{u}}]\!]$ is the velocity jump vector. One can see Equations (1-2) as a kinematic enrichment at the constitutive level due to the appearance of an additional strain rate in the constitutive description. This enrichment allows for the introduction of an additional constitutive behaviour for the material inside the localisation band. We can write the behaviour inside and outside the band in generic forms as:

$$\boldsymbol{\sigma}_o = \boldsymbol{a}_o : \dot{\boldsymbol{\epsilon}}_o,\ \dot{\boldsymbol{\sigma}}_\iota = \boldsymbol{a}_i : \dot{\boldsymbol{\epsilon}}_i \tag{3}$$

where $\boldsymbol{a}_o$and $\boldsymbol{a}_i$ are the fourth-order material tangents of the materials outside and inside, respectively.

The connection between inside/outside quantities with the homogenised ones is enforced via the Hill-Mandel equation that should be met for any arbitrary strain rate $\dot{\boldsymbol{\epsilon}}$ and velocity jump $[\![\dot{\boldsymbol{u}}]\!]$:

$$\boldsymbol{\sigma}:\dot{\boldsymbol{\epsilon}} = \eta\boldsymbol{\sigma}_i:\dot{\boldsymbol{\epsilon}}_i + (1-\eta)\boldsymbol{\sigma}_o:\dot{\boldsymbol{\epsilon}}_o \tag{4}$$

Using (1-4), it can be shown that (i) the macro homogenised stress $\boldsymbol{\sigma}$ coincides with the stress $\boldsymbol{\sigma}_o$ describing the behaviour of the material outside the localisation zone, and (ii) the traction must be continuous across the boundary of the localisation zone:

$$\boldsymbol{\sigma} = \boldsymbol{\sigma}_o \text{ and } \boldsymbol{\sigma_i}\cdot\boldsymbol{n} = \boldsymbol{\sigma_o}\cdot\boldsymbol{n} \tag{5}$$

The above traction continuity condition – together with Equations (1-3) – is the key to determine the velocity jump vector from a given macro strain rate $\dot{\boldsymbol{\epsilon}}$. Ignoring the details – these can be found in Nguyen *et al* (2014) – we can write:

$$[\![\dot{\boldsymbol{u}}]\!] = \left[\frac{\eta}{h}\boldsymbol{A}_o + \frac{1-\eta}{h}\boldsymbol{A}_i\right]^{-1}\cdot(\boldsymbol{a}_o:\dot{\boldsymbol{\epsilon}})\cdot\boldsymbol{n} = \boldsymbol{C}^{-1}\cdot\ (\boldsymbol{a}_o:\dot{\boldsymbol{\epsilon}})\cdot\boldsymbol{n} \tag{6}$$

where $\boldsymbol{C}$ is the tensor in the square brackets; $\boldsymbol{A}_o$and $\boldsymbol{A}_i$ are the acoustic tensors associated with $\boldsymbol{a}_o$and $\boldsymbol{a}_i$, respectively, $\boldsymbol{A}_{o/i} = \boldsymbol{n}\cdot\boldsymbol{a}_{o/i}\cdot\boldsymbol{n}$. From (1-3 and 5), the stress strain relationship, in rate form, can be obtained as

$$\dot{\boldsymbol{\sigma}} = \frac{1}{1-\eta}\boldsymbol{a}_o:\left[\dot{\boldsymbol{\epsilon}} - \frac{\eta}{h}(\boldsymbol{n}\otimes(\boldsymbol{C}^{-1}\cdot(\boldsymbol{a}_o:\dot{\boldsymbol{\epsilon}})\cdot\boldsymbol{n}))^{sym}\right] \tag{7}$$

Note that the second term in the above expression accounts for cracking effects by a relaxation strain rate governed by the behaviour inside the localisation zone. In other words, cracking is modelled as a material degradation process in the same manner as damage models or smeared crack models. However, unlike these existing approaches that lump everything in a single macro constitutive behaviour, the key difference here is the separation of constitutive responses inside and outside the localisation zone, and the utilisation of their connection via the traction continuity to constitute macro homogenised behaviour. Since cracking is dealt with at the constitutive level, or at the integration points in a FEM context, there is no need to enhance the element interpolation functions, and hence all element technology remains the standard one. This is the key-advantage of the continuous approach relatively to discontinuous formulations, which depend on the type of element.

The aforementioned constitutive model has been firstly used with a plastic-damage model to describe the localisation band, whereas the region outside this band was assumed to be linear elastic (Nguyen *et al*. 2014). It was then used in (Nguyen *et al*. 2015a) to model shear bands in geomaterials. In the next section, the specialisation of this general constitutive model to the case in which the localisation band can be modelled as a cohesive crack is presented.

Embedded cohesive cracks

Cohesive crack models adopt a traction-separation law instead of the stress-strain law usually used for the bulk. In a local coordinate system aligned with the crack, the cohesive law generally reads:

$$\boldsymbol{t}_{cr} = \boldsymbol{K}_{cr}[\![\dot{\boldsymbol{u}}]\!]_{cr} \tag{8}$$

where subscript '*cr*' is used to indicate that the cohesive law is defined in the crack coordinate system. The traction vector is denoted by $\boldsymbol{t}_{cr}$ and $\boldsymbol{K}_{cr}$ is the second-order cohesive material tangent.

In the case of cohesive cracks, the localisation band is simply a surface/line in three/two dimensions corresponding to $h \to 0$. Using $f = h/H$, Equations (1, 2) can be simplified into

$$\dot{\boldsymbol{\epsilon}} = \frac{1}{H}\ (\boldsymbol{n}\otimes[\![\dot{\boldsymbol{u}}]\!])^{sym} + \dot{\boldsymbol{\epsilon}}_o \tag{9}$$

The velocity jump given in Equation (5) then becomes

$$[\![\dot{\boldsymbol{u}}]\!] = \left[\frac{1}{H}\boldsymbol{A}_o + \boldsymbol{K}\right]^{-1} \cdot (\boldsymbol{a}_o : \dot{\boldsymbol{\epsilon}}) \cdot \boldsymbol{n} \tag{10}$$

where $\boldsymbol{K}$ denotes the cohesive material tangent defined in the global coordinate system. In the same manner, the stress-strain relationship is now given by

$$\dot{\boldsymbol{\sigma}} = \boldsymbol{a}_o : \left[\dot{\boldsymbol{\epsilon}} - \frac{1}{H}(\boldsymbol{n} \otimes (\boldsymbol{C}^{-1} \cdot (\boldsymbol{a}_o : \dot{\boldsymbol{\epsilon}}) \cdot \boldsymbol{n}))^{sym}\right] \tag{11}$$

where $\boldsymbol{C}$ is the tensor defined by $\boldsymbol{C} = \frac{1}{H}\boldsymbol{A}_o + \boldsymbol{K}$ (the term in square brackets in Equation (10)).

Advantages of the enriched constitutive model

The preliminary works of (Nguyen et al, 2012, 2014, 2015ab) on kinematically enriched constitutive models showed several advantages. In particular, and similarly to any continuum approach, when compared to discontinuous methods such as XFEM, the enriched constitutive modelling approach is robust and efficient (e.g. no additional unknowns are required such as with XFEM). It can be easily implemented in existing mesh-based or particle-based numerical codes (even in some commercial packages, since only a constitutive routine is needed) and able to handle crack branching, intersecting and merging. This is particularly interesting in the case of large-scale simulations involving complex cracking processes, where the discrete representation of cracks might not be feasible and the smeared crack approach limits the element size, which may not be satisfied due to the typical element sizes (in the order of meters). Current practice to solve this issue relies on artificially increasing the fracture energy or reducing the tensile strength (Levy *et al*. 2011). In this sense, compared to existing smeared crack models, the enriched approach is free of the so-called local snapback instability, which settles the limit on the finite element size for the standard smeared crack approach. The use of two inter-dependent constitutive relationships for bulk and localisation zone, and their corresponding sizes, together with a two-level stress return algorithm (Nguyen *et al*., 2015b), naturally resolves snap-back issues and gives the model an intrinsic scaling law to deal with size effects.

DISCRETE CRACK MODELLING

Among various discrete crack modelling techniques (cohesive interface elements, XFEM, embedded strong discontinuities, among others) the zero-thickness cohesive interface elements are herein adopted due to the (i) robustness, (ii) easy implementation (even for parallel computers) and (iii) ability to model complex crack patterns, see for example (Xu and Needleman 1994, Nguyen 2014a). These interface elements are inserted into the mesh prior to the simulation using the tool developed by (Nguyen 2014b), cf. Fig. 2, within the framework of a discontinuous Galerkin method. It should be emphasised that cohesive interface elements are to some extent mesh-dependent since the crack path is constrained to the element edges/surfaces, although this is not pronounced for complex crack patterns as shown in (Nguyen 2014b).

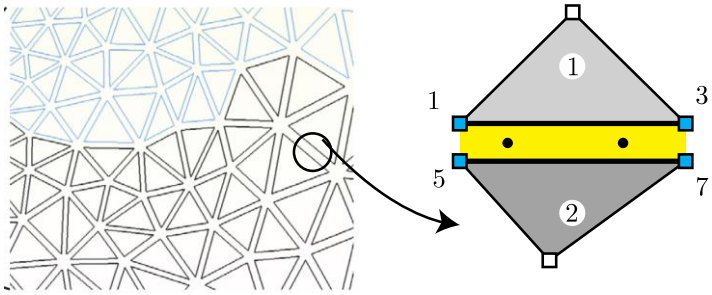

Figure 2: Zero-thickness interface elements embedded in a mesh of triangles (left) and a typical four-node linear interface element (nodes are 1, 3, 5, 7) (right).

The weak form is the standard one-field variational formulation given as follows

$$\int_\Omega \delta\boldsymbol{u} \cdot \boldsymbol{b} d\Omega + \int_{\Gamma_t} \delta\boldsymbol{u} \cdot \bar{\boldsymbol{t}}\, d\Gamma = \int_\Omega \delta\boldsymbol{\epsilon} : \boldsymbol{\sigma}(\boldsymbol{u}) d\Omega + \int_{\Gamma_d} \delta[\![\boldsymbol{u}]\!] \cdot \boldsymbol{t}^c([\![\boldsymbol{u}]\!])\, d\Gamma \tag{11}$$

where Ω is the domain of interest, Γ_t denotes the traction boundary, Γ_d is the crack surfaces (which constitute all the element edges in two dimensions and element surfaces in three dimensions), $\boldsymbol{b}$ is the body force, $\bar{\boldsymbol{t}}$ is the applied traction, $[\![\boldsymbol{u}]\!]$ is the displacement jump (that measures the crack separation) and $\boldsymbol{t}^c$denotes the cohesive traction. Note that only the last term in Equation (11), which is work done by the cohesive cracks, differs from the standard weak form. In this approach, conventional interface elements are used in conjunction with the so-called intrinsic cohesive law (cf. Figure 3-left). In this case, the initial elastic stiffness of the interface elements artificially increases the compliance of the system. One solution to this issue is to employ an initially rigid cohesive law (cf. Fig. 3-right) together with a discontinuous Galerkin (dG) formulation (Mergheim *et al* 2004) to link the solid elements before crack initiation. Details on the dG cohesive interface elements, computer implementation and applications can be found in (Nguyen 2014a).

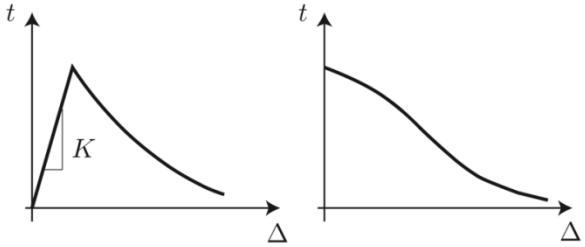

Figure 3: Two types of cohesive laws: intrinsic cohesive law or initially elastic one (left) and extrinsic or initially rigid cohesive law (right).

RESULTS AND DISCUSSIONS

This section presents some simulations of the failure of a fibre-reinforced composite sample shown in Fig. 4. Note that this sample was selected just for illustration and comparison of two approaches and it is probably not representative of a real composite material. The material properties are the following: Young's modulus and Poisson's ratio of the matrix, 4 GPa and 0.4, respectively, Young's modulus and Poisson's ratio of the fibres are 40 GPa and 0.33, respectively. For matrix cracks, a tensile strength of 30 MPa is adopted with a fracture energy of 0.25 N/mm, whereas for the interfacial cracks, the tensile strength is 10 MPa and the fracture energy is 0.05 N/mm. As can be seen, the nonlinearities are assumed to originate from cracking solely and the bulk is modelled as linear elastic.

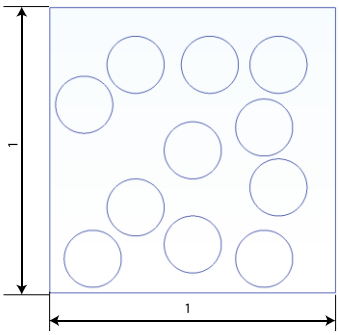

Figure 4: A unit square made of fibre-reinforced composite material. All fibres are represented by circles of the same radius of 0.1 mm. A uniaxial tensile test is performed where the left edge is fixed in both directions and the right edge is pulled horizontally. Plane stress condition is assumed.

The discretisation of the domain in Fig. 4 consists of 15680 linear triangular elements (7909 nodes), and on that discretisation basis, modifications to fit the requirements of continuous and discontinuous approaches are needed. Only a single discretisation basis is considered since the mesh objectivity of the continuous approach was already demonstrated elsewhere (Nguyen *et al*. 2012, 2014), while the discontinuous one intrinsically has dissipation scaling with surface areas and hence is free from zero dissipation modes when the element size goes to zero. In this study, for both approaches, matrix-fibre debonding is explicitly modelled using cohesive elements and this is obtained by inserting interface elements only at the matrix/fibre interface. For the discontinuous approach, a further modification is needed by inserting interface elements at every element boundaries except for elements discretising the fibres, since the fibres are assumed elastic. The continuous approach in this case employs 15680 solid elements and 616 interface elements with a total of 8525 nodes (mesh 1), while the finite element mesh for continuous approach contains 15680 solid elements and 12744 interface elements with a total of 28999 nodes (mesh 2, which has three times the number of nodes compared to mesh 1). For further details, the first mesh is used with standard cohesive elements to model matrix/fibre debonding and

the kinematically enriched constitutive model (at the integration points of the bulk elements) to model the matrix cracking. The second mesh is used with standard cohesive elements to model matrix/fibre debonding and with dG cohesive elements to model the matrix cracking.

As for the cohesive laws, the model developed by (Turon *et al*. 2006), which is a mixed-mode initially elastic bilinear cohesive law[1], is adopted. The simulations are carried out using a displacement control and the nonlinear equations are solved using a full standard Newton-Raphson method. Figure 5 shows the crack patterns obtained with the two approaches. It should be noted that modelling the matrix/fibre debonding requires a discontinuous approach (i.e. interface elements). If a continuous approach is to be used, then a thin layer around the fibres is needed (Nguyen *et al*. 2010). Finding the thickness of this thin layer is not trivial and its meshing can result in many elements. For this reason, interface elements were selected for modelling debonding.

As can be observed, similar crack patterns are obtained using both formulations. In terms of the load-displacement response (measured at the right edge), as shown in Fig. 6, there is a small discrepancy between the two approaches. The discontinuous response is more brittle than the continuous response, this difference is more pronounced at later stages of the failure process. This is expected since it is well known that continuous approaches cannot accurately capture the kinematics of strong geometrical discontinuities: in Fig. 5 true separation of the matrix phase can be obtained by the dG cohesive elements, whereas cracks are represented by widely stretched elements in the continuous approach. In the continuous approach, crack orientation is locally determined from the first principle stress at the integration point and is not restricted to a predefined orientation dictated by the element boundaries, as with cohesive interface elements. However, as noted in (Wells and Sluys, 2001), the use of a nonlocal stress field for retrieving the orientation of the crack can avoid stress-locking effects and the more ductile behaviour observed with the continuous approach could be a result of such locking. Further investigations are still needed.

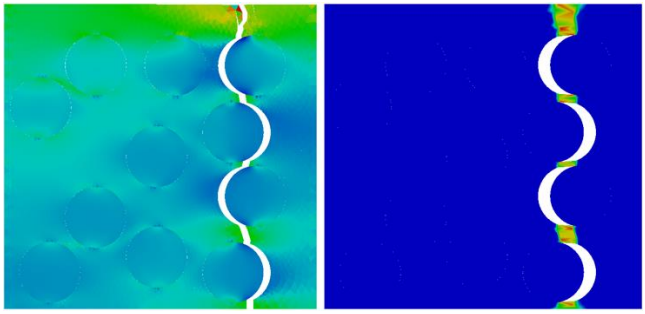

Figure 5: Crack patterns obtained with the discontinuous approach (left) and the combined continuous-discontinuous approach (right). Colour in the left denotes the stress field (σ_{xx}) and the colour in the right figure represents the damage field.

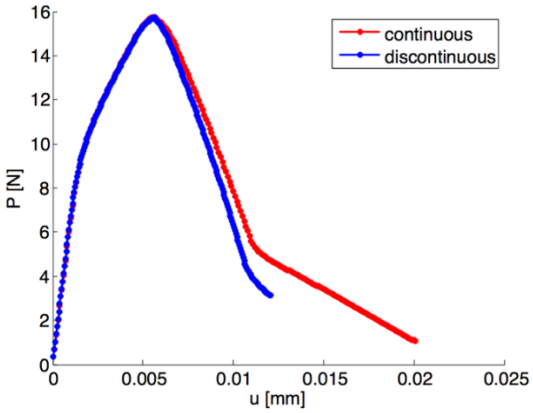

Figure 6: Response in terms of load-displacement curves. After an initial elastic regime, the debonding of the matrix/fibre interface resulted in a nonlinear hardening response with a reduced stiffness. At the peak, a dominant crack has propagated through the sample. A softening post-peak response is observed with the opening of this dominant crack.

[1] From this initially elastic cohesive law, an initially rigid cohesive law can be straightforwardly obtained by 'shifting'. Details can be found in (Nguyen 2014a).

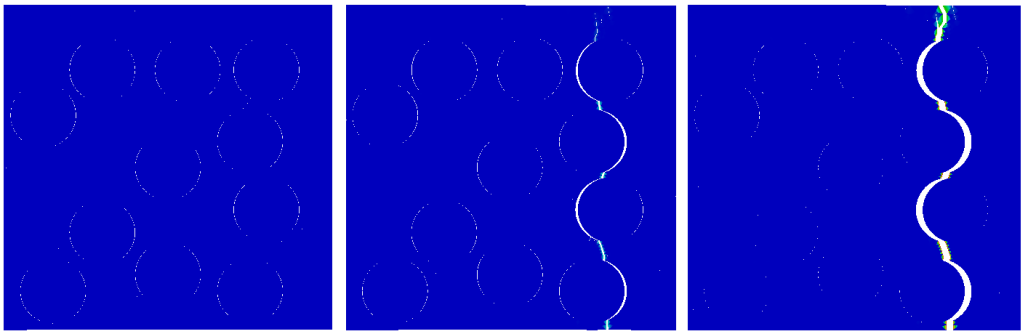

Figure 7: Cracking process of fibre-reinforced composite materials starts with interface debonding and the coalescence of the cracks into a dominant crack that runs through the sample.

The cracking process of fibre-reinforced composite materials, depicted in Fig. 7[2], starts with interface debonding (interfacial cracks) and then cracks tend to kink into the matrix, before finally coalescing into a dominant crack running through the sample. During later stages the other cracks close. This is qualitatively in good agreement with experimental observations by París *et al*. (2006), example shown in Fig. 8.

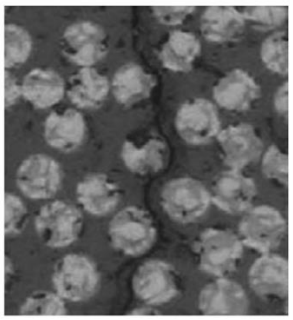

Figure 8: Failure of fibre-reinforced composite materials from experiments (París et al. 2006).

DISCUSSION AND CONCLUSIONS

In terms of computational cost and robustness, the continuous approach performs better than the discontinuous approach, thanks to its design that does not need any other element enrichments that may introduce additional degrees of freedom to the system. As a consequence, the simulation using the enriched constitutive model for the matrix cracking ran in about 360 seconds while the one using dG cohesive interface elements took about 2790 seconds, which is approximately 7 times slower. Note that this is not only due to a higher number of nodes (28999 nodes compared with 8525 nodes) but also due to the fact that the dG cohesive elements suffered from convergence issues with large increments, and hence small displacement increments (half of those used in the continuous approach) were needed. The discontinuous approach could, however, be optimised such that the interface elements would be introduced in the region of interest, thus reducing the number of degrees of freedom. Advanced solution-finding techniques such as non-iterative solution methods, see (Graça-e-Costa et al. 2012) and references therein, and viscous regularisation techniques can also be used to improve the robustness of the discontinuous analyses.

The proposed continuous approach however suffers from the well known stress locking issue when elements with multiple integration points are used. The use of linear triangle elements in the presented example does inhibits the stress locking issues due to the fact that only a single integration point in the element is used to capture the effect of a single crack within the element. In this sense, the orientation of the crack crossing the element is correctly represented by a single cohesive crack at the constitutive (or integration point) level (Fig. 1). However, when elements with multiple integration points (for example quadrilateral elements or quadratic triangle elements) are used, the elements contain several cohesive cracks, each one with its own orientation. This is a source of severe stress locking, as experienced by Nguyen *et al*. (2014) as the separation of the element into two parts cannot be guaranteed. Therefore, a simple resolution is to base the determination of crack orientations at all integration points in an element on a nonlocal stress field and enforce the same orientation for

[2] Animation of these simulations can be found at
https://www.youtube.com/watch?v=QPb_vqUlx7o&feature=youtu.be.

all cracks in the element. Alternatively transition from constitutive enrichment to element based enrichment (Dias-da-Costa *et al*., 2009, 2013) is also expected to alleviate this locking effect. These issues and corresponding resolutions will be addressed in our future work.

ABSTRACT

During the past decades, the use of concrete filled double skin steel tube (CFDST) members has gained much attention in the construction industry due to its beneficial properties such as light weight, high strength and excellent ductility. Many studies have discussed the behaviour of normal strength concrete filled CFDST member under a variety of load conditions; however, the knowledge of UHPC filled CFDST member is relatively lacking. This paper presents a numerical study on the ultra-high performance concrete filled double-skin tubes subjected to blast loading. Numerical models were developed in LS-DYNA and then validated against recently obtained experimental data.

KEYWORDS

Steel-fibre reinforced concrete; CFDST members; Blast loading; Numerical simulation

INTRODUCTION

Concrete-filled double skin steel tubes (CFDSTs), which are a newly developed steel-concrete composite structure, have the potential to be widely used in many engineering application ranging from columns of skyscrapers through to bridge piers. It involves the use of two concentrically placed steel tubes that is filled with concrete in between. This type of composite structure has advantages over other steel-concrete composite structures in the follow aspects: 1) the steel tubes can be directly used as permanent framework to the concrete filler; 2) The steel tubes provide confinement to the concrete filler while the infill of concrete can reduce the likelihood of local buckling of steel tubes (Zhao et al., 2010a).

A number of experimental investigations showed that, for CFDSTs under axial compression, the passive confining pressure induced by steel tubes can effectively enhance the overall axial capacity by up to 30%; also, its failure mode was reported to be primarily decided by the ratio between the steel tube thickness and cross-sectional diameter (Wei et al., 1995, Zhao et al., 2010b). Furthermore, efforts were also put into studying the behaviours of CFDSTs under transverse loading (Han et al., 2006), tensile loading (Li et al., 2014), torsional loading (Huang et al., 2013) as well as fire (Lu et al., 2010), and they all have evidenced that CFDSTs are able to yield excellent performance under a variety of loading conditions.

Although many studies have investigated the behaviours of CFDSTs under different circumstances, surprisingly little research has been on CFDSTs filled with ultra-high performance concrete (UHPC) considering its increasing popularity in the field of engineering. It is well known that, in comparison of normal strength concrete (NSC), UHPC is of higher strength and better ductility, enabling it to absorb a significant amount of energy before failure. Due to the presence of steel fibres, crack propagation within UHPC is also effectively delayed thus making it less prone to crushing or spalling damage when subjected to excessive loads. This property along with its superior strength and ductility together make UHPC an effective means of protecting important infrastructures against blast and impact loading as a result of increasing terrorist threats over the past years (Wu et al., 2009, Dragos et al., 2012).

This paper numerically investigates the behaviours of CFDSTs filled with UHPC under transverse static loading as well as blast loading. The numerical modelling was conducted by using finite element tool LS-DYNA. The concrete material models in LS-DYNA, which was primarily developed for normal strength concrete only, was modified accordingly to accommodate the behaviours of UHPC. The proposed numerical model was also validated using data from a number of recent tests conducted on UHPC members.

FINITE ELEMENT MODELLING

Material Constitutive Models

The numerical model was developed with 8-node solid elements with single point integration algorithm in LS-DYNA (Hallquist, 2007). There are several material models in LS-DYNA that can be used to simulate the behaviour of concrete structures (Wu et al., 2013, Wu et al., 2012). Among the available constitutive models, the K&C concrete model (also known as "MAT CONCRETE DAMAGE REL3") is most widely used for its ability to model the behaviours of concrete members under complex loading conditions, including situations involving active/passive confining stress and/or high strain rate effect, with efficiency and accuracy (Crawford et al., 2012, Shi et al., 2008). The behaviours of UHPC differ from NSC significantly due to steel fibres and different mixture, however all concrete constitutive models in LS-DYNA were developed particularly based on normal strength concrete. Therefore, the default K&C concrete model, or any other existing models for this matter, cannot be directly applied to model UHPC.

The K&C concrete model is defined by a number of material parameters, users can either manually input the values obtained from actual material tests or directly use the default values generated by the program itself. The mechanics behind this constitutive model along with each material input have been thoroughly explained by (Crawford et al., 2012, Mao et al., 2014), thus are not further discussed herein. In order to extend the existing K&C model to accommodate UHPC, the following material inputs were modified according to material tests that were conducted by the authors: w_{lz}, which governs the strain softening behaviour; ω, which governs the volume expansion (i.e. the confinement effect in this matter); λ and η, which governs the damage function and scale factor respectively. The key parameters for UHPC used in this research are listed in Table 1. It is evident from Figures 1 that, when validating against the four points bending test, good correlations were achieved between the numerical model and experiment result.

Table 1: Key parameters for K&C concrete model

Model parameter	Value
f'_c	170 MPa
f_t	20 MPa
Poisson's ratio	0.19
B1	1.6
B2	1.35
w_{lz}	6.35 mm
Omega	0.9 (circular section) 0.1 (square section)

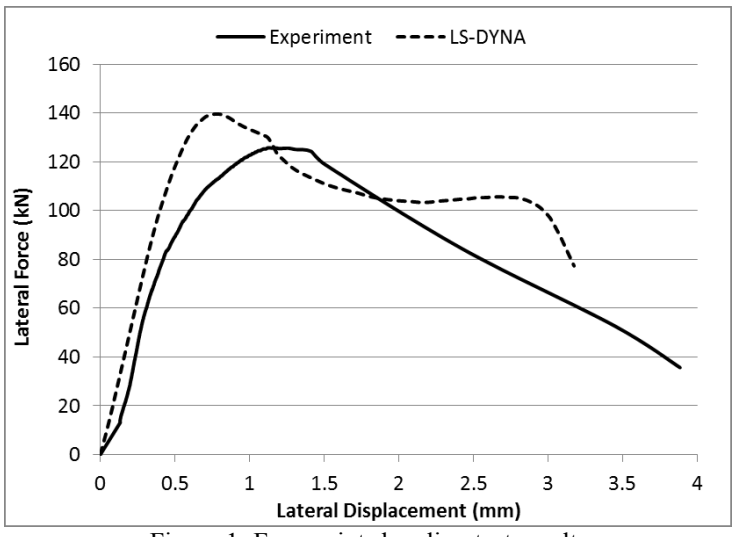

Figure 1: Four points bending test results

It is well known that under high strain rate impact, the strength of NSC increases significantly, by more than 100% for concrete in compression and by more than 600% for concrete in tension and the dynamic increase factor (DIF) for NSC can be calculated by the CEB Code (Béton, 1993, Malvar and Crawford, 1998). However,

limited research on the strain rate effect on UHPC was conducted. Ngo et al. (Ngo et al., 2007) developed DIF model for UHPC with compressive strength up to 160 MPa, it was reported that the strain rate effect on UHPC was significantly smaller than the CEB Code prediction. In the current research, the dynamic properties of UHPC were investigated by using Split Hopkinson's Pressure Bar (SHPB) test and the results are listed in Figure 2 (Su et al., 2015). It can be seen that, in comparison to NSC, the strain rate of UHPC did not have a significant effect until it reached 200/s for tension and 50/s for compression and the maximum DIF was also much smaller.

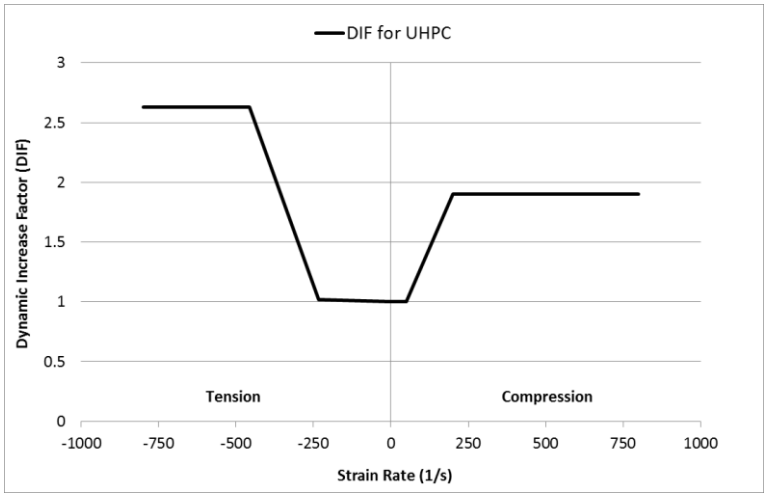

Figure 2: DIF for UHPC

Material model 24, namely MAT PIECEWISE LINEAR PLASTICITY, was used to represent the steel tubes. The actual stress-strain relationship obtained from tensile coupon test was inputted (as shown in Figure. 3) and the strain rate effect on the steel tube was incorporated by the Cowper and Symonds law which multiplies the yield stress by a factor given as:

$$DIF\ of\ steel = 1 + \left(\frac{\dot{\varepsilon}}{C}\right)^{\frac{1}{P}}$$

where $\dot{\varepsilon}$ = strain rate of steel.

C = 808 s^{-1} and P = 3.585 were used because good success was achieved by the authors in previous research by using this combination (Zhang et al., 2015).

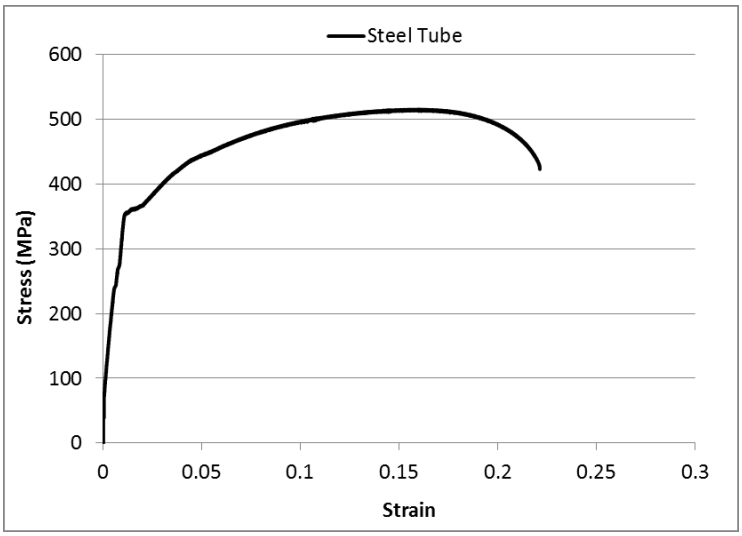

Figure 3: Stress-strain relationship for the steel tube

Three Points Bending Test

Three points bending tests were carried out to study the behaviours of UHPC filled CFDST specimens when subjected to static lateral load combined with axial load. As shown in Figure 4 that, the vertical hydraulic jack

was displacement-controlled and the horizontal hydraulic jack was force-controlled. The specimen was simply supported near both ends by rollers and the axial load was applied by the horizontal hydraulic jack to only one end of the specimen.

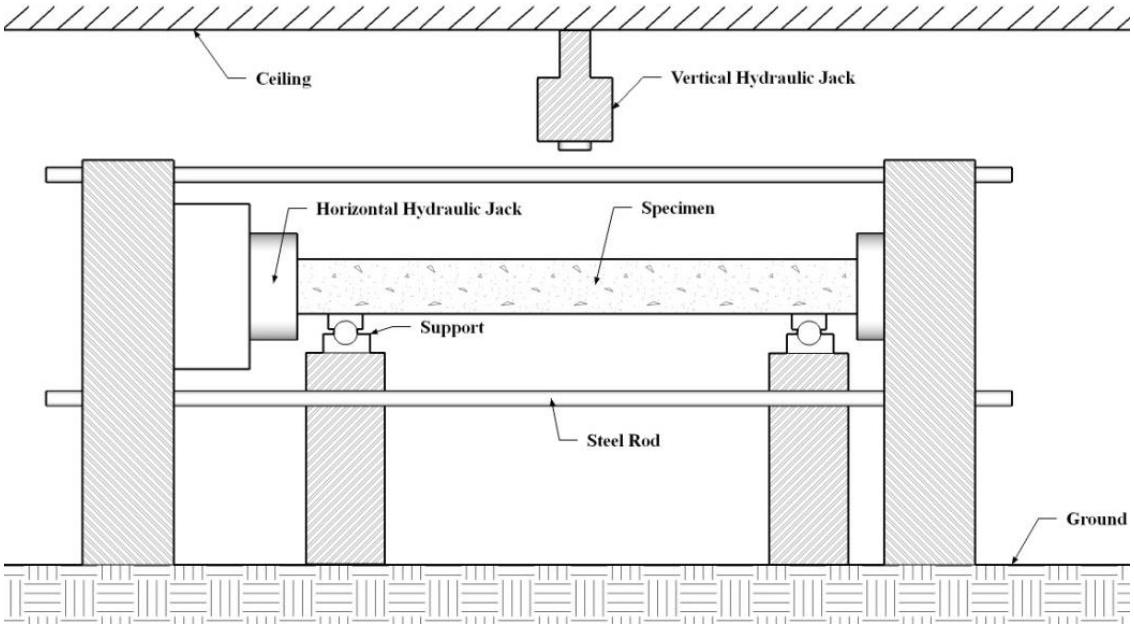

Figure 4: Three points bending test setup

Figure 5 depicts the meshing of the numerical models. In both models, the characteristic length of each element was approximately 7.5 mm. Mesh convergence study suggested that, by further refining the mesh, only minor improvement can be made, however with a great increase in the computation time.

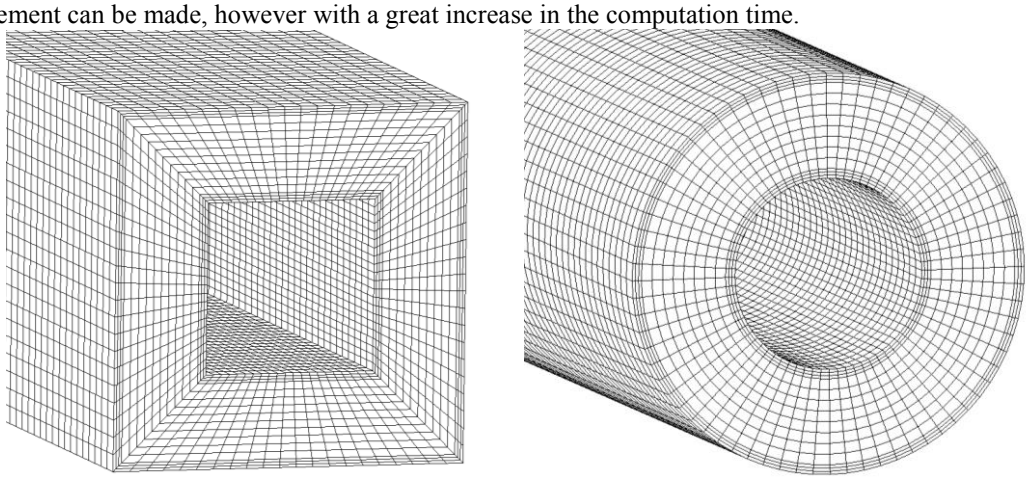

Figure 5: Meshing of numerical models

Table 2 and Figure 6 compare the numerical results to the experimental results of the three points bending test. It can be seen that, both circular and square models yielded less than 10% error in peak load and the overall behaviours also well agreed with the experimental observations. These results evidently confirmed the practicability and fidelity of numerically modelling UHPC filled CFDST specimens under static loads. Therefore, in the following section, the behaviours of UHPC filled CFDST specimens under blast loads were also numerically investigated in a similar manner.

Table 2: Summary of three points bending tests

Specimen No.	Outer dimensions (mm)	Inner dimensions (mm)	Tube thickness (mm)	Axial Load (kN)	Experimental Peak Load (kN)	LS-DYNA Peak Load (kN)	Error
C1	210	100	5	1000	484	440	-9.1%
S1	210	100	5	1000	660	700	+6.1%

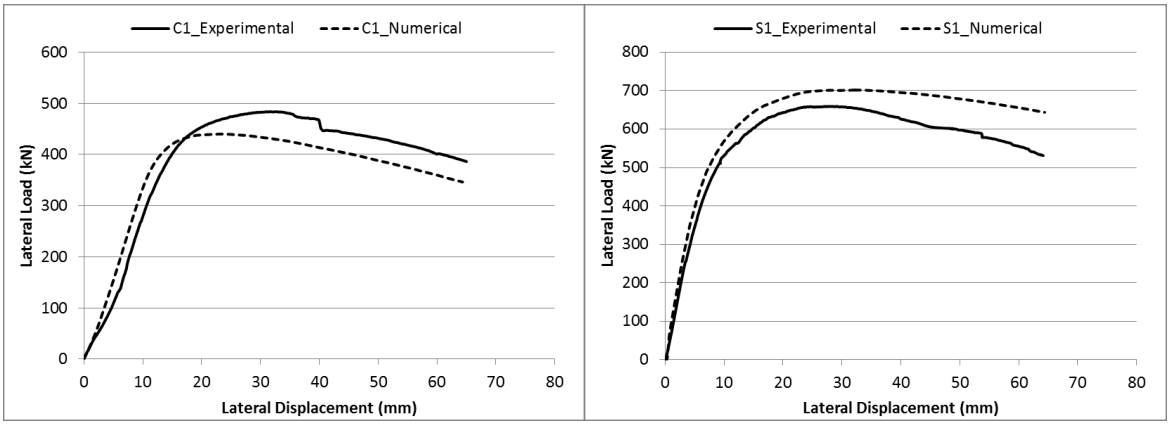

Figure 6: Force-displacement histories of three points bending tests

Blast Test

The experimental setup has been discussed by the authors in the previous study (Zhang et al., 2015), therefore only some important details are reiterated hereby. As shown in Figure 7, the test specimen was simply supported at both ends and bolts were used to provide an upward restraint against column rebound, thus making the effective span 2300 mm. The axial load was applied through a pneumatic jack at one end of the specimen only. Three LVDTs were installed along the specimen with 380 mm space between each other, in this paper, only the LVDT reading at the mid span is used for validation purpose.

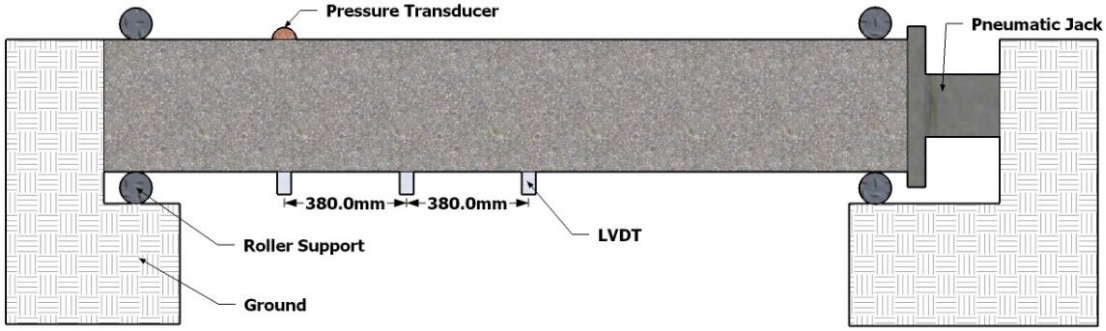

Figure 7: Blast test setup

It can be concluded from Table 3 and Figure 8 that, the proposed numerical model not only accurately predicted the maximum mid-span deflection, with or without axil load, the predicted period of oscillation also corresponded with the experimental curve very well. Although discrepancy was found in the residual deflection, the difference was still within the acceptable range considering the complexity and uncertainty associated with blast experiments.

Table 3: Summary of blast tests

Specimen No.	TNT Equivalent (Kg)	Axial Load (kN)	Standoff Distance (mm)	Mid-span Deflection (mm)		
				Measured	LS-DYNA	Error (%)
S2A	50	0	1500	48	43	-10%
S2B	50	1000	1500	40	37.1	-5%

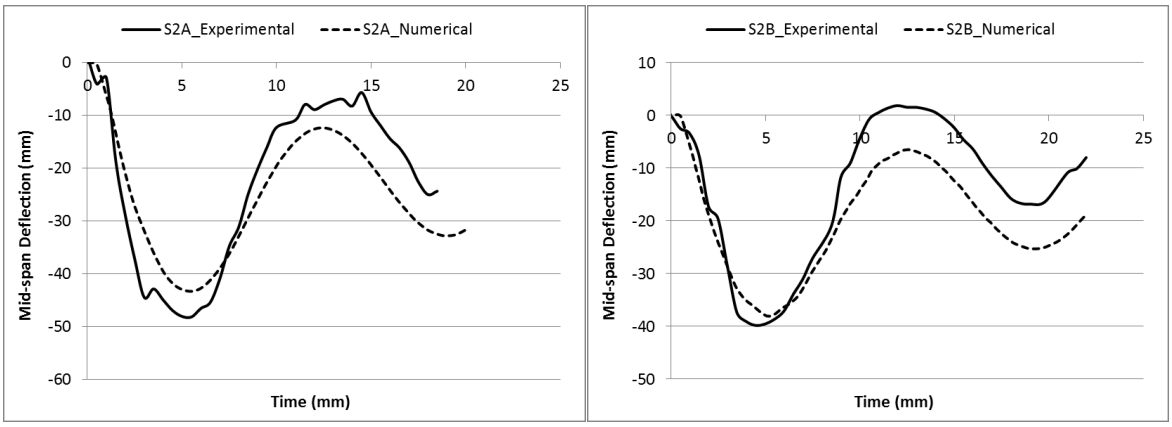

Figure 8: Displacement-time histories of blast tests

Effect of the axial load ratio

Figure 9 shows the effect of axial load level on structural responses of CFDST specimens. It can be seen that, specimens with a small axial load ratio (e.g. 0.16 & 0.32) can result in a smaller maximum and plastic deflection compared to the axial-load-free specimen while a larger axial load ratio (e.g. 0.48) can significantly amplify the deflection. The amplification of deflection is caused by the "P-Δ" effect: when a column deflects due to blast loads, the applied axial load causes a moment at each end which can further increases the deflection and as the deflection increases, the column reaches its plastic limit, transitioning from a gradual strength degradation to a rapid loss of strength due to buckling. Table 4 lists the results of the effect of axial load ratio.

Table 4: Effect of the axial load ratio

Axial load (kN)	Axial load ratio	Max. deflection (mm)	Plastic deflection (mm)
0	0	41.2	21.1
1000	0.16	37.1	14.5
2000	0.32	38.2	20
3000	0.48	44.4	33.6

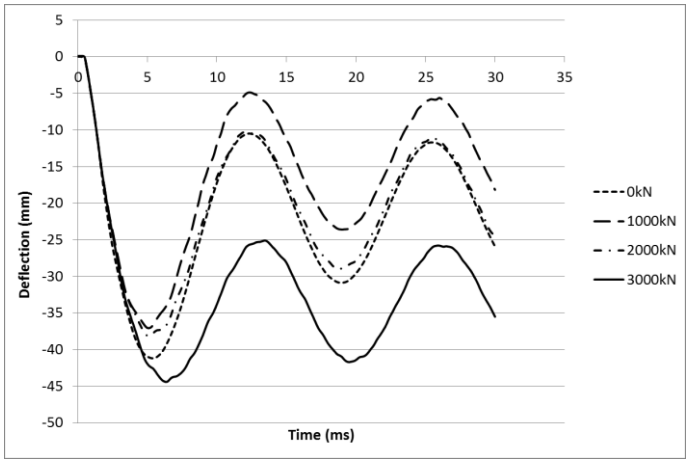

Figure 9: Effect of axial load ratio

Effect of the outer & inner tube thickness

It is suggested by Tables 5 & 6 and Figures 10 & 11 that, a thicker outer or inner steel tube can both reduce the deflection with having a thicker outer tube (for the same nominal steel ratio) being slightly more effective. Moreover, a thicker outer steel tube also shortens the column's natural period of oscillation while this is not observed on a thicker inner steel tube.

Table 5: Effect of the outer tube thickness

Outer steel tube thickness (mm)	Nominal steel ratio	Max. deflection (mm)	Plastic deflection (mm)
1.67	0.124	63	35.4
3.33	0.173	45.8	20.7
5	0.222	37.1	14.7

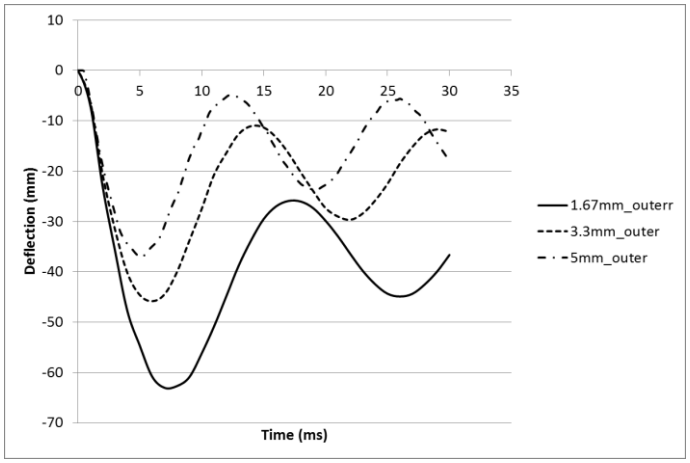

Figure 10: Effect of the outer tube thickness

Table 6: Effect of the inner tube thickness

Inner steel tube thickness (mm)	Nominal steel ratio	Max. deflection (mm)	Plastic deflection (mm)
1.67	0.173	46.7	24.7
3.33	0.198	39.6	17.5
5	0.222	37.1	14.7

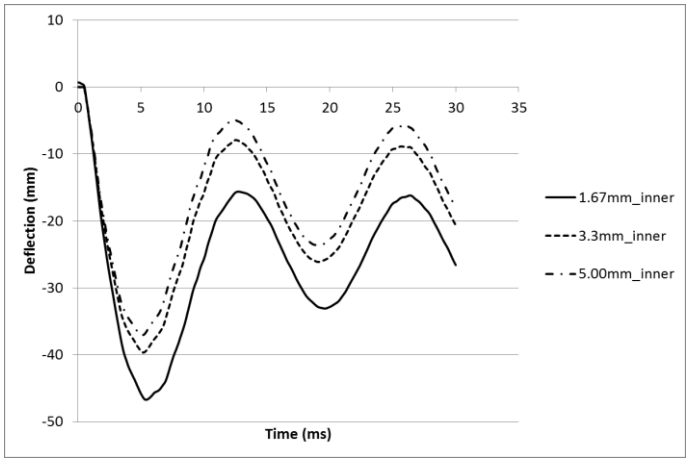

Figure 11: Effect of the inner tube thickness

CONCLUSIONS

This paper presents a means of numerically modelling ultra-high performance concrete filled steel tubes under static as well as blast loading. The following conclusions can be made based on the content of this current research:

1. The existing concrete constitutive model, namely K&C concrete model, can be extended to accommodate the behaviour of UHPC by modifying some of its key parameters.

2. Based on the validation studies presented in this paper, the proposed numerical models correlated well with the experimental results. For both static and dynamic loading cases, the errors yielded by the numerical models were kept well below 10%.
3. Compared to non-axially loaded columns, a small axial load can result in a smaller deflection while a large axial load level can significantly amplify the column deflection.
4. A thicker outer or inner steel tube can both reduce the deflection, however this effect is more noticeable on with a thicker outer tube rather than a thicker inner tube for the same nominal steel ratio.

ABSTRACT

The objective of this study is to provide insight into the expected slip demand in composite steel-concrete beams through numerical simulations. A wide parametric analysis is carried out evaluating the partial interaction performance of simply-supported beams designed considering a variety of floors, i.e. span length, slab thickness, shear connection strength, dead load to live load ratio and slab concrete strength. For each of these beams, the slip demand required to achieve the expected design capacity is evaluated. In this process, key parameters influencing the slip requirements are identified. These also include the construction sequence (propped or unpropped) and the shear connection distribution (uniform or non-uniform with different layouts).

KEYWORDS

Composite steel-concrete beams, nonlinear analysis, partial interaction, shear connection, slip demand, Eurocodes.

INTRODUCTION

The design of composite steel-concrete beams requires specific attention to the shear connection, fundamental for achieving an effective and efficient collaboration between the steel and reinforced concrete components. The design should include not only the evaluation of the required strength of the shear connection system but also its slip capacity compared to the slip demand at the ultimate limit state, e.g. (Oehlers et al, 2001; Oehlers and Sved, 1995). Many experimental and numerical studies have been performed on the behaviour of various connections systems aimed at assessing their capacity at the ultimate limit state. On the other hand, less attention has been devoted to establishing the expected slip demand at the ultimate limit state, despite the numerous research work that in the past decades involved the nonlinear analysis up to collapse of composite beams. In this context, the objective of this work is to review some results recently published in (Zona and Ranzi, 2014) involving a study on the expected slip demand in composite steel-concrete beams as used in building applications through numerical simulations. A wide parametric study is carried out evaluating the partial interaction performance of simply-supported beams designed considering a wide range of floor scenarios, i.e. varying span length, slab thickness, shear connection strength, dead load to live load ratio and slab concrete strength. For each of these beams, the slip demand required to achieve the expected design capacity is evaluated. In this process, key parameters influencing the slip requirements are identified. These also include the construction sequence (propped or unpropped) and the shear connection distribution (uniform or non-uniform with different layouts). The results are expected to provide an overview of the key parameters influencing the slip deformations of composite steel-concrete beams, useful in future modifications and refinements of current design recommendations regarding the required ductility of the shear connection, currently implemented as limitations of the minimum degree of shear connection.

EVALUATION OF THE SLIP OF THE SHEAR CONNECTION

Nonlinear structural model

The nonlinear behaviour up to collapse of steel-concrete composite beams is predicted in the parametric analysis of this study by using a material-nonlinear beam model with partial interaction where two Timoshenko beams in small deformation, one for the steel beam and one for the reinforced concrete slab, are coupled by an interface model with a continuously distributed bond, allowing interlayer slip and enforcing equal vertical deflection and rotation between the steel and concrete components (Zona and Ranzi, 2011). Numerical solutions are obtained through assemblies of a 16 degree of freedom (DOF) finite element, previously validated against a wide range

of experimental tests, shown to provide accurate predictions of the experimental behaviour up to collapse and good numerical efficiency in terms of convergence for both local and global response quantities (Zona and Ranzi, 2011). The adopted nonlinear constitutive models are described in details in reference (Zona and Ranzi, 2011). Considering its importance for the purpose of this study, the material model adopted for the shear connection constitutive model is briefly outlined. Its expression is based on the Ollgaard et al. (1971) relationship, which consists of an empirical equation providing good approximation of experimentally measured load-slip curves regardless of the failure mode, i.e. concrete failure in the region of the shear connectors, failure of steel studs, or combined failure of the two. This can be expressed as follows:

$$p_s = \mathrm{sgn}(\delta) \cdot p_{s,\max} \cdot \left(1 - e^{-\beta \cdot |\delta|}\right)^{\alpha} \tag{1}$$

where δ is the slip between the two components of the composite beam, p_s is the value of the shear force corresponding to δ, $p_{s,\max}$ is the connection shear strength (determined as the smaller value between the force causing failure in the concrete slab and the force causing failure of the connector), α and β are parameters controlling the stiffness (slope of the curve) for small and intermediate (of the order of β^{-1}) values of the slip, respectively, and sgn(…) is the sign function. The curve in Equation (1) tends asymptotically to the rigid-plastic model for α approaching zero. Since the stiffness at the origin is infinite when $\alpha < 1$, the exponential law is substituted with a linear segment (with stiffness k_a) from the origin to an assigned slip $\delta_a = 0.01$ mm (with $\delta_a << \beta^{-1}$) to avoid numerical problems. The shear connection is supposed to have infinite ductility to evaluate the maximum expected slip demand. The shape of the constitutive model for typical values (Zona and Ranzi, 2011), i.e. $\alpha = 0.588$ and $\beta = 1$ mm^{-1}, is depicted in Figure 1 (continuous line) together with other variations of the values for α and β considered in this study (dotted and dashed lines).

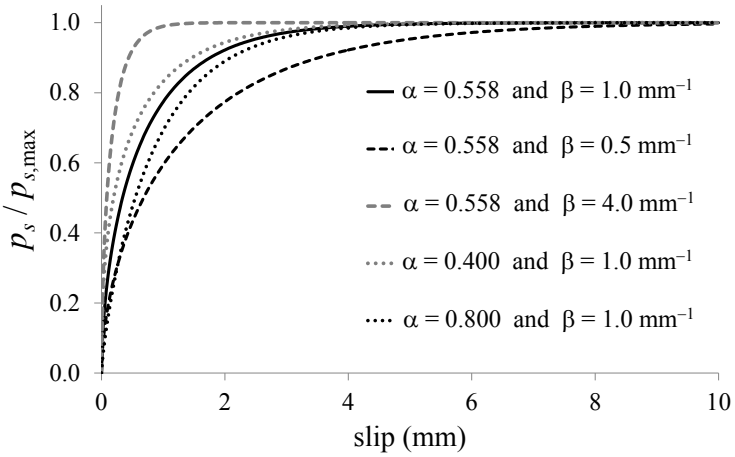

Figure 1 Shear connection constitutive law with adopted parameters.

Safety format for nonlinear analysis

In this study, given that the beams considered in the parametric analyses are designed according to Eurocode 4 Part 1 (Eurocode 4, 2004), the nonlinear analyses are performed according to the indications of the Eurocodes for the nonlinear analysis of composite steel-concrete structures, i.e. paragraph 5.4.3 of Eurocode 4 Part 1 and relevant parts there quoted, as illustrated in (Zona et al., 2010). According to these recommendations, the structural model must include all relevant failure modes and the nonlinear behaviour of the materials (concrete, steel of reinforcements, constructional steel, shear connectors) must be described by the mean values of their constitutive properties. The model should include the behaviour of the shear connection, necessary to realistically evaluate the shear connection slip demand, while it does not have to rely on concrete tensile strength as a primary load resisting mechanism. The nonlinear analysis is performed with loads increased from their serviceability values by incremental steps, so that the value of $\gamma_G G_k$ and $\gamma_Q Q_k$ are reached in the same step, where G_k and Q_k denote the characteristic values of permanent and variable actions, respectively, and γ_G and γ_Q are the partial factors for permanent and variable actions, respectively (in buildings γ_G =1.35 and γ_Q = 1.50 in locations where loads are unfavourable while γ_G = 1.00 and γ_Q = 0 where loads are favourable). From this point, the incremental loading process is continued until load q_{ud} is reached, at which, based on the Eurocode definition, one region of the structure reaches the ultimate strength or there is global failure of the structure. The safety verification is then carried out evaluating the following condition:

$$E(\gamma_G G_k + \gamma_Q Q_k) \leq R\left(\frac{q_{ud}}{\gamma_{Rd}\gamma_O}\right) \quad (1)$$

where $E(X)$ is the effect of action X, $R(Y)$ represents the resistance under load Y, $\gamma_O = 1.20$ is the overall safety factor, and $\gamma_{Rd} = 1.06$ is the partial factor for model uncertainty for resistance. An example of applications of this safety format to steel-concrete composite girders is presented in (Zona et al., 2010). Being this work dedicated to the analysis of the slip demand in the shear connection, attention is given on the left-hand-side of Equation (1), with particular focus at the slip behaviour exhibited at the design load levels, i.e. when subjected to the sum of $\gamma_G G_k$ and $\gamma_Q Q_k$.

PARAMETRIC ANALYSIS

Design parameters and assumptions

The parametric study carried out involves the analysis of 1680 composite steel-concrete beams with solid slabs designed in accordance with Eurocode 4 and obtained varying the design parameters reported in Table 1. The constructional steel is of grade S355 (nominal yield strength $f_y = 355$ N/mm^2 and nominal ultimate strength $f_u = 510$ N/mm^2), while the steel for the reinforcement is of grade B450 (characteristic yield strength $f_{yk} = 450$ N/mm^2 and characteristic ultimate strength $f_{tk} = 540$ N/mm^2). Three different concrete classes are considered, i.e. characteristic compressive strengths $f_{ck} = 25$, 32, and 40 N/mm^2. Two variable load conditions are investigated, one for a typical office building floor with $Q_k = 3.00$ kN/m^2 and one for a typical garage floor with $Q_k = 5.00$ kN/m^2. The floor system is formed by parallel composite beams, with span lengths L varying between 10 m and 40 m, whose spacing ranges between 2.50 and 3.50 m. Given that the shape of the steel beam influences the design of the composite cross-section, three steel section shapes with double-T profiles are considered (Figure 2): sections with equal flanges (referred to in the following as sections S1), sections with the area of the bottom flange equal to twice the one of the top flange (denoted as sections S2), and sections with bottom flange area three times the top flange area (referred to as sections S3). The reinforced concrete solid slab is assumed be cast in place and three constant thicknesses are used: 125 mm (referred to as C1 in the following), 175 mm (C2), and 225 mm (C3) with 0.5% geometric reinforcement ratio. The effective slab width is taken constant and equal to the smaller value between L/4 and the spacing between two adjacent beams in accordance with Eurocode 4 Paragraph 5.4.1.2.

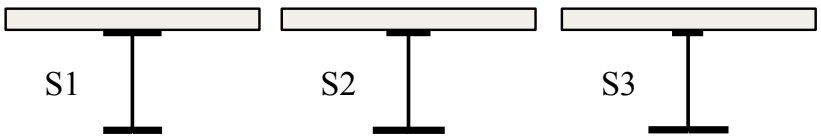

Figure 2 Cross-section shapes considered in the design.

Table 1 Considered design variables

Design parameter	Considered values
Span length L (m)	10, 15, 20, 25, 30, 35, 40
Girder spacing i (m)	2.50, 3.50
Slab thickness h_c (mm)	150, 175, 225
Variable load Q_k (kN/m^2)	3.00, 5.00
Ratio between bottom flange to top flange areas in the steel beam r	1, 2, 3
Degree of shear connection η	0.4, 0.7, 1.0
Shear connection distribution	uniform, non-uniform 2 tracts, non-uniform 3 tracts
Steel yield strength (N/mm^2)	355
Concrete compressive strength f_{ck} (N/mm^2)	25, 32, 40
Construction sequence	propped, unpropped

Three levels of shear connection are considered: one full shear connection design with connection degree 1.0 and two partial shear connection designs with connection degree 0.4 and 0.7. Three distributions of shear connection (equivalent in terms of total amount of shear connectors) are adopted for each beam and for each shear connection degree (Figure 3): uniform (U), piecewise uniform over two (N2) and three (N3) segments, where the latter two arrangements have stronger connections near the supports.

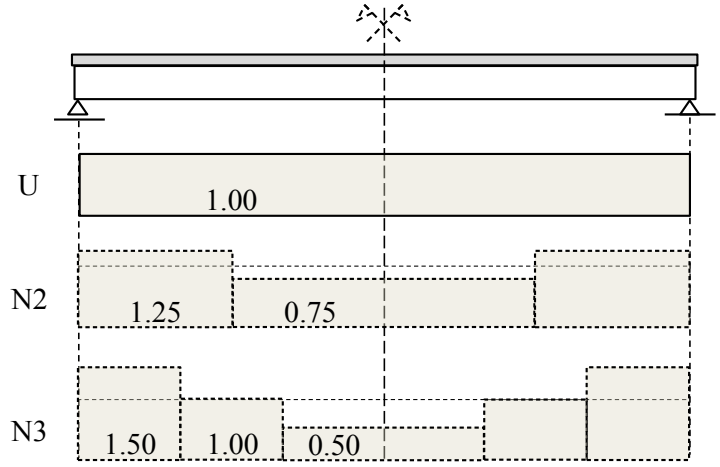

Figure 3 Shear connection distributions considered.

The construction sequences considered are propped (PR) and unpropped (UPR), resulting in different design procedures and relevant verifications. In propped construction, the design is based on the conditions: (i) the composite beam has to resist the entire permanent and variable load applied; (ii) the composite beam has to have adequate stiffness to limit vertical deflections to L/250 under service conditions (loads are G_k and Q_k for the short-term verification and G_k for the long-term verification in the hypothesis of 55% relative humidity). Given that the cross-sectional capacity is computed with plastic theory, only compact cross-sections are considered, i.e. sections of class 1 or class 2 according to Eurocode 4. In unpropped construction, the design is based on the conditions: (i) the steel beam has to carry the reinforced concrete slab when cast in place; (ii) the steel beam has to have adequate stiffness to limit deflections to L/250 during casting; (iii) the composite beams has to carry the entire subsequent load; (iv) the composite beams has to have sufficient stiffness to limit deflections to L/250 including the deflection already developed in the first construction stage. In the case of unpropped construction, both the resistance of the steel beam and the resistance of the composite beams are computed with plastic theory, thus, attention is given to verify that in both situations the cross-sections are compact (class 1 or class 2).

The designed beams are labelled with the first part indicating propped or unpropped construction (PR or UPR), followed by the indication of the shear connection degree (10, 07 and 04 for $\eta = 1.0$, 0.7, and 0.4, respectively), the shear connection distribution (U, N2, or N3), the slab thickness (C1, C2 or C3), the steel section shape (S1, S2 or S3), the design load entity (E1 and E2 for office floor with beam spacing of 2.50 and 3.50 m, respectively, E3 and E4 for garage floor with beam spacing of 2.50 and 3.50 m, respectively). The concrete strength is f_{ck} = 25 N/mm^2 unless otherwise noted.

Results

Given the space limitation for this paper, results for 84 of the 1680 beams considered in the parametric analysis are presented and discussed. For a complete report of the outcomes of the illustrated parametric study the interested readers are referred to (Zona and Ranzi, 2014).

The maximum slip demand when the designed beams reach the design load ($1.3G_k + 1.5Q_k$) is plotted in Figure 4 for the of full shear connection designs (degree of shear connection $\eta = 1.0$) with propped (left-hand side diagrams) and unpropped (right-hand side diagrams) construction sequences. Diagrams in the first row are relevant to the uniform (U) shear connection distribution, diagrams in the second and third rows to the non-uniform N2 and N3 shear connection distributions, respectively. Each single diagram reports the maximum slip demand calculated for 84 composite beams: 12 beams for a given span length having three steel cross-section shapes (S1, S2, and S3) and four design load conditions (E1, E2, E3, and E4). Three different marks are used to indicated the slip demand for the three cross-section shapes, i.e., circle for S1, x-cross for S2, and triangle for S3. The load conditions are not marked in the diagrams in order to avoid too many symbols, nevertheless, the four design loads can be identified knowing that the slip demand increases moving from E1 to E4.

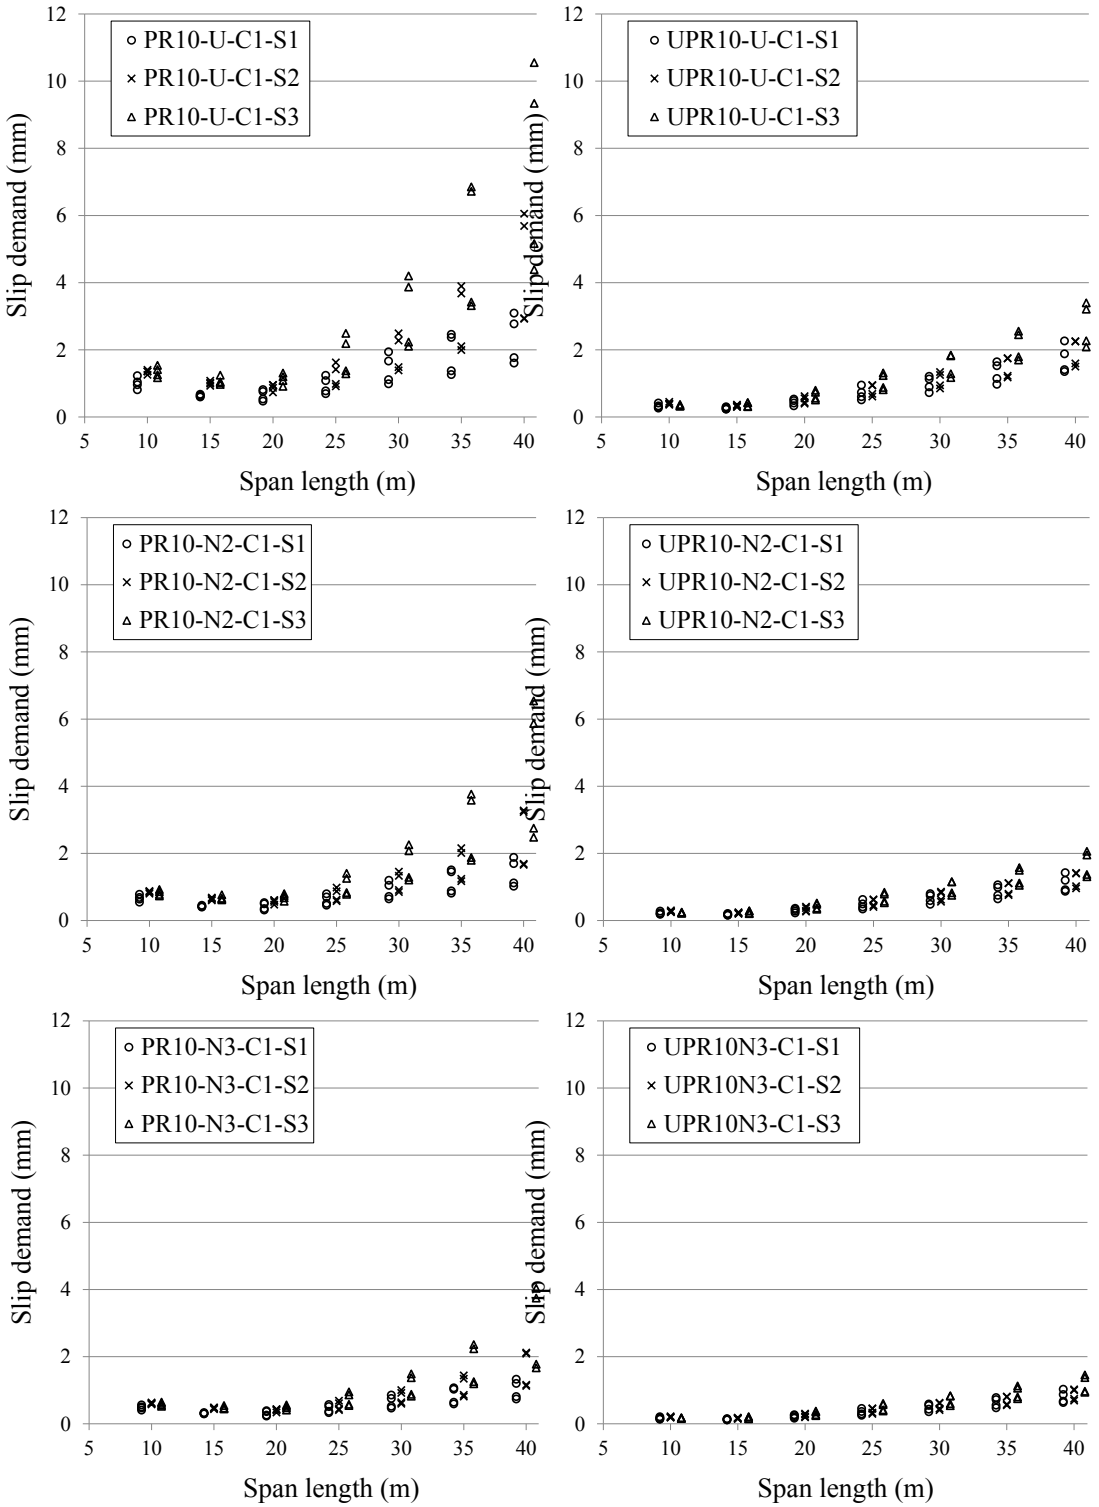

Figure 4 Slip demand at design load for propped (left-hand side) and unpropped (right-hand side) beams with full shear connection.

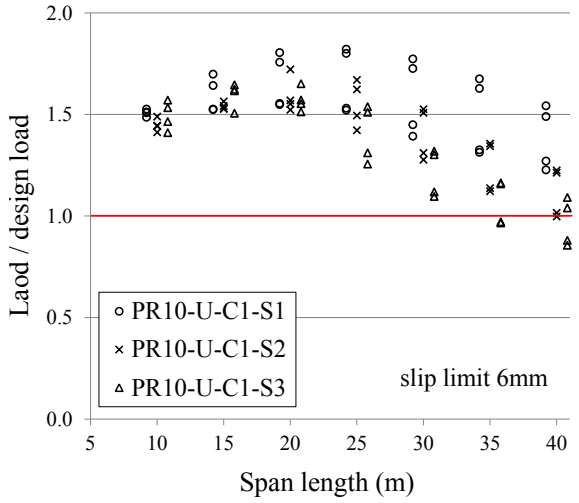
It is observed that: (i) the slip demand steadily increases with the span for lengths larger than 20 m; (ii) the ratio between the top and bottom flange of the steel cross-section has a significant influence on the slip demand (slip increases from shape S1 to shape S2 and further to S3) and this effect is more important for longer spans, particularly for propped construction; (iii) the construction sequence has a major influence on the slip demand with the propped design (PR) demanding slips about three times the slips in the corresponding unpropped design (UPR) cases; (iv) the shear connection non-uniform distributions (N2 and even more N3) have a substantial effect on the reduction of the maximum slip when compared to the uniform distribution (U).

The first three observations can be explained considering that in composite beams the slip demand increases: (a) when the distance between the shear connection and the plastic neutral axis of the composite cross-section grows and all other parameters are fixed; (b) when the span-to depth ratio of the composite beam is incremented and all other parameters are fixed. When the span length grows, the plastic neutral axis lowers its position given that the thickness of the concrete slab is kept constant while the steel beam necessarily increases its cross-section. Hence, a longer span length has a larger distance between the shear connection and the neutral axis, that in turn causes the observed increment in the slip demand. The effect of the shape of the steel section has a similar interpretation, as a non-symmetric cross-section with bigger bottom flange allows a higher span-to-depth ratio (causing increased slip demand) and simultaneously lowers the neutral axis (also causing increased slip demand).

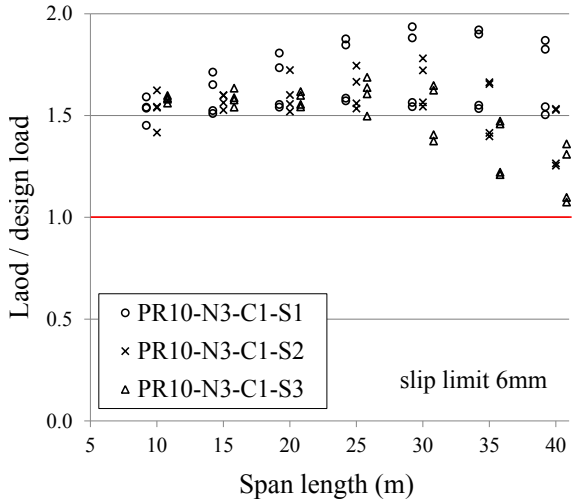
Regarding the differences in slip demand observed between propped and unpropped construction, they are inherent to the design assumptions. Given that, in the unpropped construction, the steel beam has to resist alone the applied gravitational loads during slab casting, a stronger and stiffer steel beam is adopted, resulting in a smaller span-to-depth ratio (causing reduced slip demand) that has more important effects than the lower neutral axis (causing higher slip demand). The differences in slip demand between propped and unpropped construction are also incremented, although with a minor contribution, by the fact that, in propped construction, the beam self-weight is carried by the composite section, therefore producing slip, while this is not the case in unpropped construction, where slip starts after the concrete slab has hardened, thus, the composite beam self-weight does not contribute to the attained slip.

The variation in slip demand for the different shear connections distributions (U, N2, N3) can be explained given that the amount of required shear force redistribution along the beam span is reduced when the arrangement of the shear connectors approaches the shear distribution proportional to the shear force, as can be seen, for example, from the shear force distributions produced by arrangements U, N2 and N3.

The influence of the magnitude of the variable load assumed in the design appears generally small but not negligible for beams with full shear connection and span lengths less than 25 m. Slightly higher slip demands are required with the garage floor loads (E4 and E3) when compared to the cases subjected to office building floor loads (E2 and E1). The differences between solutions having the same span length, but designed with different variable loads, become more pronounced for span lengths equal or larger than 25 m and for lower degrees of the shear connection, with constantly higher slip demands for higher variable loads, i.e. moving from E1 to E4. This effect can be explained as a higher design load, when all other design parameters are fixed (i.e. concrete slab, steel beam shape, materials, shear connection degree, construction sequence), results in generally stronger steel cross-sections, obtained in the parametric study by increasing the top and bottom flange areas while keeping their ratio constant as well as maintaining the overall steel section height unmodified. Such an increase in flange area leads to a lowering of the neutral axis which in turn causes the increase in slip demand.
The results presented in Figure 4 show the slip demand at the design load (1.3Gk + 1.5Qk) under the assumption of unlimited slip capacity (infinite ductility) of the shear connection. In Figure 5 the magnitude of the load obtained limiting the maximum slip to 6 mm to highlight the effect of the actually limited shear connection slip capacity on the overall load carrying capacity of composite beams. If the maximum slip attained during the nonlinear analysis is below the assigned limit, then the beam load carrying capacity is not affected by the shear connection limitation. On the other hand, if the slip reaches the assigned limit value, the nonlinear analysis is terminated and the corresponding load level is taken as the carrying capacity for the composite beam. Results are given for the case of propped construction shown to be the most critical cases in terms of slip demand. It is observed that for spans longer that 30 m the beams with section S3 and uniform shear connection distribution do not reach the design load when the shear connection slip is limited to 6 mm. As already noted, more results and details can be found in reference (Zona and Ranzi, 2014).



(a) slip limited to 6 mm



(b) slip limited to 8 mm

Figure 5 Maximum carried load for shear connection slip limited to 6 mm and 8 mm for propped beams with full shear connection.

CONCLUSIONS

In this work an extensive parametric study involving simply-supported composite steel-concrete beams with solid slabs designed according to Eurocode 4 was conducted to evaluate the influence of various parameters on the predicted slip demand in the shear connection at the ultimate limit state. The presented results show that, for a given shear connection degree, three design parameters are the most influential on the slip demand in the shear connection: construction sequence (propped construction results in slip demand always larger than unpropped construction); span length (longer spans are the most critical in terms of slip demand); steel section shape (sections with equal flanges are less critical). In addition, the shear connection distribution can have an important effect as the non-uniform shear connection distributions with more connectors near the supports are effective in limiting the slip demand mostly for the full shear connection designs. While the span length and the steel section shape are considered in current European design codes, no mention is explicitly made to the construction sequence and to the distribution of shear connectors.

ABSTRACT

The calcium leaching of hydrated cement system when in contact with external solution has long been recognised as a critical problem for cementitious materials, and it can result in degradations on mechanical properties. In this research, an integrated numerical scheme is developed to simulate the degradation of Young's modulus of cementitious materials under leaching. Firstly, a cement hydration module is proposed and employed to predict the characteristics of the hydrated cement including pore structures, contents of hydrates and concentrations of initial interstitial solution. Then the hydration data obtained are incorporated into a coupled reactive diffusion procedure to evaluate the change of hydrate contents under the prescribed boundary conditions. Finally, a micromechanical approach, Mori-Tanaka method, is employed to evaluate the degradation of Young's modulus of the cementitious material. The accelerated leaching tests in 6M (6 mol/L) of ammonium nitrate solution, which became popular recently in view of the extremely slow degradation kinetics of leaching in deionized water, are studied numerically in this study. The developed numerical scheme is employed to model two experiments, and the good agreements between the numerical results and the experimental measurements in terms of hydration outputs, leaching profiles and Young's moduli, demonstrate the applicability and accuracy of the proposed numerical scheme.

INTRODUCTION

As a very reactive media, the physical and mechanical properties of cementitious materials may be subjected to degradation from the external environment (Baur et al. 2004). Leaching is the most common reason for degradation as cementitious materials are often in contact with the actions of rain or flowing water (Carde et al. 1997). The external water solutions with low ionic concentrations readily generate concentration gradient which results in the diffusion of ions in the pore solution of cementitious materials. The ionic transport disturbs the original equilibriums between cement hydrates and the interstitial solution, leading to dissolution/precipitation of cement hydrates and thus the leaching of multiple ions. The alteration of hydrate compositions contributes to changes of pore structure and material integrity. The collective influences would finally degrade the mechanical properties such as elastic moduli and strength.

A large number of experiments were conducted to investigate the degradation of cementitious material by leaching. The extremely low degradation kinetics of natural leaching have been widely recognized as the main factor that has hindered this study (Wan et al. 2013). It was reported that the leaching front of concrete submerged in field water for 100 years was only about 5 to 10 mm (Alonso et al. 2006). The widely adopted laboratory leaching by deionized water possesses faster leaching kinetics in compared with field water (Moranville et al. 2004). However, the general leaching speed of deionized water was still too slow to generate considerably degraded specimens for further mechanical testing. Recently, an increasing number of laboratory tests applied the accelerated leaching protocol by using 6M (6 mol/L) ammonium nitrate solution (Gallé et al. 2004, Moranville et al. 2004). Thanks to this testing scheme, the leaching kinetics could be accelerated at two orders of magnitude while the tests still generated the same end products (Thomas et al. 2004). These features make the accelerated leaching a very attractive method to experimentally study the calcium leaching influence on the mechanical properties.

In view of the increasing popularity of accelerated leaching tests using 6M of ammonium nitrate solution, numerical simulations were also performed by many researchers (Gérard et al. 2002, Wan et al. 2013, Wan et al. 2013). In these reported numerical studies, a simplified method, i.e. the solid-liquid equilibrium curve, was generally applied to simulate the calcium leaching under the action of 6M of ammonium nitrate. The mechanism

of this method is to force the equilibrium between calcium in solid hydrate and interstitial solution to follow the experimentally defined curve. This method has restricted applications as the solid-liquid equilibrium curve has to be predefined experimentally. Therefore, the method could become invalid if there were a minor change of the boundary conditions, such as using 5M of ammonium nitrate solution instead of 6M. Besides, the accuracy of this method dropped significantly when simulating those tests under long-term degradation or the specimens prepared with different water-to-cement ratios (Gérard et al. 2002, Wan et al. 2013). In addition, most of the published studies focused on the understanding and the modelling of chemical degradation and mechanical degradation separately. Few researches studied the integrated problem including simulations of both leaching and mechanical properties. The difficulty majorly lies in obtaining appropriate data for mechanical studies from the simplified method of solid-liquid equilibrium curve. Usually, the detailed cement compositions are required for the application of micromechanical method for the modelling of elastic properties, such as self-consistent method and Mori-Tanaka method (Hill 1965, Mori et al. 1973). However, the reported numerical research on the simulation of chemical degradation by using solid-liquid equilibrium curve could only generate total content of calcium in the hydrates and the pore solutions. In terms of studies on mechanical properties, most of the published researches assumed that the hydrated cement was composed of calcium-silicate-hydrate (C-S-H) as matrix while portlandite and capillary pores as inclusions (Bernard et al. 2003, Constantinides et al. 2004). This assumption ignored the contributions from other hydrates, which generated predictions with poor accuracy under long-term and severe degradations.

In this study, an integrated numerical scheme is developed to simulate the degradation of Young's modulus of hydrated cement paste subjected to the accelerated leaching in 6M ammonium nitrate solution. Firstly, a cement hydration module is proposed and employed to predict the characteristics of the hydrated cement including pore structures, contents of hydrates and concentrations of initial interstitial solution. Then the hydration data obtained are incorporated into the coupled diffusion, chemical reaction and damage evaluation modules to evaluate the changes of hydrate contents under the prescribed boundary conditions. Finite element method is adopted to solve the system of PDEs resulted from the multi-ionic diffusion problem. Finally, the micromechanical approach, Mori-Tanaka method, is employed to evaluate the degradation of Young's modulus of the cementitious material. An overview of the proposed numerical scheme, which is module-oriented, is introduced firstly. Then the detailed methodologies adopted in each module are illustrated. The proposed numerical scheme is validated through simulating laboratory experiments. The advantages of the proposed numerical scheme and research findings are summarised finally.

NUMERICAL FRAMEWORK

The proposed numerical scheme consists of five modules, i.e. the hydration module, the ionic diffusion module, the chemical reaction module, the damage evaluation module and the micromechanical module. An overview of the proposed numerical framework is shown in Figure 1.

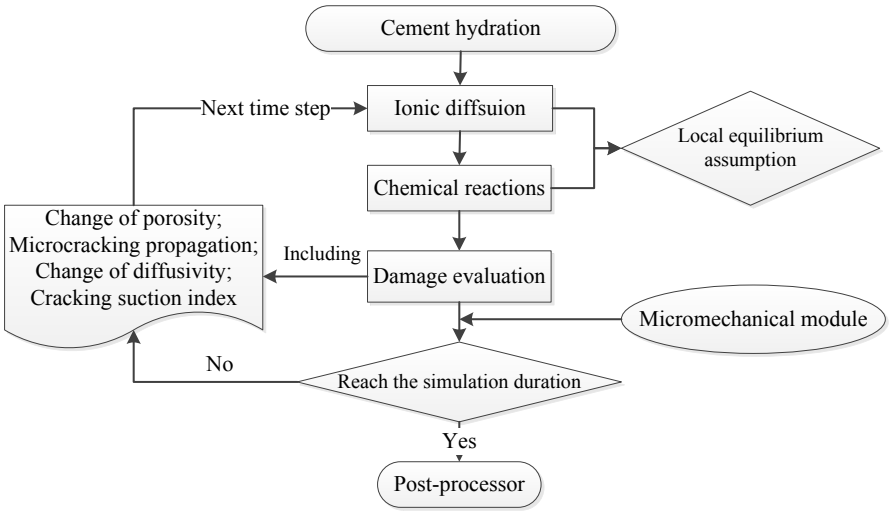

Figure 1 Overview of the proposed numerical framework

Most of the reported experiments only provided basic information for test specimens such as cement type, water-to-cement ratio, curing duration and so on. The information such as initial hydrate compositions, pore structures, ionic concentration of interstitial solution, which is required in the numerical analysis, was usually not provided. Thus in the first step, a hydration module is employed to generate the required data. Then, the ionic diffusion

module and the chemical reaction module are run sequentially through operator splitting approach (OSA) (Kaluarachchi et al. 1995). According to OSA, the simultaneous diffusion-reaction problem is able to be decoupled and modelled separately. The validity of using OSA for the present research was proven based on the local equilibrium assumption (LEA) (MacQuarrie et al. 2005). Through the application of OSA, the degrees of freedom are therefore classified into two categories: primary and secondary degrees of freedom. All the diffusive ions and the diffusion-related variables are listed as primary degrees of freedom while the cement hydration products subjected to chemical equilibriums are stored as secondary degrees of freedom. By doing so, the computational time can be reduced significantly. At the end of each time step, the damages and the corresponding influences on the diffusivities are evaluated in the damage evaluation module by using the output from chemical reaction module and updated for next time step. Moreover, the standalone micromechanical module can readily be coupled into the main procedures to evaluate the elastic properties of cementitious material at any degradation duration.

METHODOLOGIES

Hydration Module

To generate a comprehensive set of input data for the subsequent reactive-diffusion analysis, a hydration module is applied to characterize the hydrated cement specimens including degree of hydration (DOH), capillary porosity, gel porosity, hydrate contents, ionic concentration of initial pore solution and pH value.

The prediction of DOH follows two sequential steps. First, the maximum DOH under the given conditions is calculated from Eq. 1-4 according to the work by Lin et al. (Lin et al. 2009), which majorly depends on the Blaine fineness of cement clinker, water-to-cement ratio and curing temperature. Then, the overall DOH is obtained by calculating the weighted average of DOH of the four major cement compounds including C3S, C2S, C3A and C4AF. The calculation of DOH of each cement compound follows the Avrami equation (Dalziel et al. 1986), see Eq. 5-7. The model is modified in the present research as shown in Eq. 5 by taking the maximum DOH (Lin et al. 2009) into consideration.

$$\beta_1 = \frac{1.0}{9.33\left(\frac{Blaine}{100}\right)^{-2.82}+0.38},\quad \beta_1(Blaine<270)=\beta_1(Blaine=270) \tag{1}$$

$$\beta_2 = \frac{Blaine-220}{147.78+1.656(Blaine-220)},\quad \beta_2(Blaine<270)=\beta_2(Blaine=270) \tag{2}$$

$$\alpha_{u,theoretical} = \frac{\beta_1\cdot\frac{w}{c}}{\beta_2+\frac{w}{c}}e^{\left[-0.00003(T-293)^2\cdot \mathrm{SGN}(T-293)\right]} \tag{3}$$

$$\alpha_u = \min\left(1,\ \frac{w/c}{0.38},\ \alpha_{u,theoretical}\right) \tag{4}$$

$$\alpha_i = \alpha_u - e^{\left[-a_i(t-b_i)^{c_i}\right]} \tag{5}$$

$$weight(i) = \frac{C_{compound(i)}}{\sum C_{compound(i)}} \tag{6}$$

$$\alpha_{ave} = \sum_{i=1}^{n} weight(i)\cdot\alpha_i \tag{7}$$

where $Blaine$ is the Blaine fineness (m^2/kg), w/c is the water-to-cement ratio, β_1 and β_2 are two coefficient calculated based on Blaine fineness, SGN is the sign function, and $\alpha_{u,theoretical}$ is the theoretical maximum DOH calculated based on clinker fineness, water-to-cement ratio and curing temperature. In terms of Avrami equation (Eq. 5), a_i, b_i and c_i are the experimentally defined parameters specified for the ith compound, which can be found in the literature (Jennings et al. 1994).

Other hydration data, such as capillary porosity, gel porosity and tortuosity for the pore structure can be easily determined by using the well-developed analytical models (Powers 1958, Garboczi et al. 1992). In addition, the hydrate contents and the initial ionic concentration of pore solution can also be determined from the well-established theories (Taylor 1987, Taylor 1997).

Ionic Diffusion Module

Generally, the interstitial solutions of hydrated cementitious materials are highly concentrated with multiple kinds of ions. The ionic diffusion of such a solution in the gradually degraded hydrated cement system has been recently studied by the authors (Yu et al. 2015). A modified Poisson-Nernst-Planck model (MPNP) model as shown in Eq. 8 was proposed. In the MPNP model, an additional term denoted as, cracking suction, which accounts for the acceleration effect on diffusion and was caused by newly-formed unsaturated cracks, was added to the original PNP model (Samson et al. 2005). The detailed procedures for evaluating the cracking suction effect can be found in the reference (Yu et al. 2015).

$$\frac{\partial(wc_i)}{\partial t} - \frac{\partial}{\partial x}\left(\underbrace{wD_i\frac{\partial c_i}{\partial x}}_{Diffusion} + \underbrace{w\frac{D_i z_i F}{RT}c_i\frac{\partial \psi}{\partial x}}_{\substack{Electrical \\ coupling}} + \underbrace{wD_i c_i\frac{\partial \ln\gamma_i}{\partial x}}_{\substack{Chemical \\ activity}} + \underbrace{D_w c_i\frac{\partial w}{\partial x}}_{Advection} + \underbrace{wD_i c_i\frac{\partial \mathrm{CSI}}{\partial x}}_{\substack{Cracking \\ suction}} \right) = 0 \tag{8}$$

where w is the volumetric water content ($\mathrm{m^3/m^3}$), c_i is the ionic concentration of the ith ion ($\mathrm{mmol/L}$), D_i is the diffusion coefficient of the ith ion ($\mathrm{m^2/s}$), z_i is the valence number of the ith ion (-), F is the Faraday constant (96488.46 $\mathrm{C/mol}$), R is the ideal gas constant (8.4143 $\mathrm{CV/K/mol}$), T is the thermodynamic temperature (K), ψ is the electrical potential (V), γ_i is the chemical activity coefficient of the ith ion calculated using modified Davies' relationship (-) (Samson et al. 1999), D_w is the moisture diffusivity ($\mathrm{m^2/s}$), ϵ is the permittivity of the medium (7.08×10^{-10} $\mathrm{C/V/m^2}$ for room temperature), CSI is the cracking suction index calculated at every cracked location, which is updated at each time step according to the saturation level of the cracks.

Chemical Reaction Module

As cement is a very reactive material, the change of ionic concentration by diffusion disturbs the equilibriums between the cement hydrates and the interstitial solution, which leads to progressive dissolution/precipitation of hydrates. The simultaneous diffusion-reaction problem is modelled sequentially in this study using operator splitting approach (OSA) on the basis of local equilibrium assumption (LEA). The validity of this approach has been proven in reference (Samson et al. 2007). The chemical reactions are solved through the chemical equilibrium relationship expressed as Eq. 9.

$$K_m = \prod_{i=1}^{N} c_i^{\nu_{mi}} \gamma_i^{\nu_{mi}} \quad m = 1, \ldots, M \tag{9}$$

where K_m is solubility constant of the mth hydrate which can be easily found in the chemical handbook (Lide 2004), υ_{mi} is the stoichiometric coefficient of the ith ion on the mth hydrate. If the number of hydrates considered in equilibrium is M, then M of Eq. 6 should be solved simultaneously at every node when finite element method is applied.

In terms of the complex decalcification of the C-S-H (Chen et al. 2004), the major difficulty in the simulation lies in modelling its incongruent chemical behaviour (Berner 1988). C-S-H is usually considered to be amorphous which contains several hydration products that follow their own stoichiometry individually. The key parameter characterizing the C-S-H is the calcium-to-silicate ratio (Ca/Si). The C-S-H is modelled as two solid phases in equilibrium in this study, including Jennite ($1.7\mathrm{CaO \cdot SiO_2 \cdot 2.1H_2O}$) with a Ca/Si ratio of 1.7 and calcium metasilicate ($\mathrm{CaH_2SiO_4}$) with a Ca/Si ratio of 1.0 to represent decrease of Ca/Si ratio in C-S-H during decalcification (Yu et al. 2015).

Damage Evaluation Module

Three major types of damages resulted from chemical reactions are evaluated in this module i.e. change of porosity, cracking propagation and cracking suction effect. First, the change of porosity can be easily calculated through hydrate contents acquired in the previous chemical reaction module. The corresponding influences on ionic and moisture diffusivity are then evaluated according to the work by Samson et al. (Samson et al. 2007). The cracking propagation is calculated on the basis of the current porosity through the method proposed in Sarkar et al. (Sarkar et al. 2010). Finally, the cracking suction effect is evaluated using the model recently developed by the authors (Yu et al. 2015).

Micromechanical Module

The micromechanical module proposed in this study is a standalone procedure which can be incorporated with the previous modules at any given degradation duration. The methods applied are the well-developed analytical methods such as dilute-approximation method (DAM) (Eshelby 1957), self-consistent method (SCM) (Hill 1965), and Mori-Tanaka method (MTM) (Mori et al. 1973). These methods were all established on the framework of the isotropic matrix-inclusion system (Mura 1987), which depended solely on the composition and elastic property of each component in a composite. Accordingly, it is straightforward to apply them to evaluate the elastic property of hydrated cement with changing hydrate compositions.

In view of the simplicity and high accuracy of the MTM, which considers the interaction between inclusions in an explicit manner, the MTM is applied in the present study to evaluate the Young's modulus of a cement paste leaching in 6M of ammonium nitrate solution.

NUMERICAL VALIDATIONS

Two accelerated leaching tests by 6M of ammonium nitrate solution, reported in the literature (Gallé et al. 2004, Moranville et al. 2004), are simulated using the proposed numerical scheme. The experiments were all conducted on hydrated cement pastes prepared with different water-to-cement ratio and curing conditions. The leaching durations of both tests were also different. The experiment conducted in the Ref. (Moranville et al. 2004) only lasted for 19 days to show the accelerating effect of highly concentrated ammonium nitrate solution compared with the deionized or field water. The other experiment (Gallé et al. 2004) lasted for a 210-day duration to generate a portlandite-depleted specimen, which was then applied to evaluate degradation of elastic properties by measuring the dynamic elastic modulus. The chemical compositions of cements and the preparation details of specimens are listed in Table 1. One-dimensional finite element analyses are carried out, according to the test setup detailed in the reference (Gallé et al. 2004, Moranville et al. 2004), to simulate the reactive diffusion process.

Table 1Properties of the cement-paste specimens

	Test 1 (Moranville et al. 2004)	Test2 (Gallé et al. 2004)
Chemical compositions of cement (% in mass)		
CaO	67.4	67.3
SiO_2	23.4	23.7
Al_2O_3	3.05	2.8
SO_3	2.1	1.9
Fe_2O_3	2.15	2.3
K_2O	0.15	0.2
Na_2O	0.1	0.2
Blaine fineness (m^2/kg)	380	310.5
W/C (-)	0.4	0.45
Curing temperature (℃)	20	20
Curing duration (months)	5	72
Leaching duration (days)	19	210

Simulation of Test 1

Following the numerical framework discussed above, the hydration module is run first to generate the input data for the subsequent simulations of chemical degradation. The paper (Moranville et al. 2004) provided the experimentally determined total porosity and initial portlandite content for the sound specimen. These data are compared with the numerical results obtained from the proposed method in Table 2. In the experiment, the chemical degradation of specimen is mainly characterized by leached depth, which is usually determined by using phenolphthalein or X-Ray diffraction (XRD) to measure the depletion front of portlandite. The leached depth obtained through the proposed numerical scheme is also confronted with the experimental result in Table 2.

Table 2 Numerical validation through Test 1

	Experiment (Moranville et al. 2004)	Simulation	Error
Total porosity (%)	39	36.9	5.4%
Initial portlandite (g/kg)	196	198.003	1.02%
Leached depth (mm)	6.8±0.5	6.6±0.4	2.9%

In terms of the total porosity and the initial portlandite content, the proposed hydration module gives accurate predictions. The leached depth obtained through the coupled diffusion, reaction and damage evaluation modules matches the experimental result well, and this demonstrates the applicability and accuracy of the proposed numerical scheme. In addition, detailed evolutions of hydrate compositions are also predicted from the numerical scheme and the results are shown in Figure 2. In Figure 2, the hydrate contents are shown against the ionic diffusion path where the origin of X axis represents the exposure surface of specimen. From the figure, the dissolution front of portlandite can also be found easily, which is around 6.6 mm. These data form the bases for the later application of micromechanical module for the prediction of the degradation of Young's modulus. It should be mentioned that the mechanical properties were not tested in the Ref. (Moranville et al. 2004), thus the developed micromechanical model is not applied for this test.

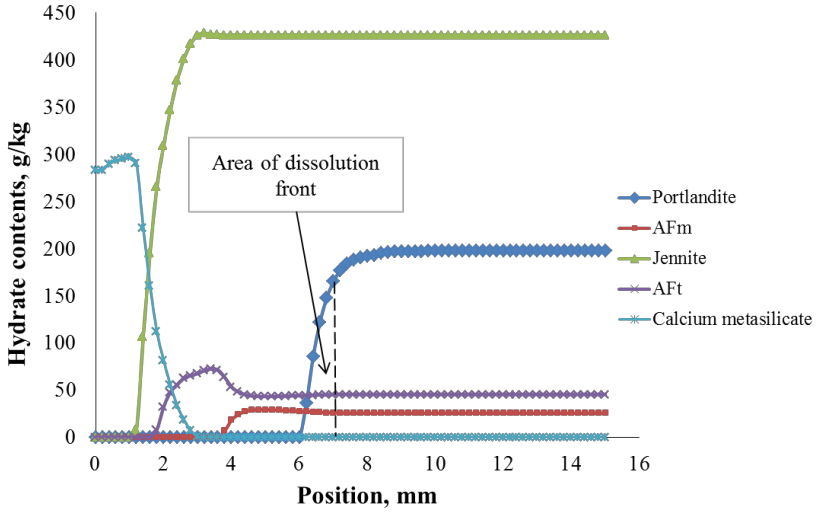

Figure 2 Evolution of hydrate compositions

Simulation of Test 2

Long duration (210 days) of leaching in 6M of ammonium nitrate solution was conducted to obtain a portlandite-depleted specimen (Gallé et al. 2004). An ultrasonic testing system was applied to both sound and leached specimens to measure the dynamic Young's moduli, which is considered to be the same in mechanical definition with Young's moduli that measured statically, however, possesses a higher accuracy (Plachy et al. 2009). This test is also simulated using the proposed numerical scheme, including the micromechanical module, to predict the elastic properties of both the sound and degraded cement paste.

Intrinsic elastic properties for hydrated cement components

To apply the micromechanical method to predict the Young's moduli of composites with random compositions of matrix and inclusions, the elastic property of the individual component that contributes to the overall behaviour should first be known. Applying nanoindentation technique, the elastic properties for most of the inclusions in the hydrated cement such as portlandite, monosulfate (AFm), gypsum and ettringite (AFt) can be measured in a very small size (Nano-scale), which can ensure the elastic properties obtained are the intrinsic properties of the hydrated cement components (Constantinides et al. 2004).

In terms of calcium-silicate-hydrate (C-S-H), a recent study (Constantinides et al. 2004) confirmed the existence of two types of C-S-H, namely the low-density C-S-H and high-density C-S-H. They have their own intrinsic elastic properties for both sound and leached state, and do not change according to cement mixture or curing

conditions. The experimentally measured elastic properties of the two types of C-S-H obtained by nanoindentation (Constantinides et al. 2004) are shown in Table 3.

Table 3 Elastic properties of two types of C-S-H obtained by nanoindentation (Constantinides et al. 2004)

	Young's moduli (GPa)		Poisson's ratio	
	Nondegraded	Degraded	Nondegraded	Degraded
Low-density C-S-H	21.7±2.2	3.0±0.8	0.24	0.24
High-density C-S-H	29.4±2.4	12.0±1.2	0.24	0.24

Furthermore, the relative content of the two types of C-S-H is also a necessary parameter for the prediction of the overall elastic property of hydrated cement. An analytical model for predicting the relative content of the two types of C-S-H was proposed (Tennis et al. 2000). Applying this model, the relative volumetric fraction can be easily calculated. According to the study (Constantinides et al. 2004), the relative volumetric fraction of the two types of C-S-H is not affected by decalcification of C-S-H. As a result, the relative fraction is decided only by water-to-cement ratio and the initial DOH calculated in the hydration module.

The theory of the two types of C-S-H is applied in this study to determine the intrinsic elastic properties of Jennite and calcium metasilicate (Tennis et al. 2000, Constantinides et al. 2004). As C-S-H is modelled as Jennite and calcium metasilicate in this study to represent the progressive decalcification, the properties of nondegraded C-S-H are assigned to Jennite, while the degraded ones are assigned to calcium metasilicate. The intrinsic elastic properties of each hydrate components are shown in Table 4. The values applied are all defined experimentally by other researchers except the values for Jennite and calcium metasilicate, which are calculated in this study.

Table 4 Intrinsic elastic properties of hydrated cement components

Component	Young's modulus (GPa)	Poisson's ratio	Reference
Portlandite (CH)	38±5	0.305	(Kamali et al. 2004)
Monosulfate (AFm)	42.3	0.324	(Kamali et al. 2004)
Gypsum (G)	38±5	0.33	(Kamali et al. 2004)

Gibbsite	0	0.01	(Bernard et al. 2008)
Jennite	27.1	0.24	*
Calcium metasilicate	6.6	0.24	*

* Calculated values from this study

Application and validation of micromechanical module

Mori-Tanaka method (MTM) (Mori et al. 1973) is applied to predict the elastic properties of the macroscopically isotropic materials such as cement paste. The two-level homogenization approach proposed in reference (Constantinides et al. 2004) is used to upscale the contributions of cement components from micro scale to macro scale.

The C-S-H related components including Jennite, calcium metasilicate and amorphous silica gel present at a scale of $10^{-6} - 10^{-8}$m, which is considered as the first level (Level I) of homogenization. Among them, Jennite is functioned as a matrix while the rest two are considered as inclusions. The elastic properties of the homogenized C-S-H are then adopted in a larger level of homogenization, which is regarded as Level II ($10^{-4} - 10^{-3}$m). At this level, the homogenized C-S-H is a matrix together with larger crystals as inclusions which include portlandite, AFm, AFt, gypsum, pores and unhydrated cement clinkers if hydration was not complete. This is also the level that was assessed by ultrasonic testing system to measure the dynamic elastic modulus (Gallé et al. 2004).

Through simulating the long-duration test conducted by Gallé et al. (Gallé et al. 2004), a portlandite-depleted specimen is obtained numerically in this study. The detailed hydrate compositions of the main components are shown in Figure 3. From this figure, it is found that portlandite is completely depleted while other hydrates are also severely degraded. For the area close to the exposure surface (around 4 mm), hydrated cement is fully replaced by the amorphous silica gel. The evolution of Young's moduli along the diffusion path is also obtained from numerical modelling and is shown along with the total calcium content in the hydrates in Figure 4.

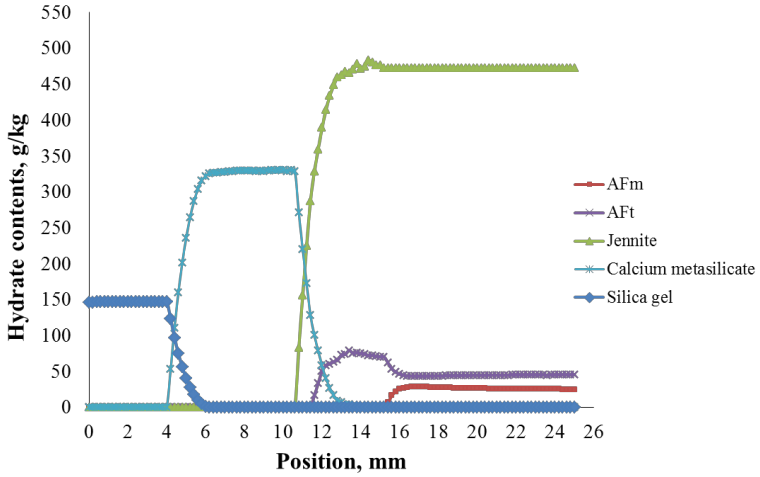

Figure 3 Evolution of hydrate compositions

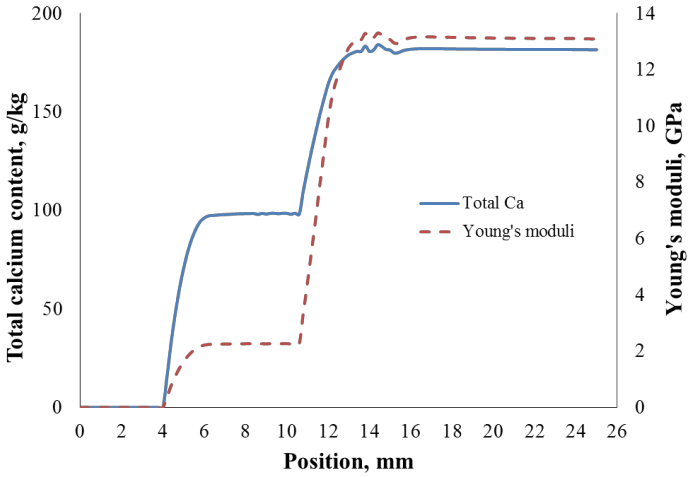

Figure 4 Evolutions of total calcium contents and Young's moduli

As seen in Figure 4, the evolution of Young's modulus follows the tendency of the evolution of total calcium content very well. The depletion of portlandite clearly introduces a major decrease of Young's modulus. The complete decalcification of C-S-H then vanish the elastic properties of degraded cement. Furthermore, the average Young's moduli for both the sound and degraded specimens are also calculated and they are shown in Table 5. Good agreements can be found between the calculated moduli and experimental results.

Table 5 Comparisons of Young's moduli

	Experiment (GPa) (Gallé et al. 2004)	Simulation (GPa)
Sound paste	23±0.5	22.5
Degraded paste	7±0.5	7.64

CONCLUSIONS

An integrated numerical scheme with five modules including hydration module, diffusion module, chemical reaction module, damage evaluation module and micromechanical module is proposed in this study. The

maximum degree of hydration is considered in the hydration module to generate accurate input data for the physical-chemical simulations. The recently developed MPNP model for the modelling of ionic diffusion and an alternative method for simulating the decalcification of C-S-H are also applied in this research. The proposed numerical scheme is proven to be accurate in modelling the accelerated leaching problem from the good agreements between the numerical results and experiments. Finally, the micromechanical module is incorporated to predict the elastic properties of cementitious material. Mori-Tanaka method and a two-level homogenization technique are adopted, and the degradation of Young's moduli of cement paste is predicted with high accuracy. In addition, a clear relation between the evolution of the Young's modulus and total calcium content is found from the numerical simulation. This relation could be useful for the development of an engineering-oriented model for the prediction of Young's modulus of cementitious materials in the future.

ABSTRACT

A global-local higher order model taking into account transverse normal deformation is presented for the analysis of laminated composite plates subjected to the actual temperature field. The in-plane temperature field is expressed as a harmonic series expansion whereas the nonlinear temperature profile across the thickness direction is determined by solving the heat conduction equation. The validity of the proposed model is verified by comparing results with existing publications. Moreover, influence of the temperature fields along the thickness direction on the thermal behaviors of laminates is also investigated. A merit of the present model is that transverse shear stresses can be evaluated directly from the constitutive equations without stress smoothing.

KEYWORDS

Global-local higher order model, laminated composite plates, actual temperature fields, finite elements.

INTRODUCTION

With the increased use of composite materials in thermal environments, the thermal stress analysis of laminated composite materials has aroused considerable interests. Thermal deformation and stress in laminates have been analyzed by using equivalent single-layer models (ESLMs) (Reddy and Hsu 1980, Kheider and Reddy 1991, Kant and Khare 1994, Rohwer *et al*. 2001, Cho and Oh 2003, Wu and Chen 2006), in which the unknown variables are independent of the number of layers. More ESLMs for thermomechanical problems of laminated plates can be found in the review articles by (Tauchert 1991), (Noor and Burton 1992) and (Argyris and Tenek 1997). In addition, (Cho *et al*. 1989) and (Murakami 1993) used layerwise models to predict thermal response of multilayered plates. Based on the Reissner mixed variational theorem (RMVT), (Carrera 2000) employed the mixed layerwise model to predict thermal stresses of multilayered plates. In the mixed layerwise model, the transverse stress fields and the displacement fields within each layer are independently assumed.

Most of the previous research was concerned with the constant and linear temperature fields through the thickness of laminates. (Carrera 2002) studied the influence of the temperature fields on the response of multilayered plates. Analytical and numerical results showed that the temperature fields obtained by solving the heat conduction equation and the assumed linear temperature fields lead to rather different stresses and displacements. Moreover, Carrera concluded that the advanced zig-zag models could not produce accurate thermal stresses for temperature fields derived from the heat conduction equation. On the other hand, (Robaldo 2006) used finite element method based on layerwise model to investigate the influence of temperature profile on thermal response of multilayered plates. Layerwise model is more accurate than ESLMs, however this model is computationally expensive with increasing number of layers because the number of unknown variables depends on the number of layers of the laminate. Moreover, this model is unable to satisfy the continuity condition of transverse shear stresses at interfaces. In this paper, the global-local higher order model is used to analyze thermal response of laminated plates under temperature fields derived from the differential heat conduction equation in the thickness direction as proposed by (Tungikar and Rao 1994). In the finite element implementation, by means of the quadrilateral element DKQ developed by (Batoz and Tahar 1982), C^1 continuity of transverse displacement at the element interfaces is enforced.

GLOBAL-LOCAL HIGHER-ORDER THEORY

In the present model, the initial displacement fields are written as follows:

$$
\begin{aligned}
u^k(x,y,z) &= u_G(x,y,z) + \bar{u}_L^k(x,y,z) + \hat{u}_L^k(x,y,z) \\
v^k(x,y,z) &= v_G(x,y,z) + \bar{v}_L^k(x,y,z) + \hat{v}_L^k(x,y,z) \\
w^k(x,y,z) &= w_G(x,y,z)
\end{aligned} \tag{1}
$$

where u_G, v_G and w_G present global components of displacement; $\bar{u}_L^k$ and $\bar{v}_L^k$ are local displacements up to order ζ_k^2; $\hat{u}_L^k$ and $\hat{v}_L^k$ are local displacement of order ζ_k^3 as shown in eqn (3); the superscript *k* represents the layer order of laminated plates. The global coordinates associated with the plate are x, y, z. The reference plane ($z=0$) is taken at the mid-surface of the laminate. The local coordinates for a layer are denoted by x, y, ζ_k where $\zeta_k \in [-1,1]$. The relations between global coordinates and local coordinates are depicted in Figure 1. The global-local higher order theory has been studied (Wu and Chen 2006) and conclusion has been drawn that the fifth-order global-local theory is adequate for the problems of multi-layered plates. Based on the fifth-order in-plane components, the global displacement components are written as follows

$$
\begin{aligned}
u_G(x,y,z) &= \sum_{i=0}^{5} z^i u_i(x,y) \\
v_G(x,y,z) &= \sum_{i=0}^{5} z^i v_i(x,y) \\
w_G(x,y,z) &= \sum_{i=0}^{2} z^i w_i(x,y)
\end{aligned} \tag{2}
$$

The local components can be written as

$$
\begin{aligned}
\bar{u}_L^k(x,y,z) &= \zeta_k u_1^k(x,y) + \zeta_k^2 u_2^k(x,y) \\
\bar{v}_L^k(x,y,z) &= \zeta_k v_1^k(x,y) + \zeta_k^2 v_2^k(x,y) \\
\hat{u}_L^k(x,y,z) &= \zeta_k^3 u_3^k(x,y) \\
\hat{v}_L^k(x,y,z) &= \zeta_k^3 v_3^k(x,y)
\end{aligned} \tag{3}
$$

where $\zeta_k = a_k z - b_k$; $a_k = \dfrac{2}{z_{k+1} - z_k}$; $b_k = \dfrac{z_{k+1} + z_k}{z_{k+1} - z_k}$

Displacement continuity conditions

There are *6n+15* unknown variables in the initial displacement fields. By enforcing the displacement continuity conditions, 4(*n*-1) unknown variables can be eliminated. The continuity conditions proposed by (Li and Liu 1997) can be written as

$$
\begin{aligned}
\bar{u}_L^k(x,y,z_k) &= \bar{u}_L^{k-1}(x,y,z_k) \\
\hat{u}_L^k(x,y,z_k) &= \hat{u}_L^{k-1}(x,y,z_k) \\
\bar{v}_L^k(x,y,z_k) &= \bar{v}_L^{k-1}(x,y,z_k) \\
\hat{v}_L^k(x,y,z_k) &= \hat{v}_L^{k-1}(x,y,z_k)
\end{aligned} \qquad \text{where } k = 2,3,4,\cdots n \tag{4}
$$

Transverse shear stress continuity conditions

By imposing the continuity conditions of transverse shear stresses at interfaces, *2(n-1)* unknown variables can be eliminated. The transverse shear stress continuity conditions are given by

$$
\begin{aligned}
\tau_{xz}^k(x,y,z_k^-) &= \tau_{xz}^{k-1}(x,y,z_{k-1}^+) \\
\tau_{yz}^k(x,y,z_k^-) &= \tau_{yz}^{k-1}(x,y,z_{k-1}^+)
\end{aligned} \tag{5}
$$

where z_k^+ *and* z_k^- are respectively the z-coordinates at the top and at the bottom of the k[th] ply.
Now the number of unknown variables is reduced to 21. Further enforcing the free conditions of the transverse shear stresses on the upper and the lower surfaces, the number of independent unknowns is reduced to 17. Thus, the final displacement fields for cross-ply laminated plates are

$$u^k(x,y,z)=u_0(x,y)+\Phi_1^k(z)u_1^1(x,y)+\sum_{i=1}^{5}\Phi_{i+1}^k(z)u_i(x,y)+\sum_{j=0}^{2}\Phi_{i+7}^k(z)w_{i,x}$$
$$v^k(x,y,z)=v_0(x,y)+\Psi_1^k(z)v_1^1(x,y)+\sum_{i=1}^{5}\Psi_{i+1}^k(z)v_i(x,y)+\sum_{j=0}^{2}\Psi_{i+7}^k(z)w_{i,y} \quad (6)$$
$$w^k(x,y,z)=\sum_{i=0}^{2}z^i w_i(x,y)$$

where detailed expression for Φ_i^k and Ψ_i^k are given in (Wu Zhen and Chen Wanji, 2009).

TEMPERATURE FIELD

The initial temperature field proposed by (Tungikar and Rao 1994) is given by

$$T(x,y,z)=f(z)\sin(m\pi x/a)\sin(n\pi y/b) \quad (7)$$

where m and n are the wave number on the two principle directions of the plate; a and b are length and width of the laminated plate, respectively.

$$f(z)=T_0e^{sz} \quad (8)$$

T_0 is a constant and s is an unknown parameter. The Fourier equation of heat conduction for homogeneous orthotropic is given by

$$K_1\frac{\partial^2T}{\partial^2x}+K_2\frac{\partial^2T}{\partial^2y}+K_3\frac{\partial^2T}{\partial^2z}=0 \quad (9)$$

where K_1, K_2, K_3 are the thermal conductivities in the x, y and z directions. Substituting equations (7) and (8) into equation (9), expressions for unknown parameter s is given by

$$s_{1,2}=\pm\sqrt{\frac{K_1(m\pi/a)^2+K_2(n\pi/b)^2}{K_3}} \quad (10)$$

Hence, the temperature field for the *k*th layer is given by

$$T^k(x,y,z)=\left(C_1^k\cosh s_1z+C_2^k\sinh s_2z\right)\sin(m\pi x/a)\sin(n\pi y/b) \quad (11)$$

The temperature field equation (11) can also be found in Tungikar and Rao's paper and Carrera's paper. Enforcing the continuity conditions of temperature and heat flux q_z at interfaces as well as temperature boundary conditions on the upper and lower surfaces, $2N$ constants C_1^k and C_2^k can be determined. Continuity conditions of the temperature and the heat flux along the thickness direction at interfaces are given by

$$T^k(x,y,z_k^-)=T^{k-1}(x,y,z_{k-1}^+) \quad (12)$$
$$q_z{}^k(x,y,z_k^-)=q_z{}^{k-1}(x,y,z_{k-1}^+) \qquad \text{where } k=2,3,4,\cdots n \quad (13)$$

The heat flux for the *k*th ply is given by

$$q_z^k=K_3^k\frac{\partial T^k}{\partial z} \quad (14)$$

THE FOUR-NODE QUADRILATERAL LAMINATED PLATE ELEMENT

The strain components in the higher-order shear deformation theory possess first and second derivatives of transverse displacement *w*, and C^0 and C^1 continuity transverse displacement functions are required.

Transverse displacement function w^c satisfying C^0 continuity condition

Firstly, the transverse displacement function *w* is given by

$$w=\sum_{i=1}^{4}N_iw_i+\sum_{j=5}^{8}N_jw_j \quad (15)$$

where N_i is the shape function of the 8-node serendipity element.

To obtain the 4-node quadrilateral element, w_j at the mid-node along the element boundary can be eliminated using the Hermite cubic polynomials. For instance, using parameters θ_{si} and w_i at nodes 1 and 2, the interpolation of displacement $\widetilde{w}_s$ can be written as

$$\widetilde{w}_s = \sum_{i=1}^{2} H_i w_i + \sum_{i=1}^{2} H_{\theta i} \theta_{si} \tag{16}$$

where

$$\begin{aligned} H_1 &= L_1 + L_1 L_2 (L_1 - L_2) \\ H_2 &= L_2 + L_1 L_2 (L_2 - L_1) \\ H_{\theta 1} &= (L_1 L_2 + L_1 L_2 (L_1 - L_2)) S_1 / 2 \\ H_{\theta 2} &= (-L_1 L_2 + L_1 L_2 (L_1 - L_2)) S_1 / 2 \end{aligned} \tag{17}$$

in which θ_{si} is the tangential slopes at the node i (i=1,2) on the boundary; S_1 is the length between nodes 1 and 2; $L_1 = 1 - \dfrac{S}{S_1}$ and $L_2 = \dfrac{S}{S_1}$ in which S is the coordinates along the 1-2 edge. Substituting $L_1 = L_2 = 0.5$ in equation (16), w_5 at the mid-node 5 on the 1-2 boundary is given by

$$w_5 = \frac{1}{8}\left(4w_1 + S_1\theta_{s1} + 4w_2 - S_1\theta_{s2}\right) \tag{18}$$

where θ_{sj} ($j = 1,2,5$) on 1-2 boundary are given by

$$\theta_{sj} = \begin{bmatrix} -m_1 & \ell_1 \end{bmatrix} \begin{Bmatrix} \theta_{xj} \\ \theta_{yj} \end{Bmatrix} \quad (j=1,2,5) \tag{19}$$

where l, m are the direction cosines normal to the boundary. Substituting equation (19) in equation (18), the following equation for w_5 can be obtained

$$w_5 = \frac{1}{8}\begin{bmatrix} 4 & -m_1 S_1 & \ell_1 S_1 & 4 & m_1 S_1 & -\ell_1 S_1 \end{bmatrix} \begin{Bmatrix} w_1 \\ \theta_{x1} \\ \theta_{y1} \\ w_2 \\ \theta_{x2} \\ \theta_{y2} \end{Bmatrix} \tag{20}$$

Similarly other mid-node parameters w_j ($j = 6,7,8$) are expressed by nodal parameters $[w_j \quad \theta_{xj} \quad \theta_{yj}]^T$ ($j = 1 \sim 4$). Substituting mid-node parameters w_j ($j = 5 \sim 8$) into equation (15), finally, an explicit expression for the C^0 continuity displacement function can be written as follows

$$w^c = Fq \tag{21}$$

where $F = \begin{bmatrix} F_i & F_{xi} & F_{yi} \end{bmatrix}$, $q = \left\{ w_i, w_{xi}, w_{yi} \right\}^T$ and

$$\begin{aligned} F_1 &= 0.5(m_1 N_5 / S_1 - m_4 N_8 / S_4) + N_1^{\oplus} \\ F_{x1} &= -0.125(m_1^2 N_5 + m_4^2 N_8) \\ F_{y1} &= 0.125(\ell_1 m_1 N_5 + \ell_4 m_4 N_8) \\ N_i^{\oplus} &= \frac{1}{4}(1 + \xi\xi_i)(1 + \eta\eta_i), \; i = 1,2,3,4. \end{aligned} \tag{22}$$

Other shape functions, namely, $\begin{bmatrix} F_i & F_{xi} & F_{yi} \end{bmatrix} (i = 2,3,4)$ can be obtained by cyclic permutation.

Transverse displacement function w^* satisfying C^1 continuity condition

To obtain the transverse displacement function w^* satisfying C^1 continuity condition, the rotation function of the thin plate quadrilateral element DKQ (Batos and Tahar 1982) is adopted as C^1-continuity requirement is satisfied at the inter-element boundaries in strict sense and continuity condition in the element in an average sense (Chen and Cheung 1997). The explicit expressions for rotations of element DKQ are given by

$$\begin{Bmatrix} \theta_x \\ \theta_y \end{Bmatrix} = \overline{N} q \tag{23}$$

where

$$\overline{\boldsymbol{N}} = \begin{bmatrix} \overline{\boldsymbol{N}}_1 & \overline{\boldsymbol{N}}_2 & \overline{\boldsymbol{N}}_3 & \overline{\boldsymbol{N}}_4 \end{bmatrix} \tag{24}$$

$$\overline{\boldsymbol{N}}_j = \begin{bmatrix} P_j & P_{xj} & P_{yj} \\ Q_j & Q_{xj} & Q_{yj} \end{bmatrix}, \quad (j = 1,2,3,4) \tag{25}$$

$$\begin{aligned} P_1 &= 1.5(m_1 N_5 / S_1 - m_4 N_8 / S_4) \\ P_{x1} &= -0.75(m_1^2 N_5 + m_4^2 N_8) + N_1^{\oplus} \\ P_{y1} &= 0.75(\ell_1 m_1 N_5 + \ell_4 m_4 N_8) \\ Q_1 &= 1.5(-\ell_1 N_5 / S_1 + \ell_4 N_8 / S_4) \\ Q_{x1} &= 0.75(\ell_1 m_1 N_5 + \ell_4 m_4 N_8) \\ Q_{y1} &= -0.75(\ell_1^2 N_5 + \ell_4^2 N_8) + N_1^{\oplus} \end{aligned} \tag{26}$$

with

$$\ell_1 = \frac{y_{21}}{\sqrt{x_{12}^2 + y_{21}^2}};\ m_1 = \frac{x_{12}}{\sqrt{x_{12}^2 + y_{21}^2}};\ \ell_4 = \frac{y_{14}}{\sqrt{x_{41}^2 + y_{14}^2}};\ m_4 = \frac{x_{41}}{\sqrt{x_{41}^2 + y_{14}^2}}$$

$$y_{21} = y_2 - y_1;\ x_{12} = x_1 - x_2;\ y_{14} = y_1 - y_4;\ x_{41} = x_4 - x_1$$

Using the rotations function of DKQ element, the second derivatives of transverse displacement function w^* satisfying C^1 continuity condition is given by

$$\begin{aligned} \frac{\partial^2 w^*}{\partial x^2} &= \frac{\partial \theta_x}{\partial x} \\ \frac{\partial^2 w^*}{\partial y^2} &= \frac{\partial \theta_y}{\partial y} \\ \frac{\partial^2 w^*}{\partial x \partial y} &= \frac{1}{2}\left(\frac{\partial \theta_y}{\partial x} + \frac{\partial \theta_x}{\partial y} \right) \end{aligned} \tag{27}$$

Displacement functions

In terms of nodal variables and shape functions, primary displacement unknowns can be expressed as follows

$$\begin{aligned} \overline{U} &= \sum_{i=1}^{4} N_i^{\oplus} \overline{U}_i \\ w^c &= \sum_{i=1}^{4} (F_i w_{0,i} + F_{xi} w_{0,xi} + F_{yi} w_{0,yi}) \\ w^* &= \sum_{i=1}^{4} (F_i^* w_{0,i} + F_{xi}^* w_{0,xi} + F_{yi}^* w_{0,yi}) \end{aligned} \tag{28}$$

where $\overline{U} = \begin{bmatrix} u_0 & v_0 & u_1^1 & u_1 & u_2 & u_3 & u_4 & u_5 & v_1^1 & v_1 & v_2 & v_3 & v_4 & v_5 \end{bmatrix}$.

Strain matrix and stiffness matrix

According to linear strain-displacement relations, the strain for the kth layer can be written as follows:

$$\varepsilon^k = \partial u^k = \begin{bmatrix} B_1 & B_2 & B_3 & B_4 \end{bmatrix} \delta^e \tag{29}$$

where $\delta^e = [\delta_1^e \quad \delta_2^e \quad \delta_3^e \quad \delta_4^e]^T$, and for i = 1, 2, 3, 4

$$\delta_i^e = \begin{bmatrix} u_{0i} & v_{0i} & w_{0i} & w_{1i} & w_{2i} & u_{1i}^1 & u_{1i} & \cdots & u_{5i} & w_{0xi} & w_{1xi} & w_{2xi} & v_{1i}^1 & v_{1i} & \cdots & v_{5i} & w_{0yi} & w_{1yi} & w_{2yi} \end{bmatrix}$$

$$[\partial] = \begin{bmatrix} \frac{\partial}{\partial x} & 0 & 0 & \frac{\partial}{\partial z} & 0 & \frac{\partial}{\partial y} \\ 0 & \frac{\partial}{\partial y} & 0 & 0 & \frac{\partial}{\partial z} & \frac{\partial}{\partial x} \\ 0 & 0 & \frac{\partial}{\partial z} & \frac{\partial}{\partial x} & \frac{\partial}{\partial y} & 0 \end{bmatrix}^T$$

The detailed expression of the strain matrix can be obtained by the method proposed by (Wu et al. 2005, 2014). From strain matrix *B* of the refined nonconforming element, the element stiffness matrix K^e is given by

$$\left[K^e\right] = \sum_{i=1}^{n} \int_{i-1}^{i} \left(\iint B^T Q_i B dx dy \right) dz \tag{30}$$

On solving the global stiffness equation, nodal displacement $\left\{\delta^e\right\}$ for load vector $\{r\}$ can be obtained

$$\sum \left[K^e\right]\left\{\delta^e\right\} = \{r\} \tag{31}$$

NUMERICAL EXAMPLES

To assess the performance of the proposed model for laminates under actual temperature field, two examples are presented. Owing to symmetry, only one-quarter of the laminated plate has been modeled. The plate geometry and a 4×4 mesh configuration are shown in Figure 2. The following publications are referred to for comparison.

(Robaldo 2006) - T_1: Layerwise finite element results according to actual temperature profile through the thickness direction.

(Robaldo 2006) - T_2 : Layerwise finite element results according to the assumed temperature profile.

(Kapuria and Achary 2004) Exact thermo-elasticity solution.

HZIGT (Kapuria and Achary 2004) Analytical results based on higher order zig-zag model including transverse normal deformation. Transverse shear stresses are calculated using the 3D equilibrium equations.

ZIGT (Kapuria and Achary 2004) Analytical results based on higher order zig-zag model neglecting transverse normal deformation. Transverse shear stresses are calculated using the 3D equilibrium equations.

Example 1. Simply-supported 3-ply square plate $(0^\circ/90^\circ/0^\circ)$ subjected to actual temperature field $T_1(z)\sin\frac{\pi x}{a}\sin\frac{\pi y}{b}$ and assumed temperature field $T_2(z)\sin\frac{\pi x}{a}\sin\frac{\pi y}{b}$. Actual temperature profile through the thickness direction $T_1(z)$ can be obtained by solving heat conduction equation as discussed in the section of TEMPERATURE FIELD. Temperatures at the top and bottom surfaces are $T_t = 1$ and $T_b = -1$, respectively. Linear through-the-thickness temperature profile $T_2(z)$ is assumed as $T_2(z) = T_0 \frac{2z}{h}$ where $T_0 = 1$. Distributions of two temperature profiles along the thickness direction can be found in Figure 3. The material constants are given as follows

$$E_L / E_T = 25,\ G_{LT} / E_T = 0.5,\ G_{TT} / E_T = 0.2,\ v_{LT} = v_{TT} = 0.25$$

$$\alpha_T / \alpha_L = 1125,\quad K_L = 36W/m^\circ C,\ K_T = 0.96W/m^\circ C$$

where *L* and *T* respectively represent directions parallel and perpendicular to the fibers. The displacements and stresses are normalized by

$$\bar{u}(a/2,0,z) = \frac{u(a/2,0,z)}{a\alpha_L};\ \bar{\tau}_{yz}(0,b/2,z) = \frac{\bar{\tau}_{yz}(0,b/2,z)}{E_T\alpha_L}$$

In-plane displacements for both the assumed and the actual temperature fields are compared with results of layerwise model in Figure 4. It is found that the present results agree well with those of layerwise model. Moreover, the difference of in-plane displacements between the actual temperature field and the assumed temperature field is quite noticeable. Furthermore, the influence of temperature profile on the transverse shear stress can be seen in Figure 5.

Example 2. Simply-supported 3-ply square plate ($0^o/90^o/0^o$) subjected to specified temperature fields $T_3(z)\sin\frac{\pi x}{a}\sin\frac{\pi y}{b}$ and $T_4(z)\sin\frac{\pi x}{a}\sin\frac{\pi y}{b}$. For temperature profile $T_3(z)$, temperatures at the top and bottom surfaces are defined as $T_t=1$ and $T_b=1$. However, temperatures at the top and bottom surfaces for $T_4(z)$ are $T_t=1$ and $T_b=-1$, respectively. Temperature fields $T_3(z)$ and $T_4(z)$ are shown in Figures 6 and 7. The material constants used are given as follows

$$E_L=181GPa,\ E_T=10.3GPa,\ G_{LT}=7.17GPa,\ G_{TT}=2.87GPa,\ v_{LT}=0.28,\ v_{TT}=0.33$$

$$\alpha_L=0.02\times10^{-6}/K,\ \alpha_T=22.5\times10^{-6}/K,\ K_L=1.5W/mK,\ K_T=0.5W/mK$$

The displacements and stresses are normalized by

$$\bar{u}(a/2,0,z)=\frac{100u(a/2,0,z)}{a\alpha_T T_0},\ \bar{v}(0,b/2,z)=\frac{100v(0,b/2,z)}{a\alpha_T T_0},\ \bar{w}(0,0,z)=\frac{100w(0,0,z)h}{a^2\alpha_T T_0},$$

$$\bar{\sigma}_x(0,0,z)=\frac{\sigma_x(0,0,z)}{\alpha_T E_T T_0},\ \bar{\sigma}_y(0,0,z)=\frac{\sigma_y(0,0,z)}{\alpha_T E_T T_0},\ \bar{\tau}_{xz}(a/2,0,z)=\frac{\tau_{xz}(a/2,0,z)L}{\alpha_T E_T T_0 h},$$

$$\bar{\tau}_{yz}(0,b/2,z)=\frac{\tau_{yz}(0,b/2,z)L}{\alpha_T E_T T_0 h},\ T_0=1$$

Distributions of through-the-thickness displacements and stresses for plates under temperature profile $T_3(z)$ obtained from the present model are compared with the exact thermo-elasticity solutions and the existing zig-zag models (HZIGT and ZIGT) in Figures 8-11. It is found that the present results agree well with exact solutions whereas higher order zig-zag model (HZIGT) as well as ZIGT seems less accurate. Moreover, transverse shear stresses $\bar{\tau}_{xz}$ computed directly from constitutive equations are also in good agreement with the exact solutions. Results for displacements and stresses of laminated plates subjected to temperature profile $T_4(z)$ are presented in Figures 12-14.

CONCLUSIONS

Thermal response of laminated composite plates under actual temperature field has been studied by using the global-local higher-order theory. The results are compared with exact solutions and those previously published. From the comparison, the following conclusions can be drawn:

1. When the actual temperature field through the thickness direction differs significantly from the assumed temperature field over a thick plate, the two temperature profiles do lead to very different thermal response.
2. Higher-order zig-zag model neglecting transverse normal deformation is not adequate for the thermal problems of laminated plates subjected to general temperature fields.
3. Compared with higher-order zig-zag models, the present model usually gives more accurate results for the thermal response of laminated plate. For a laminated plate with different thickness and materials at each ply, the transverse shear stress can be determined directly from the constitutive equations.

ABSTRACT

Many concrete structures are vulnerable to extreme loadings such as accidental impact, terrorist attack and earthquake disasters. Retrofitting of existing concrete structures for enhanced performance under these loadings has been an important topic of research for a long time, especially since the 911 terrorist attack. Among the different retrofitting techniques, external bonding of fibre reinforced polymer (FRP) composites has been a popular one. This paper presents a brief review of recent research on FRP strengthened concrete structures under blast, impact, earthquake and cyclic loading.

Fibre reinforced polymer (FRP) composites; concrete structures; blast; impact; seismic; fatigue; bond interface.

INTRODUCTION

Fibre reinforced polymer (FRP) composites have been widely used for retrofitting concrete structures as externally bonded reinforcement, mainly because of their high strength to weight ratios, ease of handling and application which eliminates the need for heavy equipment, fast installation and the fact that they do not corrode (ACI440, 2008). Whilst the vast majority of research in this area has been concerned with static behaviour of FRP strengthened concrete structures, significant progress has been made on the behaviour of such structures under extreme loadings such as blast and impact, earthquake, fire and repeated fatigue loading, in light of devastating consequences of some major terrorist attacks and earthquakes. This paper presents a brief review of recent research on FRP strengthened structures under a) blast and impact; b) earthquake and c) cyclic (fatigue) loadings.

The blast and impact behaviour of FRP retrofitted concrete structure is reviewed first below. A number of experimental and finite element (FE) studies have indicated clearly that FRP and polymer retrofitting can significantly increase the dynamic resistance of structures, by increasing either strength or ductility or both, with reduced fragmentation. However, the analysis of the dynamic response of structures induced by blast and impact load is very complex as it involves the effect of high strain rates, non-linear inelastic material behaviour, uncertainties in predicting the load and the time-dependent deformations.

The seismic resistance of FRP-strengthened structures have been researched experimentally, analytically and numerically. These studies can be generally classified based on the types of structures and members: (a) reinforced concrete (RC) columns, (b) concrete and masonry walls, (c) beam-column joints, and (d) RC frame structures. Most of the experimental studies have been conducted for structural members such as beams, columns and joints, and frame structures under quasi-static test (cyclic) or pseudo-dynamic loadings. These are reviewed next.

Fatigue behaviour is a major concern for some concrete structures such as bridges strengthened with FRP. A number of studies have demonstrated that the application of FRP can reduce the stress in the longitudinal steel bars and increase the fatigue life of RC members (Shahawy and Beitelman 1999, El-Tawil *et al*. 2001). However, other studies have showed that, while the stress level of reinforcing steel was initially reduced due to the presence of FRP, it was subsequently returned to the stress level corresponding to the non-strengthened specimens (Masoud *et al*. 2001, Brena *et al*. 2005). Local debonding of the interface between FRP and concrete resulting in stress redistribution is believed to explain this behaviour (Harries and Aidoo 2005, Diab *et al*. 2009). Thus, debonding is an important aspect for the strengthened members during the damage procession under

fatigue loads. Although an extensive amount research has been conducted on the behaviour of FRP-concrete bond interface, very limited information is available regarding the fatigue performance of FRP-concrete interface. The third part of this paper presents a review of the fatigue behaviour of concrete structures strengthened with externally bonded FRP, focusing on the fatigue performance of FRP-concrete bond interface.

BLAST AND IMPACT BEHAVIOUR OF FRP-STRENGTHENED STRUCTURES

Buchan and Chen (2007) and Malvar et al. (2007) summarized experimental and finite element (FE) studies conducted to investigate the behaviour of FRP strengthened concrete structures under blast loads available in the public literature before 2006. Thus, this section presents a review of the more recent studies on FRP strengthened concrete structure under blast and impact loads conducted since then.

FRP Retrofitted Concrete Columns

The blast or impact resistance of concrete columns is of crucial importance for the stability of concrete frame structures when they are subject to such extreme loadings. Crawford (2013) summarized studies conducted by Karagozian and Case (K&C) in the last two decades on concrete columns strengthened with CFRP for resisting blast loads. Their work includes numerical analysis, full-scale blast tests on concrete frame structures and quasi-static tests of concrete columns. To assess the efficiency of FRP in strengthening concrete column, a numerical research (Crawford *et al*. 1996, 2001) was conducted for the bombing of the Alfred P. Murrah Federal Building in Oklahoma City in 1995, which ultimately led to the collapse of about half of the building structure due to the failure of one or more main load-bearing columns. It was concluded that that the columns of the Murrah building could have been upgraded using FRP composite wraps to enhance their blast resistance, limit their lateral deflection, and prevent its collapse. Malvar *et al*. (2007) also showed that both steel jackets and FRP wraps could be used to successfully prevent column damage and building collapse. Elsanadedy *et al*.'s (2011) numerical study on CFRP-retrofitted concrete column using the K&C concrete damage model indicated that charge weight and stand-off distance in a blast event plays the critical role on the response of the concrete columns under explosion but even a light retrofitting could provide considerable increase of blast resistance of columns. The FRP was assumed to be perfectly bonded to the column in all the relevant numerical studies.

There have been a small number of studies on FRP strengthened concrete columns under impact loading. Ferrier and Hamelin (2005) conducted impact tests on CFRP retrofitted concrete columns and observed that the loading capacity of CFRP strengthened concrete columns were 88% higher than that of the reference columns without strengthening. Uddin *et al*. (2008) conducted a serial of tests by using a drop-tower testing machine to investigate the effect of low velocity impact on high-strength concrete confined by either a prefabricated polypropylene (PP) jacket or a CFRP wrap. The PP-confined columns exhibited much higher energy absorption capacity and deformability but lower peak load compared with the CFRP retrofitted columns. Note that both 3 and 6mm PP were less stiff than the 1 layer CFRP used. The control specimen failed in the test under 246N impact weight with a drop height of 30cm, but the 1 layer CFRP strengthened specimen remained intact after test with the same drop parameters. Xiao and Shen (2012) reported a set of axial impact tests of concrete-filled steel tubes (CFT) and CFRP-confined CFT columns with different impact energies. The latter were wrapped with two to four layers of 0.11mm CFRP confined in hoop direction. The results indicated that the failure patterns were related to the impact energy, the steel tube thickness and additional CFRP strengthening. An increase in the confinement enhanced the impact resistance of the columns.

FRP Retrofitted Concrete Slabs

Many studies have been conducted on the blast and impact behavior of FRP strengthened RC slabs. Silva and Lu (2007) examined the feasibility of using CFRP and steel fiber reinforced polymers (SRP) for strengthening on either one side only or both sides. It was observed that slabs retrofitted with CFRP on both sides exhibited better blast resistance than that retrofitted on only one side mainly because the former has better resistance against negative bending moment due to rebounding. Slabs retrofitted with the SRP behaved in a similar manner. Wu et al. (2007) strengthened one-way RC slabs with near surface mounted (NSM) CFRP strips on either the tensile or compressive face. The test results indicated that the NSM retrofitting technique was effective for increasing the flexural capacity of RC slabs. Based on the limited test results, it was shown that tensile face NSM CFRP strips did not increase the blast resistance, but the compressive face NSM CFRP strips enhanced the energy absorption capacity. Razaqpur *et al*. (2007) investigated the blast performance of RC slabs retrofitted with two cross-layered 500*mm* wide GFRP strips covering the middle half of the slabs on both sides. The test results were mixed: the GFRP retrofitted slabs had either higher or lower residual strength than the control specimens depending on the charge and stand-off distance. Garifield *et al*. (2011) conducted a similar

study with slabs bonded with two layers of GFRPs orthogonal to each other. The test results indicated that the GFRP strengthening reduced the fragmentation, cracking and damage. Slabs with thicker GFRP strengthened exhibited significantly less damage, fragmentation and crack width. Razaqpur *et al*. (2007) observed no GFRP delamination, but Garifield *et al*. (2011) observed GFRP delamination from the whole back face of the RC slabs, while it remained bonded in the front face, which might be due to the different charge weights and stand-off distances used in the two studies.

Attention has also been paid to FRP strengthening of RC slabs under both low speed (1-6m/s) impact and high-speed (92-158m/s) penetration. Bhatti *et al*. (2011) conducted a series of falling-weight low speed impact tests one-way slabs. All the slabs were retrofitted with FRP sheets bonded on the bottom face. The results showed that all the strengthened slabs performed better than the reference un-strengthened ones. Slabs with bi-directional aramid fiber reinforced polymer (AFRP) strengthening had both higher static and dynamic loading capacities than those with uni-directional AFRP/CFRP sheets, because the former could more effectively restraint the development of the bi-directional crack pattern experienced in the slabs. Almusallam *et al*. (2015) conducted a series of high velocity penetration tests using rigid hemispherical nosed 0.8kg steel projectiles and corresponding finite element (FE) analysis of both un-strengthened and CFRP strengthened one way RC slabs. The strengthening system included one layer of unidirectional CFRP sheet on the bottom face with fibres in the slab span direction. The CFRP strengthening was found to increase the ballistic limit velocity by 18% and perforation the energy of RC slabs by 57%, reduce the front damage crater and contain concrete fragmentation at the lower face.

FRP Retrofitted Concrete Beams

Very limit research on FRP strengthened beams under blast has been conducted. To the best knowledge of the authors, only Ross et al. (1997) tested six simply supported RC beams, which has been reviewed in Buchan and Chen (2007). In contrast, a number of studies have been conducted on beams under impact loading (Erki and Meier 1999, Tang and Saadatmanesh 2003, Kabir and Shafei 2009).

Erki and Meier (1999) tested a number of RC beams strengthened with CFRP laminates or steel plates (with similar tensile capacity to CFRP) at the tensile face. The beams were tested by raising one end and then dropping from a specified height. The test results showed that under the same drop height, the CFRP strengthened beams had smaller deflections compared with the un-retrofitted reference beam, whereas the external steel plate yielded before the maximum deflection was attained resulting in larger mid-span deflection for the steel plated beams than the CFRP strengthened ones. CFRP debonding was observed, suggesting that additional anchorage of the CFRP laminates would improve the efficiency of the strengthening. Steel plate strengthening provided a higher energy absorption capacity than CFRP strengthening due to yielding. Tang and Saadatmanesh (2003) tested RC beams strengthened with CFRP or Kevlar composites bonded to the top and bottom faces for resisting impact. The impact load was applied by dropping a steel cylinder onto its top face. The test results revealed that both CFRP and Kevlar composite strengthening significantly increased the impact resistance and reduced the maximum deflection compared with the un-retrofitted control beams at the same drop height. The gain from FRP strengthening depends on the type, thickness, weight, and material properties of the composite laminate. The stiffer CFRP strengthening resulted in smaller deflections. Both CFRP and Kevlar composite strengthening reduced the number of cracks and crack width. Kabir and Shafei (2009) conducted both analytical and FE analyses of FRP retrofitted RC beams under low velocity impact. The analytical analysis based on the idealized elastic spring-mass model and flexural wave propagation theory showed that externally bonded CFRP can significantly enhance the impact resistance of the beams with reduced maximum deflection and increased maximum impact loading capacity. The FE analysis results showed that CFRP strengthening increased the initial and residual stiffness and the CFRP strengthened beam is more ductile than the un-retrofitted ones due to an increase of the number of flexural-shear cracks. Concrete cover separation failure is highly probable for CFRP retrofitted slender beams, but for deeper beams with smaller span to depth ratios debonding of CFRP is less critical.

SEISMIC BEHAVIOUR OF FRP-STRENGTHENED STRUCTURES

Earthquake resistance of structures is usually evaluated by the loading capacity, stiffness, deformability of the whole structures or critical structural members, and energy absorption capacity. A huge amount of research has been conducted in seismic retrofitting of existing concrete structure using FRP.

FRP- Strengthened RC Columns

Numerous studies have been devoted to the seismic performance of FRP strengthened RC columns because they are particularly vulnerable to failure in earthquakes (Teng et al 2003). The envelop extracted from the stress-strain curves of FRP wrapping columns under cyclic axial compression is close to the stress-strain response of monotonically loaded FRP wrapping columns (Lam *et al*. 2006, Abbasnia and Ziaadiny 2010, Ozbakkaloglu and Akin 2012, Wang *et al*. 2012). When a column is subjected to seismic loading, its energy absorption capacity, rather than its load capacity is the main concern. RC columns can be strengthened with either partial or continuous FRP wrapping in the potential plastic hinge zones at the top and bottom, or along the full height (Parvin and Brighton 2014). Numerous studies have concluded that the FRP wrapping of concrete columns can significantly enhance both strength and ductility (Parvin and Wang 2002, Ozcan *et al*. 2008, Wu *et al*. 2008, Lam and Teng 2009, ElSouri and Harajli 2011).

The energy dissipation capacity of retrofitted columns is influenced by FRP jacket confinement stiffness (Promis *et al*. 2009, Gu *et al*. 2010), the axial load ratio (Ozbakkaloglu and Saatcioglu 2007, Gu *et al*. 2010, Zhou *et al*. 2013a) and the aspect ratio of the column section (Ozbakkaloglu and Saatcioglu 2007, Gu *et al*. 2010, Bui *et al*. 2015). The improvement of the strength and ductility capacity by using FRP wrapping the full height of columns is not in proportion with that contributed from FRP wrapping in the potential plastic hinge locations (Parvin and Brighton 2014).

An increase in energy dissipation due to FRP wrapping means an increase of ductility and thus increased sectional curvature capacity and inter-storey drift capacity (Wu *et al*. 2008, Gu *et al*. 2010, Goksu *et al*. 2012, Pantelides and Moran 2013, Parvin and Brighton 2014), because the drift capacity of columns is dominated by the plastic hinge length and the section curvature (Ozbakkaloglu and Saatcioglu 2007, Gu *et al*. 2010, Parvin and Brighton 2014). FRP wrapping can also prevent buckling of longitudinal reinforcement, and reducing the damage in non-seismically designed RC columns (Wu *et al*. 2008, Gu *et al*. 2010, Goksu *et al*. 2012,Pantelides and Moran 2013, Parvin and Brighton 2014).

The formation and expansion of inclined cracks were effectively delayed by the actively confined stress from the FRP wrapping. As a consequence, the failure mode of a strengthened column often changes from brittle shear failure to flexural failure or flexural-shear failure (Bailey and Yaqub 2012, Goksu *et al*. 2012, Zhou *et al*. 2013a).

The FRP retrofitting technique is less effective for RC columns in near-fault ground motion compared with far-fault ground motion because the plastic hinge length in FRP strengthened RC column subjected to near-fault motion is shorter (Fakharifar *et al*. 2015).

FRP-Strengthened Concrete and Masonry Walls

Concrete and masonry walls can be subjected to shear force both in the in-plane and out-of-plane under seismic action. The FRP strengthening system can significantly improve the strength, displacement capacities and energy dissipation ability for concrete and masonry walls (ElGawady *et al*. 2007, Hamed and Rabinovitch 2008, Capozucca 2011, Konthesingha *et al*. 2013, El-Sokkary and Galal 2013, Umair *et al*. 2015), and it is especially effective for masonry walls (Hamed and Rabinovitch 2008, Bui *et al*. 2015). If sufficient FRP strengthening is applied, the failure can change from a shear dominant mode to a flexural dominant mode. Note that the FRP strengthening would not make a significant difference in the initial stiffness of walls (Zhou *et al*. 2013b, Umair *et al*. 2015).

Cruz-Noguez *et al*. (2015) showed that FRP strengthening is effective for increasing loading capacity, ductility and energy dissipation capacity of RC shear walls. It has also been shown that the application of a hybrid FRP-modified mortar strengthening system leads to better ductility but lower strength than the externally bonded FRP alone for both masonry and RC walls (Papanicolaou *et al*. 2011, Todut *et al*. 2015, Umair *et al*. 2015, Bui *et al*. 2015). Appropriate application of anchorage systems can allow the FRP to develop its ultimate tensile strength without premature debonding and this signficantly improves the strengthening efficiency (El-Sokkary and Galal 2013, Cruz-Noguez *et al*. 2015, Todut *et al*. 2015, Umair *et al*. 2015).

FRP-Strengthened Beam-Column Joints

Failure of beam-column joints has been identified as the prime cause of collapse for many moment-resisting frame buildings. A large number of studies have been carried out to investigate the seismic performance of

beam-column joints strengthened using FRP systems. The FRP strengthening for exterior or interior beam-column joints can be usually classified in six schemes: (a) L-shape overlay on the beam-column joint (Li and Chua 2009, Attari *et al*. 2010, Li and Kai 2011, Fakharifar *et al*. 2014,), (b) column wrapping (Pantelides *et al*. 2008, Li and Kai 2011, Fakharifar *et al*. 2014 , Realfonzo *et al*. 2014), (c) column and beam wrapping (Li and Chua 2009, Sasmal *et al*. 2011, Akguzel and Pampanin 2012, Agarwal, *et al*. 2014, Hadi and Tran, 2015), (d) column warping in addition to U-shape external bonding under beam (Al-Salloum and Almusallam, 2007, Li and Chua 2009, Alsayed *et al*. 2010, Alhaddad *et al*. 2012, Fakharifar *et al*. 2014,), (e) web-bonded FRP (Pantelides *et al*. 2008, Li and Kai 2011, Fakharifar *et al*. 2014, Realfonzo *et al*. 2014), (f) near surface mounted FRP on beam and/or column (Sasmal *et al*. 2014). These schemes may be jointly applied in order to dramatically improve the seismic performance of the joints (Li and Kai 2011).

Hinge failure in the beam is usually the preferable failure mode for beam-column joints. FRP wrapping of the beams in the joint vicinity has been found to be efficient and essential for a ductile response of retrofitted frames because it enables the formation of plastic hinges in the beams to achieve an energy dissipation mechanism (Fakharifar *et al*. 2014). However, care must be exercised for such a strengthening scheme because the most common failure mode in the experimental studies is the shear failure in the joint if the beam and column are properly strengthened (Pantelides *et al*. 2008, Del Vecchio *et al*. 2014), and the failure mode can turn to the catastrophic column failure if the FRP strengthening results in a strong-beam weak-column system (Bousselham 2010).

It is generally agreed that the application of externally bonded FRP can improve the shear resistance, ductility and energy dissipation of beam-column joints. It makes little difference for the initial stiffness of the joint but leads to a more gradual stiffness degradation after the appearance of the first crack in the joint (Mahmoud *et al*. 2014, Del Vecchio *et al*. 2015, Hadi and Tran 2015). The application of an appropriate anchorage system can delay or prevent the premature FRP debonding failure and this significantly improves the effectiveness of FRP strengthening (Li and Chua 2009, Sasmal *et al*. 2014).

FRP- Strengthened RC Frame Structures

As FRP strengthening can enhance the capacity and ductility of RC beams, columns and joints, it can naturally be used to retrofit RC frames to enhance their seismic performance. For example, FRP shear reinforcement (wraps) may be deployed to prevent the shear failure of columns and FRP flexural reinforcement of columns may be used to reduce drift ratios of a frame structure, leading to enhanced strength and ductility (El-Sokkary and Galal 2009, Choi *et al*.2014). An important topic of research is the choice of appropriate choice strengthening schemes and locations for optimal performance of the whole structure (Zou *et al*. 2007).

In design of seismic resistant RC frame structures, the principle of weak beam-strong column is usually followed in order to ensure that plastic hinge occurs in the beams so that frame is capable of dissipating significant energy while remaining stable (Mahini and Ronagh 2011, Cao and Ronagh 2014). If a frame structure does not satisfy a given seismic design standard, appropriate FRP strengthening may be employed to rectify the problem (Cao and Ronagh 2014, Hadigheh *et al*. 2014).

For low-rise RC frame structures, the relative strength of beams to that of columns is usually high, which can result in column failures. FRP strengthening of columns is usually effective in increasing the peak ground acceleration (PGA) of the structure and its maximum drift capacity (Galal and El-Sokkary 2008). For medium and high rise RC frame structures, the relative strength of beams to that of columns is usually low, which can lead to failure in beams. FRP strengthening of beams is effective in increasing the PGA of the structure and its drift capacity (Galal and El-Sokkary 2008).

Similar to RC columns, the FRP strengthening technique is also less effective for frame structures in near-fault ground motion than far-fault ground motion (Cao and Ronagh 2014).

FATIGUE BEHAVIOUR OF FRP STRENGTHENED CONCRETE STRUCTURES

Many concrete structures such as crane girders and bridge are subjected to fatigue loading. For FRP strengthening of these structures, the fatigue behaviour is often of concern. This section presents a review of the fatigue behaviour of concrete beams strengthened with externally bonded FRP.

Fatigue Behaviour of FRP-Concrete Interface

Existing research has shown that the bond interface between FRP and concrete in concrete beams strengthened with externally bonded FRP plays a crucial role (Chen and Teng 2001). FRP debonding failure is very frequently observed in these structures under both static and fatigue loadings. Although extensive research has been conducted to investigate the behaviour of the FRP-concrete bond interface, the vast majority of the work has been concerned with monotonic static loading. Only a very limited studies have been concerned with the bond behaviour under cyclic loading (which can due to seismic excitations or traffic loads) (Martinelli and Caggiano 2014). Experimental study of the bond fatigue behaviour is usually undertaken using the single shear, double shear, or bending test. (Chen et al. 2001, Chen et al. 2012, Xie et al. 2015).

Failure mode

Two typical fatigue failure modes occur in a FRP-concrete bond system: FRP fracture and FRP debonding. For pure shear tests, FRP rupture usually occurs when the maximum applied cyclic stress approaches the static bond strength of the FRP (Bizindavyi *et al*. 2003) at the loaded end where local bending is evident (Chen et al. 2001). For the bending test, FRP rupture usually occurs near the transverse crack where high stress concentration is present (Xie *et al*. 2015). FRP debonding is the most common failure mode for the FRP-concrete interface under cyclic loading (Bizindavyi *et al*. 2003, Ferrier *et al*. 2005, Ko and Sato 2007, Yun *et al*. 2008, Diab *et al*. 2009, Mazzotti and Savoia 2009, Nigro *et al*. 2011, Carloni *et al*. 2012, Carloni and Subramaniam 2013, Xie *et at*. 2015). The debonding failure occurs generally in the concrete at a few millimetres away from the concrete-to-adhesive surface (Yun *et al*. 2008, Kim and Heffernan 2008). Failure in the adhesive is rare because the tensile strength of adhesive is usually much higher than that of the concrete.

Fatigue load-slip response of FRP-to-concrete bond interface

A number of experimental and theoretical studies have been concerned with the fatigue load versus the loaded-end slip response of the bond interface (Bizindavyi *et al*. 2003, Ko and Sato 2007, Diab *et al*. 2009, Carloni *et al*. 2012, Carloni and Subramaniam 2013, Marinelli and Caggiano 2014, Carrara and Lorenzis 2015). These studies have shown that the stiffness of the bond load-slip response decreases as the number of fatigue cycles increases due to the propagation of fatigue damage along the interface. The rate of stiffness reduction is affected by the fatigue load level, e.g., rapid deterioration is experienced under a high cyclic stress (Bizindavyi *et al*. 2003).

Fatigue life

The fatigue life of a FRP-concrete bond interface is affected by the modulus of elasticity of FRP, the concrete strength, the cross-sectional area of FRP and the FRP bond length. The fatigue life increases with an increase of these parameters. It should be noted that when the bond length is larger than the effective bond length, the static bond capacity of FRP-concrete interface is constant (Chen and Teng 2001), but the fatigue life increases with the FRP bond length (Bizindavyi *et al*. 2003) because a longer bond length takes more cycles for the fatigue crack to propagate. Based on experimental observations, the debonding process can be divided into three stages: rapid propagation, stable propagation and unstable failure (Diab *et al*. 2009, Bizindavyi *et al*. 2003). The first and second stage cover about 90% of the fatigue life.

It may be noted that Diab *et al*. (2009) concluded that no failure occurred for specimens if the maximum fatigue loading is less than 60% of the static bond capacity of the FRP-concrete bond interface, but Iwashita *et al.'s* (2007) test results indicated that debonding failure occurred if the maximum fatigue loading was over 30% of the static loading capacity.

Post-fatigue behaviour

Some experimental studies have been conducted to investigate the post-fatigue monotonic behaviour of FRP-concrete interface. Yun et al. (2008) showed that the post-fatigue bond strength under monotonic static load was not influenced by the fatigue damages if a sufficient intact bond length was still available. Similar observations were also reported by Ko and Sato (2007), Diab *et al*. (2009) and Mazzotti and Savoia (2009). However, after high-level fatigue loading, the FRP-concrete has a significant reduction in the bond stiffness under monotonic loads (Yun *et al*. 2008). This is understandable as the fatigue loading has resulted in to damage to the interface.

Fatigue Behaviour of FRP-Strengthened RC Beams

Many studies have been conducted to investigate the performance of FRP-strengthened concrete members subjected to fatigue loading, but only the fatigue behaviour of RC beams flexurally strengthened with FRP laminates is discussed in this section. Kim and Hefferan (2008) and Oudah and El-Hacha (2013) produced two comprehensive reviews of the fatigue behaviours of RC beams flexurally strengthened with FRP laminates.
The fatigue failure process of FRP-strengthened beams can usually be described in three stages: cracks initiation, stable damage, and unstable failure (Xie *et al*. 2012). In generally, the first phase covers about 3% to 5% of the fatigue life. Rapid stiffness degradation of the beam is experienced in this stage. The second stage covers about 90% of the fatigue life during which little change in the deformation of the beam is experienced. The third stage is a rapid failure stage, in which the tensile steel fractures first followed by FRP debonding or rupture (Xie *et al*. 2012).

The most commonly observed fatigue failure mode of FRP strengthened beams is the rupture of the tensile reinforcing steel followed by FRP debonding or FRP rupture. In such a failure mode the fatigue failure of the beam is primarily governed by the fatigue life of the steel reinforcement, rather than the concrete or FRP (Barnes and Mays 1999; Masoud *et al*. 2001; El-Hacha *et al*. 2003; Aidoo *et al*. 2004; Heffernan and Erki 2004; Brena *et al*. 2005; Toutanji *et al*. 2006). However, in all previously reported studies, some extent of debonding of the FRP from the concrete substrate has been observed. Once local debonding occurs, some of the stress carried by the FRP is redistributed back to the internal reinforcing steel in the regions of debonding. This implies that there may be complicated interactions between FRP debonding with steel stress under fatigue loading which requires further research.

SUMMARY

External bonding of FRP composites has become a very popular technique for strengthening concrete structures and much of recent research has been concerned with the applications of this technique for retrofitting concrete structures under extreme actions. This paper has presented a brief review of recent research on FRP strengthened concrete structures under some extreme actions including blast, impact, earthquake and fatigue. The main conclusions may be summarised as follows, together with recommended further research:
1. Although some studies have been conducted on the blast and impact behaviour of FRP strengthened structures, much of the understanding is still qualitative. A significant amount of further research is required to advance quantitative understanding of the behaviour of such strengthened structures leading to rational design methods.
2. The fatigue life of the FRP-concrete interface increases with an increase of the elastic modulus of FRP, concrete strength, cross-sectional area of FRP and bond length of FRP. If a sufficient intact bond length is still available, the fatigue history does not influence the debonding load capacity of the FRP-concrete interface under post-fatigue monotonic loading. Further research is required to establish a more precise bond-slip model to evaluate the fatigue damage of the bond interface. This would lead to improved understanding and thus more rational design of structures under seismic and other cyclic actions.
3. Numerous studies have been contributed to seismic strengthening of concrete structures. Whilst it is well understood that externally bonded FRP is very effective for seismic retrofitting of concrete structures, further research is required on the optimal strengthening schemes and mechanisms for beam-column joints, and how to choose the optimal strengthening schemes, locations and amount of material in order to achieve the best retrofitting of complex structures such as frames.
4. The most commonly observed fatigue failure mode of FRP strengthened beams is the rupture of the tensile reinforcing steel bars followed by FRP debonding or FRP rupture. Some extent of debonding of the FRP from the concrete substrate usually occurs before the ultimate failure which may lead to stress re-distribution between FRP and steel. The role of the FRP debonding is not clear yet with respect to the overall fatigue behaviour of the strengthened RC beam. Therefore, further research is needed to investigate of the relationship between FRP debonding with steel stress under fatigue loading leading to improved design mythologies.

ABSTRACT

Relaxation is a key factor controlling the application of prestressing tendons. This paper focuses on the relaxation behavior of newly developed BFRP tendon for prestressing applications. A series of relaxation tests on BFRP tendons with three different initial stresses of 0.4 f_u 0.5 f_u and 0.6 f_u (f_u = tensile strength) were first conducted through a specially designed setup to eliminate the adverse impact of slippage at anchor zone. Theoretical value of relaxation rate based on an existing theory was calculated. An additional group of test was designed to clarify the effect of pretension on the relaxation behavior. The results show that the setup can effectively measure the relaxation loss of specimen, with monitoring the slippage at anchor zone simultaneously. Higher stress level can lead to larger relaxation loss. Theoretically calculated value of relaxation rate is consistent with the experimental results. The relaxation rates of BFRP tendon at 1000 h are 4.2 %, 5.3 % and 6.4 % under 0.4 f_u, 0.5 f_u and 0.6 f_u, respectively. Pretension performs effective for the controlling of relaxation loss. Specimens with pretension treatment behave only 2.6 % relaxation rate under 0.5 f_u at 1000 h, comparable to the relaxation rate of prestressing steel strand under 0.7 f_u at 1000 h (2.5 %). The load retentions at one million hours are predicted to be 93.8 %, 91.8 % and 90.0 % for BFRP tendons under 0.4 f_u 0.5 f_u and 0.6 f_u, respectively. Also, a load retention of 93.3 % is predicted for BFRP tendon with pretension treatment, under 0.5 f_u, at one million hours.

Basalt fiber-reinforced polymer (BFRP) tendon, relaxation, prestressing, pretension, prediction

INTRODUCTION

Fiber-reinforced polymer (FRP) composites have been treated as competitive alternatives for structural strengthening, retrofitting, and members in new construction (Triantafillou 1998; Buyukozturk and Hearing 1998) owing to their integrated advantages compared to steel such as high strength, light weight and corrosion resistance. Among the wide application fields of FRP in civil engineering, tension-only prestressing tendon is considered to be the most efficient way because of its high strength only in the longitudinal direction of the fibers. Basalt FRP (BFRP) was newly developed (Wu et al. 2012) and its potential advantages in structural

reinforcement have been gradually recognized (Wang et al. 2013; Shi et al. 2013). The most significant advantage of BFRP is its superior creep behavior, displaying a creep rupture limit of 0.52 f_u (f_u = ultimate strength) (Wang et al. 2014). This property allows BFRPs to be used as competitive prestressing members to carbon FRP (CFRP) and aramid FRP (AFRP), whose creep rupture limit are 0.70 f_u and 0.55 f_u, respectively (ACI 2004). Apart from creep rupture, relaxation is also an important factor, determining the prestressing effect of tendons on prestressed structures. Systematical researches on relaxation behavior of CFRP and AFRP have been done (Saadatmanesh and Tannous 1999a and 1999b), which showed that the relaxation losses were predicted to be 5.87 % and 10.9 % for CFRP and AFRP tendons respectively, after 50 years, under 0.4 f_u. However, systematical and comprehensive researches on relaxation behavior of BFRP have not been found in the exist literatures. Thus, a comprehensive understanding of the relaxation behavior of BFRP is critical for the application of BFRP as prestressing members.

EXPERIMENTAL PROGRAM

Specimen Preparation

BFRP tendons with nominal diameter of 6 mm were adopted in the current study. The tendons were manufactured by using unidirectional basalt fiber roving of 2400 tex and vinyl ester resin through pultrusion. The fiber volume fraction of the BFRP tendon was approximately 65 %, and the total length of each specimen was 1260 mm. The two ends were treated by sand blasting and anchored with seamless steel tubes with outer diameter of 16 mm and thickness of 3 mm. For the relaxation test, the cross sections of the steel tubes at the loading end were processed to be flat, to guarantee their smooth contact with the steel plates in relaxation loading setup. For short-term tensile test, anchorage length was 300 mm, while for relaxation test, anchorage lengths were determined to be 200 mm for specimens with initial stress of 0.4 f_u or 0.5 f_u, and 230 mm for specimens with initial stress of 0.6 f_u. Epoxy resin was used to fill the gap between the steel tube and the BFRP tendon, and the resin was allowed to cure for seven days to ensure achieving sufficient strength.

Loading Setup

The short-term tensile test was conducted on electronic creep tension testers RD-200 with a load capacity of 200 kN (Figure 1(a)). The deformation of each specimen was measured simultaneously by an extensometer with a gauge length of 120 mm (Figure 1 (c)).

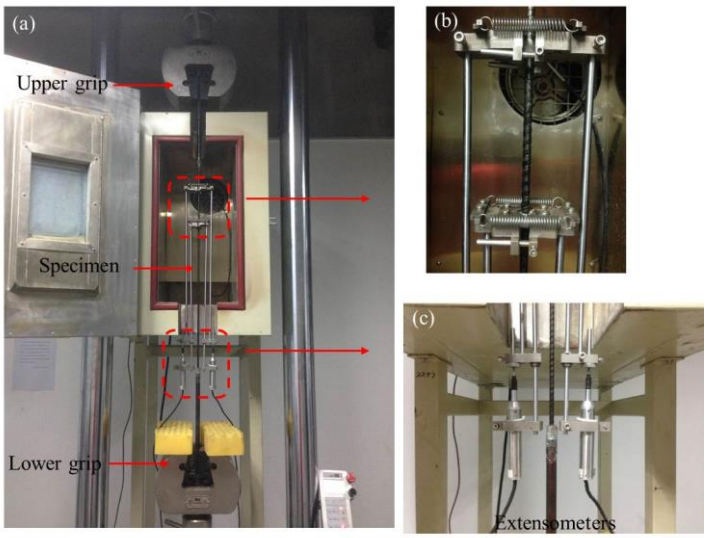

Figure 1 RD-200 tester and extensometers

For the long-term relaxation test, a set of reaction equipment was designed, as shown in Figure 2. The load was applied on the tendon, through a special loading screw. A load cell, with minimum resolution of 10 N, was set to monitor the load in tendon during both loading procedure and relaxation stage. Two aluminum sheets with thickness of 3 mm were fixed on the surface of tendon with epoxy glue near the anchorage to monitor the relative slippage between tendon and anchorage during the relaxation test. Two LVDTs were installed, in contact with the aluminum sheets, to measure the displacement caused by anchor slippage. The minimum resolution of LVDTs was 0.001 mm.

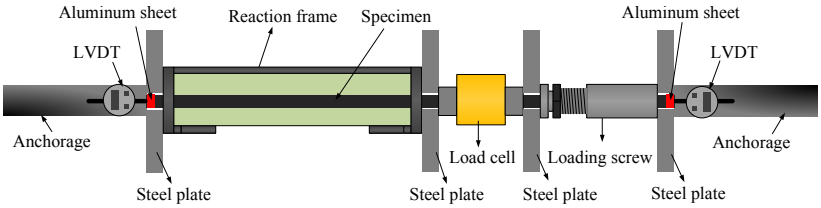

Figure 2 Loading setup for relaxation test

Loading Procedure

According to JSCE (1995a), for the short-term tensile test, the load was applied at a constant rate of 500 MPa/min until failure. The original data for load and deformation were recorded via a computer once every second. Five effective specimens without any failure at the anchorage zone were used to determine the tensile strength of BFRP tendons, which was used as reference for different levels of initial loads applied in the relaxation tests.

For the relaxation test, the load was applied on the tendon artificially by two wrenches, one was kept still on the loading screw and the other was used to twist the nut during loading procedure (Figure 3). The loading procedure lasted approximately 3 min. Initial stresses of 0.4 f_u, 0.5 f_u and 0.6 f_u were designed to investigate the relaxation behavior of BFRP tendon under different stress levels, according to JSCE (1995b). To clarify the effect of pretension, another series of test were conducted on the specimens with initial stress of 0.5 f_u, after pretension of

0.6 f_u level and 3 h duration, which was validated to be the optimum pretension treatment for BFRP tendon (Shi et al. 2015). Three specimens were prepared for each test group according to JSCE (1995b).

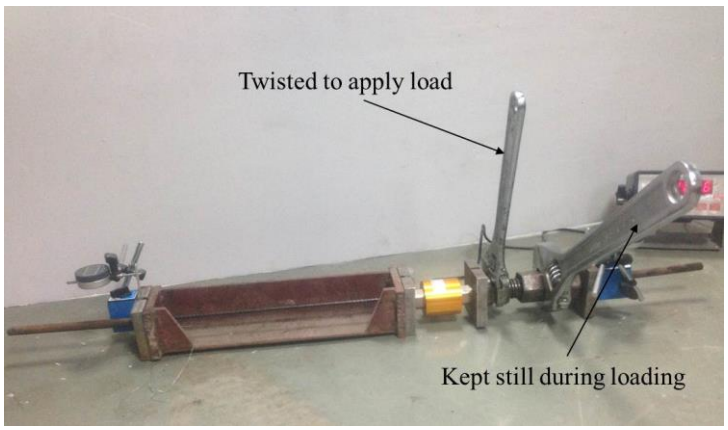

Figure 3 Loading for relaxation test

According to JSCE (1995b), the data of load and displacement were recorded at the following times: 1, 3, 6, 9, 15, 30, and 45 min; and 1, 1.5, 2, 4, 10, 24, 48, 72, 96, and 120 h. Subsequent measurements were conducted once every 120 h. Duration for each relaxation test was determined to be 1000 h.

RESULTS AND DISCUSSIONS

Short-term Tensile Property

The failure mode of the BFRP tendon is shown in Figure 4, displaying a typical dispersed failure of fibers in the FRP tendon. The results of the ultimate tensile properties are shown in Table 1. In reference to the results, the ultimate tensile strength of the BFRP tendons was determined to be 1500 MPa with a 95 % strength guarantee through Eq. 1 according to GB 50608-2010.

$$f_k = \mu_f (1 - 1.645\delta_f) \tag{1}$$

where f_k, μ_f and δ_f represent the standard value, mean value and coefficient of variation (CV) of ultimate strength, respectively. f_k serves as f_u in the following results and discussions.

Figure 4 Failure mode of short-term tensile test

Table 1 Test results of tensile properties

	Mean value	Coefficient of variation (CV)	95 % guaranteed strength
Ultimate Strength (f_u)	1571 MPa	2.74 %	1500 MPa
Elastic modulus (E)	55 GPa	1.36 %	
Fracture strain (ε_u)	2.87 %	3.14 %	

Relaxation Curves

Considering the slippage of specimens at two anchorages, the axial load in specimen was modified through Eq. 2.

$$F = F_0 + EA(d_1 + d_2)/l \tag{2}$$

where F = modified load; F_0 = measured load; E = elastic modulus; A = cross-sectional area; d_1 and d_2 = displacements measured by the two LVDTs; l = distance between the two monitoring points.

The relation curves of load retention (ratio of the modified load to initial load, in percentage) against time, i.e. the relaxation curves, are shown in Figure 5. The curves under different initial stresses perform similar tendency, which can be divided into two stages. During the first stage, an initial rapid decrease of stress in the specimen can be observed. Then, the rate of relaxation loss gradually decreases with respect to time. That tendency of relaxation loss is caused by straightening of the originally uneven fibers. The specimen performs a stable and slow rate of relaxation loss during the second stage. At this stage, fibers are straightened and relaxation loss can be controlled. Some slight fluctuations can be seen in the relaxation curves, which are caused by the difference of thermal expansion rate between steel frame and BFRP tendon. The thermal deformations of specimen and steel frame are not synchronous when ambient temperature varies.

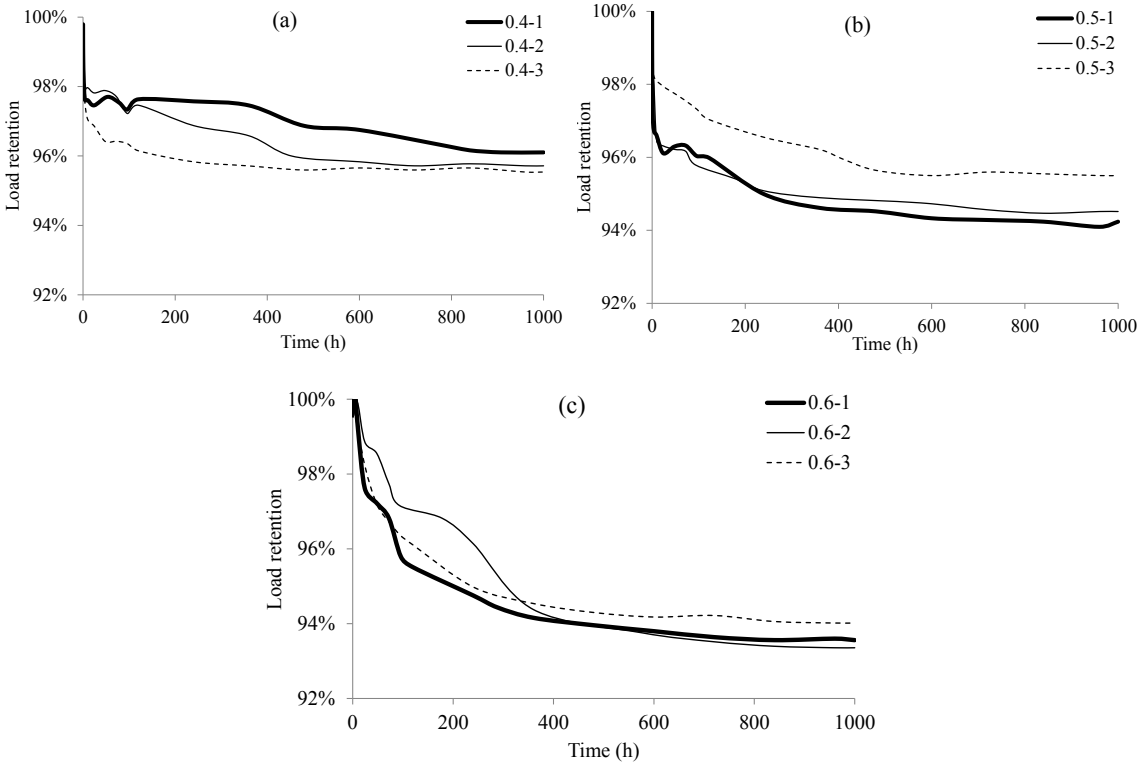

Figure 5 Relaxation curves under (a) 0.4 f_u; (b) 0.5 f_u; (c) 0.6 f_u

Effects of Initial Stress

The relaxation rates of BFRP tendon specimens with different initial stress levels are shown in Figure 6. The relaxation rate increases in direct proportion to the stress level. At 1000 h, the relaxation rates are 4.2 %, 5.3 % and 6.4 %, for the stress level of 0.4 f_u, 0.5 f_u and 0.6 f_u. Higher stress level leads to larger viscoelastic strain in BFRP tendon, resulting in larger stress loss, as speculated from Eq. 3.

$$\sigma = E \cdot \varepsilon_{total} - E \cdot \varepsilon_v(\sigma, t) \tag{3}$$

where σ = stress in tendon; ε_{total} = total strain, equal to the sum of elastic and viscoelastic strain; ε_v = viscoelastic strain, associated with stress (σ) and time (t).

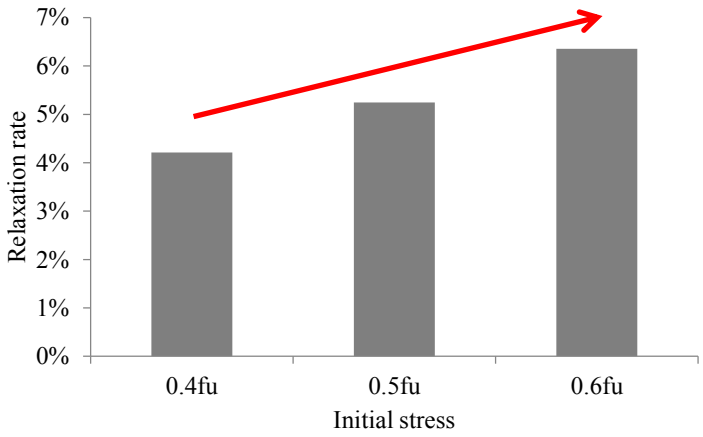

Figure 6 Relaxation rate of BFRP tendon at 1000 h

Theoretical Relaxation Rate

Theoretically, the relaxation rate can be calculated from Eq. 3, with known viscoelastic strain of specimen during 1000 h, which has been obtained by the previous research on creep behavior of BFRP tendon (Wang et al. 2014). The reduction of stress during relaxation should be taken into consideration. The viscoelastic strain is also considered to be in direct proportion to the square of stress (Wang et al. 2014). Iterative calculations were conducted at 1, 5, 10, 20, 40, 60, 80, 100, 500, 1000 h. The theoretical relaxation rate in the current study is calculated to be 5.0 % at 1000 h under 0.5 f_u, with only 5.7 % relative error compared to the experimental value.

Effects of Pretension

Pretension has been validated to be effective for creep strain controlling (Shi et al. 2015, Wang et al. 2015). Similarly, as shown in Figure 7, relaxation rate can also be effectively controlled through pretension. Pretension facilitates the straightening of uneven fibers, creating an opportunity for fibers to realize better cooperation. Furthermore, as can be seen from Figure 7, there is a slight increment of load at the beginning of relaxation after pretension treatment (0.6 f_u and 3 h). This phenomenon is caused by elastic aftereffect, defined as the gradual restoration of deformation after unloading, which can also be observed in concrete material. The above results further validate the effectiveness of pretension on relaxation controlling. The whole relaxation curves of 1000 h of specimens with pretension are shown in Figure 8, in which, P-0.5 denotes the test group with initial stress of 0.5 f_u after pretension. The relaxation rates of the three specimens are 2.5 %, 2.7 % and 2.7 % at 1000 h,

comparable to the low relaxation of prestressed steel strand, equal to 2.5 % under 0.7 f_u (JGJ/T 279-2012).

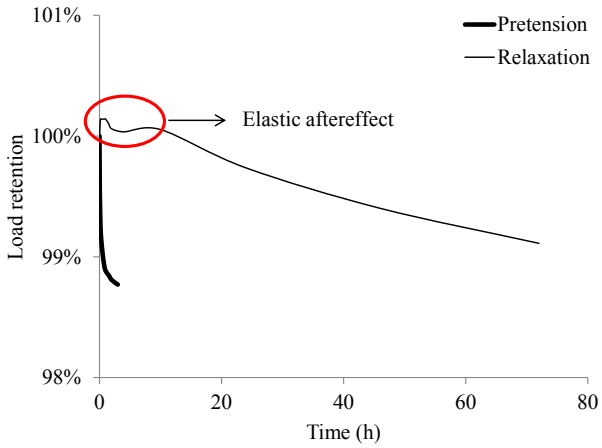

Figure 7 Relaxation controlling effect of pretension

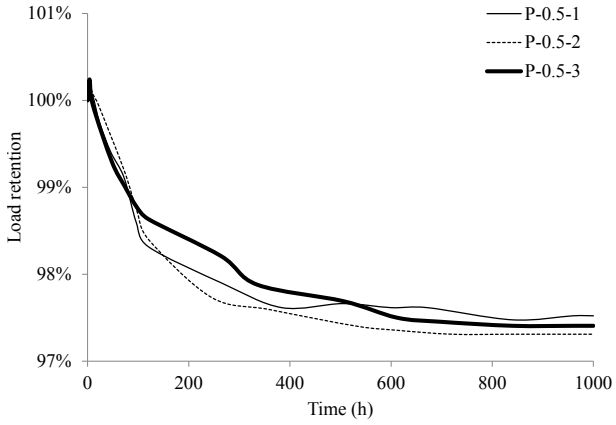

Figure 8 Relaxation curves for specimens after pretension

Prediction of Load Retention at One Million Hours

According to JSCE (1995b), the relaxation curve can be fitted with a logarithmic curve, in the form of Eq. 4.

$$R_r = a - b \ln t \tag{4}$$

where R_r = load retention rate, %; a, b = empirical constants; and t = test time, h.

Through fitting the relaxation curves, the predicted value of load retention at one million hour (114 years) can be figured out, as shown in Table 2. It is noteworthy that since the slight increase of relaxation curve at beginning, the curve fitting of specimens with pretension was conducted using the data after 10 h, otherwise, the regression coefficient will be excessively low. Under a stress level of 0.4 f_u, the load retention is predicted to be 93.8 % at one million hours. The load retention at one million hours for CFRP tendon (Leadline) under 0.4 f_u is predicted to be 89.5 % using the formula proposed by Saadatmanesh and Tannous (1999 b). The lower load retention of CFRP tendon may be caused by the inevitable long-term anchor slippage in Saadatmanesh and Tannous's test, demonstrating the effectiveness of the setup for relaxation test in this study. BFRP tendon with pretension treatment behaves 93.3 % load retention, close to that under 0.4 f_u.

Table 2 Predicted mean values of load retention at one million hours

Initial stress	0.4 f_u	0.5 f_u	0.6 f_u	0.5 f_u (with pretension)
Mean value	93.8 %	91.8 %	90.0 %	93.3 %

CONCLUSIONS

This paper investigated the relaxation behavior of BFRP tendon. Relaxation tests were conducted under 0.4 f_u, 0.5 f_u and 0.6 f_u. Theoretical relaxation rate was calculated. The method for relaxation controlling was proposed and validated. Values of load retention at one million hours were predicted. The main conclusions can be drawn as follows.

(1) The proposed specially designed setup for relaxation test has the capability of reflecting the real relaxation loss in FRP tendon by eliminating the influence of slippage at anchor zone.

(2) The relaxation rate increases in direct proportion to the stress level. At 1000 h, the relaxation rates are 4.2 %, 5.3 % and 6.4 %, under the stress level of 0.4 f_u, 0.5 f_u and 0.6 f_u.

(3) Relaxation rate can be theoretically calculated through viscoelastic strain of the material under certain stress level, obtained by creep test. The theoretical and experimental values of relaxation rate at 1000 h show a satisfactory consistence.

(4) Pretension treatment performs effectiveness of controlling relaxation loss. The relaxation rate can be lowered to approximately 2.6 % at 1000 h under 0.5 f_u, comparable to the low relaxation of prestressed steel strand under 0.7 f_u (2.5 %), further showing a great potential of BFRP tendon as prestressing component.

(5) The values of load retention at one million hours are predicted to be 93.8 %, 91.8 % and 90.0 % under 0.4 f_u, 0.5 f_u and 0.6 f_u, respectively. A load retention of 93.3 % is predicted for BFRP tendon with pretension treatment, at one million hours under 0.5 f_u.

AXIAL COMPRESSION TESTS ON HYBRID FRP-STEEL-CONCRETE COLUMNS WITH HIGH-STRENGTH STEEL PLATES

ABSTRACT

The applications of high-strength steel (HSS) products to civil engineering structures have been limited by elastic local buckling, by the perceived lack of ductility, and by the perceived difficulties of welding such steels. Against this background, the authors have recently proposed a new hybrid column (i.e. High Strength Steel Plate-Concrete Filled FRP Tube or HSSP-CFFT) consisting of an outer FRP tube, a concrete in-fill and a number of encased high-strength steel plates that are connected to each other by bolted angle brackets at discrete elevations. The new column offers an ideal opportunity for the use of HSS plates in construction, with their high yield stresses being fully utilized and without welding (and therefore without welding residual stresses). In this paper, the rationale for the new column form together with its expected advantages is first explained. Results from a series of axial compression tests are then presented to confirm some of the expected advantages. The results demonstrated that the concrete in the tested specimens was very effectively confined, and that buckling of the steel plates was prevented by the encasing concrete up to and beyond the rupture of the FRP tubes, leading to full structural utilization of the construction materials and very ductile column responses.

KEYWORDS

High-strength steel, FRP, concrete, column, confinement, buckling.

INTRODUCTION

The use of high-strength materials is often preferred when reductions in structural self-weight and/or size are important. A significant number of studies (*e.g.* Rasmussen and Hancock 1995; Ban et al. 2013) have thus been conducted on high-strength steel (HSS) products, but their applications in civil engineering structures are rather limited at present. HSS typically refers to steel with a yield stress not lower than 450 MPa, although the HSS grades available vary in different countries (Li et al. 2013). A major limiting factor for HSS is that its high yield stress cannot be fully utilized due to buckling under compression (*e.g.* in columns). Efforts to prevent local buckling of structural columns include filling a steel tube with concrete (*i.e.* concrete-filled tube or CFT) or encasing a steel section (*e.g.* I-section) in concrete (Uy 2001; Pocock 2006). However, these techniques have had limited success for HSS sections: in the former columns, local outward buckling of the steel tube still occurs; in the latter columns, the concrete typically crushes under compression at an axial strain between 0.2% to 0.3%, which may be much lower than the yield strain of HSS. As a result, in both forms of columns, the HSS component can still buckle well before the yield strain is reached. Even when buckling occurs close to the yield strain, the subsequent response of the column is non-ductile, which is highly undesirable for structures designed for seismic resistance. Furthermore, fabricated steel sections require welding of the plate components, which adds to the fabrication cost especially for high strength steel.

Against the above background, the authors recently proposed a novel solution to the problem of local buckling by fully encasing high strength steel plates in concrete that is cast in an FRP confining tube. The resulting structural member, referred to hereafter as concrete-filled FRP tube with HSS plates (or HSSP-CFFT), consists of an outer FRP tube, a concrete in-fill and a number of encased high-strength steel plates (Figure 1). In the novel column, the FRP tube offers mechanical resistances primarily in the hoop direction to confine the concrete and to enhance the shear resistance of the column, while the steel plates act as the main longitudinal reinforcement. One novel aspect of the column is that no welding is involved to fabricate the high strength steel sections, thus reducing the fabrication and transportation costs. Importantly, it obviates the perceived difficulties with welding high strength steels among the structural engineering profession. The individual steel plates can be connected to each other by angle brackets at discrete locations to facilitate their placement inside the FRP tube prior to casting concrete. By doing so, the angle brackets also serve as (1) shear connectors between the steel plates and concrete for improved composite action; and (2) restraints to the individual plates leading to reduced buckling lengths. The other novel aspect of the column is that it allows the configurations of the steel plates to be optimized for particular applications, which may not be in the shape of traditional sections such as I-section.

The novel column may be constructed in-situ or precast, with the FRP tube acting as the stay-in-place form. The section form shown in Figure 1 consists of a circular outer tube and four steel plates, but many different combinations are possible (e.g. the outer tube can be square or rectangular, while more steel plates can be used to form a polygonal shape).

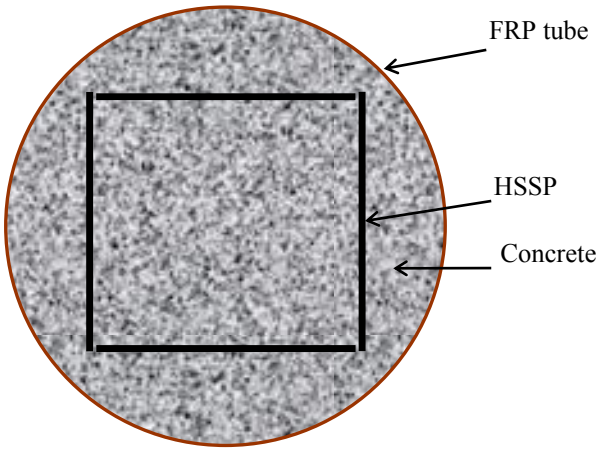

Figure 1 Typical cross-section of HSSP-CFFT

The main advantages of HSSP-CFFTs include: (1) excellent ductility, as the concrete is well confined by the FRP tube and local buckling of the steel plates are constrained by the concrete; (2) excellent corrosion resistance, as the FRP tube is highly resistant to corrosion while the steel plates are protected by the FRP tube and the concrete; and (3) ease for construction, as the FRP tube act as a permanent form for casting concrete, and the welding of high-strength steel plates is avoided in the column. In addition, the full exploitation of the high yield stress of HSSP leads to significantly lighter columns that are cheaper to construct, as well as increased floor space in building construction.

As a first step in developing the new concept into a practical construction technology that can be routinely designed by structural engineers, a series of axial compression tests on HSSP-CFFTs were conducted. In parallel, tests were conducted on corresponding CFFTs without steel plates for comparison. This paper presents results from the axial compression tests which demonstrate some of the expected advantages of the new columns.

EXPERIMENTAL PROGRAM

Test Specimens

A total of 10 specimens were constructed and tested, comprising 8 HSSP-CFFT specimens and 2 CFFT specimens without steel plates. All specimens had a nominal diameter of 203 mm (i.e. inner diameter of the FRP tube) and a height of 600 mm. For the HSSP-CFFT specimens, two configurations of steel plates were adopted, one with a single plate placed along a centre line of the cross-section while the other consisting of four plates connected together by bolted angle brackets to form a square (referred to as "square plate configuration" hereafter). The widths of the steel plates were so designed that the concrete cover had a minimum thickness of around 20 mm. As a result, the steel plates used in the single-plate specimens had a width of 160 mm, while those used in the square-plate specimens had a width of 85 mm or 95 mm, depending on the thickness of the plates. The steel plates had a yield stress of around 450 MPa or 290 MPa. Although the steel plates with a yield stress of 290 MPa were not HSS plates, they were used in the present study for comparison, and all the specimens are referred to herein as HSSP-CFFT specimens for simplicity. The other main test variables included the thickness of the steel plates and that of the FRP tube. The details of all the specimens are summarized in Table 1. For ease of reference, each specimen is given a name (see Table 1), which starts with a letter "S" to represent "specimen", followed by a number (0, 1 or 4) to represent the number of steel plates in the specimen; this is then followed by a letter (from "A" to "C") to represent the type of steel plates (for HSSP-CFFT specimens only). The second number in the specimen name defines the thickness of the FRP tube.

Material Properties

Two types of prefabricated glass FRP (GFRP) tubes were used in the present study. These GFRP tubes were all formed by a filament-winding process with a nominal fiber volume fraction of 59% and fiber winding angles of

±75 degrees to the longitudinal axis of the tube. The only difference between the two types of GFRP tubes was in their nominal thicknesses, which were 1.5 mm and 3 mm, respectively. According to the manufacturer data, the tubes had elastic moduli equal to 33 GPa in the hoop direction and 12 GPa in the longitudinal direction.

The 10 HSSP-CFFT and CFFT specimens were divided into two testing groups (see Table 1) and were tested at two different times. The specimens of Group 1 were tested after 32-34 days of curing while the others were tested two weeks later. As a result, the compressive strengths of the concretes in the two testing groups were slightly different. Plain concrete cylinders of two dimensions, namely, 150 mm x 300 mm and 100 mm x 200 mm, were tested to determine the compressive strength of concrete. The 150 mm cylinder tests showed that the concrete in Group 1 had a compressive strength of 33.1 MPa while that in Group 2 had a compressive strength of 35.9 MPa. The compressive strengths obtained from the 100 mm cylinder tests were 44.7 MPa and 48.0 MPa for Groups 1 and 2, respectively.

Tensile tests on three steel coupons were conducted for each type of steel plates. The measured yield stresses of Plates A, B and C were found to be 290 MPa, 450 MPa and 455 MPa, respectively.

Table 1. Specimen details

Specimen	Configuration of steel plates	Steel Plates			Thickness of FRP tubes (mm)	Testing group
		Type	Yield stress (MPa)	Thickness (mm)

Preparation of Specimens

The preparation process of the HSSP-CFFT specimens included the following steps: (1) preparation of steel plates, which involved cutting of the steel plates to the desired dimensions, attaching strain gauges on the steel plates and bolting the steel plates to form the square plate configurations; (2) fabrication of the mould, which consisted of an outer FRP tube with a centered steel plate configuration fixed to a wooden frame with a waterproof base plate; (3) casting the concrete; (4) strengthening of local regions which included the two regions each of a 75 mm height near the column ends and the regions near the holes drilled through the FRP tubes for passing the electric wires of the strain gauges on the steel plates. A similar preparation process was adopted for the CFFT specimens except that Step (1) was not needed and Steps (2) and (4) were simpler because of the absence of steel plates.

Test Set-Up and Instrumentation

For each specimen, four strain gauges with a gauge length of 20 mm or 30 mm were installed at the mid-height of the FRP tube to measure the hoop strains. For each steel plate in the HSSP-CFFT specimens, two axial strain gauges with a gauge length of 10 mm were attached on the two faces respectively at the mid-height. In addition, two linear variable displacement transducers (LVDTs) were used to measure the total axial shortening of each specimen. All compression tests were carried out using a 500 ton Denison compression testing machine with a displacement control rate of 0.5 mm/min. All test data, including the strains, loads, and displacements, were recorded simultaneously by a data logger.

TEST RESULTS AND DISCUSSIONS

General Behaviour

All the specimens displayed continuous load-shortening behavior with a monotonically increasing load until the ultimate failure due to rupture of the FRP tube under hoop tension, except Specimen S4C-3 for which the test was terminated when the load approached the capacity of the testing machine. The rupture of FRP tube generally initiated from a hole which was drilled for passing the electric wires, although that region was locally strengthened. This means that the hoop rupture strain of FRP recorded in these tests may be well below that could be reached in a real column with an intact FRP tube, but the effect of the small holes on the overall behavior of the column before the ultimate failure is believed to be minor.

Axial Load-Shortening Behaviour

The key test results of all the ten specimens are summarized in Table 2. In this table, P_c is the ultimate load obtained in the test, P_s is equal to the squash load of the steel plates, and P_{co} is equal to the unconfined concrete strength times the net cross-section area of concrete.

Table 2. Key test results of specimens under concentric compression

Specimen	Ultimate load P_c (kN)	Squash load of steel plates P_s (kN)	Unconfined strength of concrete section P_{co} (kN)	$\frac{P_c}{(P_{co}+P_s)}$	Hoop rupture strain $\varepsilon_{h,rup}$

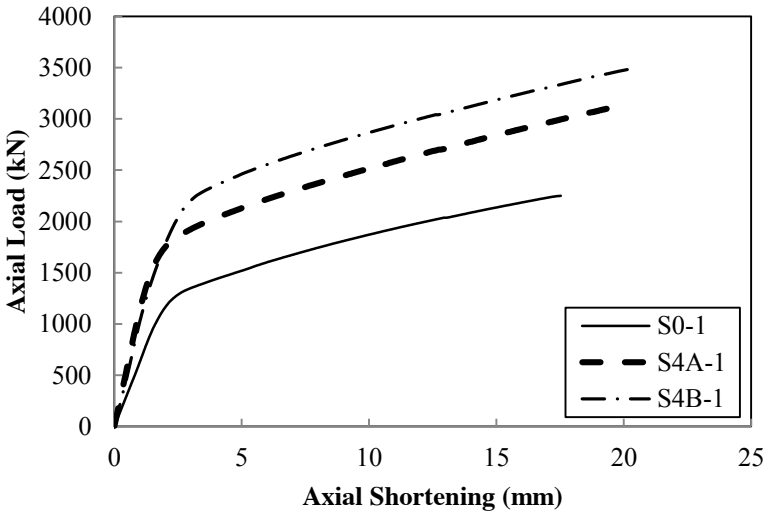

Figure 2. Typical axial load-shortening curves

Typical axial load-shortening curves of the specimens with a 1.5 mm FRP tube are shown in Figure 2, where the axial shortenings were averaged from the two LVDT readings. It is evident that all the specimens had a bilinear axial load-shortening curve with two ascending branches. Because steel has a larger elastic modulus than

concrete, the two HSSP-CFFT specimens had a larger initial stiffness than their CFFT counterparts (Figure 2). The second linear branches of the curves of the three specimens, however, were approximately parallel to each other (i.e. had a similar slope) (Figure 2). Further examination of the curves reveals that for all the three specimens in Figure 2, the transition point between the two branches of the curve happened at a load which was approximately equal to $P_{co}+P_s$ of the specimen. Considering the fact that the steel plates had yielded at the beginning of the second branch, as also evidenced by the readings of strain gauges attached on the steel plates, it can be deduced that the load increase in the second branch came mainly from the confinement effect of the FRP tube to the concrete, except that some load increase near the end of test may have been caused by the strain hardening of the steel plates. This also explains the approximately parallel second linear branches of the three curves in Figure 2, where the differences in the load of the three linear branches at an arbitrary shortening are approximately equal to the differences in the $P_{co}+P_s$ values. It is also obvious that the HSSP-CFFTs reached ultimate loads that are significantly higher than the simple sum of the squash loads of the steel plates and the unconfined strength of the concrete (Table 2). It may be noted that the direct contribution of FRP tubes to the ultimate loads was very small.

(a) Steel plates from single-plate specimens (b) Steel plates from square-plate specimens

Figure 3. Steel plates taken out from columns after test

Buckling of Steel Plates

In HSSP-CFFT specimens, the steel plates were restrained by the encasing concrete and the FRP tube. As a result, their propensity to buckle was reduced. The steel plates of all tested HSSP-CFFT specimens were taken out for examination. Figure 3a shows the plates taken out from the specimens with a single plate while Figure 3b shows those taken out from the specimens with a square plate configuration. It is evident from Figure 3a that the plates remained straight after test without any visible buckling deformation. However, for the plates which formed a square configuration, Figure 3b shows that most of them, especially those in specimens with a thin FRP tube, experienced significant buckling deformation. The only exception was the square plate configuration taken out from Specimen S4C-3 (rightmost specimen in Figure 3b). To further examine this issue, readings from the strain gauges attached on the steel plates in Specimen S4A-3 are shown in Figure 4 (the strain gauge readings from other specimens with a square plate configuration were similar). In this paper, a tensile strain is positive and a compressive strain is negative unless otherwise specified. Figure 4 shows that the four pairs of strain gauges recorded very similar strains at the beginning of test until a strain value which was approximately equal to the yield strain of the steel; after that the strain readings appeared somewhat erratic, which might be due to uneven yielding of the steel plates. Nevertheless, after a short period, all the eight strain gauges started to increase monotonically again at similar rates until the rupture of FRP tubes. There was no evidence that the two strain gauges of any pair (i.e. the two strain gauges attached on the two faces of a plate) displayed noticeable strain gradient over the thickness of a steel plate, suggesting that buckling deformation near the mid-height region was unlikely to occur before the rupture of the FRP tube. The fact that the strains of all the plates kept increasing (*i.e*. no unloading) suggests that buckling away from the mid-height region was also unlikely to occur before the FRP rupture. Considering also the fact that the four steel plates in Specimen S4C-3, whose test was terminated before the FRP rupture, did not show any visible buckling deformation, it may be reasonable to conclude that the buckling of steel plates shown in Figures 3b for specimens with a square plate configuration occurred only after the rupture of FRP tube, when the plates lost their buckling restraint. This conclusion is also

supported by the axial load-shortening curves shown in Figure 2, which suggests that the contribution of steel plates did not decrease before the FRP tubes ruptured.

CONCLUSIONS

This paper has presented the details of a newly proposed hybrid FRP-concrete-steel tubular column. The new column consists of an outer FRP tube, a concrete in-fill and a number of encased high-strength steel plates that are connected to each other by bolted angle brackets at discrete elevations. The new column, termed HSSP-CFFT (High Strength Steel Plate-Concrete Filled FRP Tube) in this paper, offers an ideal opportunity for the use of high-strength steel plates in construction, with the high yield stress of these plates being fully utilized and the perceived difficulties of welding high strength steels being obviated. No allowance needs be made for welding residual stresses, leading to simpler structural design procedures. The HSSP-CFFT column thus has many advantages compared to existing designs including its excellent corrosion resistance and ample ductility. This paper has also presented results from axial compression tests. The results demonstrated that the concrete in the tested specimens was very effectively confined, and that buckling of the steel plates with yield stresses up to 455 MPa was prevented by the encasing concrete up to and beyond the rupture of the FRP tubes, leading to full structural utilization of the construction materials and very ductile column responses.

ACKNOWLEDGMENTS

The authors are grateful for the financial supports received from the Australian Research Council through a *Discovery Early Career Researcher Award* (Project ID: DE140101349) for the first author as well as the University of Wollongong and Bluescope Ltd through a *URC Research Partnerships* project. The authors also wish to thank Prof. Jin-Guang Teng of The Hong Kong Polytechnic University for his valuable suggestions during the conceptual development of the new column form, and Messrs Jalen Price and Andrew Meharg for their valuable contribution to the experimental work.

ABSTRACT

Structures can be exposed to impact loads as a result of an explosion, falling objects, projectiles and vehicle collisions. Within the increasing threat of these impact sources, it is very important to protect the columns that are the vital members of the structural systems to ensure structural and personal safety. This study focuses on the performance of axially loaded reinforced concrete members subjected to impact loading. A dropped-weight test set-up developed to perform impact tests on reinforced concrete members. The test set-up was used to perform low elevation impact tests on reinforced concrete (RC) columns that targets to simulate vehicular impact against ground floor columns of low-rise buildings. Since, there is limited information about the transverse impact performances of RC columns; the main objective of this research is to assess the vulnerability of RC columns under transverse impact loads and to enhance their performances by using Aramid Fiber Reinforced Polymer (AFRP) sheets. The scope is limited to 300 mm square columns with 3 m height in low to medium rise buildings which were found to be more vulnerable to lateral impacts according to previous research conducted by the authors, (Gurbuz *et al*. 2010, 2011). This research provides fundamental knowledge on the behavior of RC columns under low elevation impact loading and also generates new information on impact strengthening of vulnerable concrete columns by AFRP sheets.

KEYWORDS

Aramid, drop weight, FRP, impact, reinforced concrete columns, strengthening, structural dynamics.

INTRODUCTION

Structures should provide adequate safety for the loads that they could be exposed to during their lifetime. In addition, when the structure is subjected to abrupt dynamic loads such as explosive or impulsive loads, the damage to the structure should be limited to provide life safety of occupants.

This research focuses on vehicle crash against RC columns which results in a low elevation lateral impact loading. A large number of RC beam tests have been performed to investigate RC member response against mid span impact tests, (Chen and May 2009; Fujikake *et al*. 2009; Kishi *et*. *al*. 2001, 2002; Saatci and Vecchio 2009; Tang and Saadatmanesh 2005; Abbas *et al*. 2010; Remennikov and Kaewunruen 2006). However, the former impact tests conducted by falling weight impacting at the mid height of the specimen, lack of presenting the real dynamic response of RC columns subjected vehicular impacts; since low elevation impact tests of axially loaded RC columns have not been explored extensively by the earlier researchers. Based on the limited research findings, the behavior of RC members with mid span impacts significantly differs from that of axially loaded members with low elevation impacts, (Thilakarathna *et al*. 2010). This has provided a motivation for the current experimental research, low elevation impact tests conducted on axially loaded RC columns in the Structural and Earthquake Engineering Laboratory in Istanbul Technical University (ITU). Drop weight tests were performed to gain a better understanding of impact behavior of axially loaded RC columns and a retrofit method, which utilizes AFRP sheets, against impact loading is studied.

Although, the composite materials became popular in retrofitting applications in the field of structural engineering, most of the research primarily focused on strengthening/retrofitting applications either for static or seismic loading. The current knowledge on FRP strengthening against impact is very limited, (Tang and Saadatmanesh 2003; Gurbuz *et al*. 2011). Therefore, the effectiveness of external AFRP confinement on impact performance enhancement of structural members with axial load was investigated in this research. The experimental findings will also contribute to collaboration of numerical modelling approaches such as the model by Gurbuz et al., 2010.

TEST PREPARATION

Test Specimens

There are many factors affecting the behavior of RC members under impact loading such as the dimensions and span of members, cross-section properties (steel ratio, stirrups, concrete cover), material properties (concrete, steel, FRP) and stiffness of the impact surface, (Bhatti *et al*. 2009, 2011; Fujikake *et al*. 2009; Ho 2004; Kishi and Mikami 2002; Kishi *et al*. 2002, 2006; Saatci and Vecchio 2009; Remennikov and Kaewunruen 2006). The only testing parameter in this experimental study was the strengthening effect. Two identical testing specimens were tested, one of which was strengthened and the other not. The two test specimens were designed to represent typical ground level columns of low-rise buildings. The cross-sectional dimensions of specimens were 300x300 mm and their lengths are 3200 mm. Figure 1 shows a typical test specimen, its dimensions and reinforcement layout. Four 18 mm diameter bars (4Φ18, A_s=10.18 cm^2) were used as longitudinal reinforcement spanning the specimen. They were placed symmetrically, resulting in a reinforcing ratio 0.01, ($\rho=A_s/bd$, ρ=0.01, b: width, d: depth of the specimen). Square transverse links were 8 mm in diameter (Φ8) and spaced at 150 mm along the member length (Φ8/150). The clear concrete cover was 25 mm on all sides. The members were designed so that their span at the test set-up is 3000 mm.

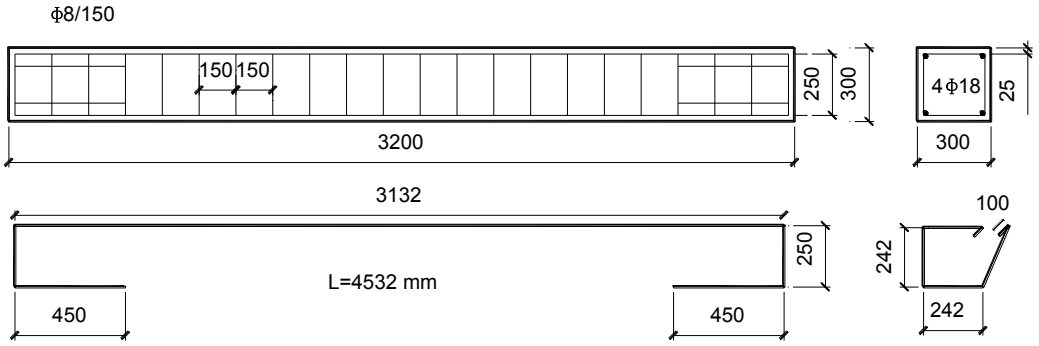

Figure 1 Geometry and reinforcement details of the specimens (all dimensions are in mm)

Strengthening

AFRP sheets were used as a retrofitting material in this research. One column specimen was wrapped externally with AFRP sheets in the transverse direction using two layers. Aramid based FRP sheets are particularly preferred in impact and blast retrofits due to their higher tensile strength and stiffness beside other fiber types, (Crawford *et al*. 1997).

At first, corners of the square column were grinded with 30 mm diameter. Then the surface preparation took place for proper bonding between the aramid fiber sheets and concrete surface. Concrete surfaces were mechanically scarified with a grinding wheel and dust was removed. Properly cleaned and dried surfaces were achieved to obtain full contact. Primer was applied with a roller on the concrete surfaces to penetrate the pores and improve the adhesion. The retrofitting system included two components as fibers and polymer. Two-component epoxy resin (epoxy and hardener), which was mixed by a ratio of 3:1 (epoxy/hardener) was used as a matrix material. It bonded the aramid fibers to concrete surfaces. Epoxy resin was applied over the whole surface of the RC column and the aramid fiber sheets were totally saturated to achieve perfect bond with the concrete surface. Constant pressure was exerted by moving the roller in both ways in the direction of the aramid fibers until they were fully saturated. Finally, the air was also removed by this application. Then these steps were then repeated for the second layer of AFRP sheets. Second coat of epoxy-resin was applied a using a roller, working in the direction of the fiber.

Materials

All the specimens were cast from the same concrete batch. Three cylinders were tested at the 28th day and the average compressive strength of concrete was determined as 28.1 MPa. The average compressive strength was increased to 30.7 MPa at the time of impact testing. Moreover, splitting tension test (Brazilian test) with three cylinder samples (150x100 mm) was also conducted at the end of the impact tests in order to determine the tensile strength of the concrete. The average tensile strength was 2.8 MPa.

Two types of steel bars with 18 mm (longitudinal reinforcement) and 8 mm (transverse links) diameters were used in the test specimens. Special care was taken to get all the reinforcement of the column specimens from the same batch. Three bar samples were tested for each diameter. The average yield stresses of Φ18 and Φ8 bars were 465 MPa and 513 MPa, respectively.

MBrace® Composite strengthening system was used for retrofitting of the RC column specimen. The method mainly consisted of primer, two component epoxy resin and unidirectional AFRP sheets. Manufacturer's specification for aramid fibers Mbrace Fiber AF 120/3200 are listed in Table 1.

Table 1 Properties of Aramid fiber

Fiber Areal Weight	Fabric Thickness	Fiber Strength	Fiber Stiffness	Elongation
280 g/m^2	0.194 mm	3200 MPa (Kevlar 49)	120 GPa (Kevlar 49)	0.024

Test Set-up

Loading situation seen in vehicle crash was simulated by the impact testing set-up. The column was tested with axial compression and width of the impact loading zone was 30 cm, which represented the contact zone height of a vehicle. Additionally impact was applied 1 m away from the column east end support, considering the average vehicle height from the ground. The impact tests performed by drop weight test set-up. The freely falling weight dropped from a predefined height and impact was applied to the selected location of the member. The members were placed horizontally and the impactor was dropped freely from different heights.

An existing test set-up in ITU Structural and Earthquake Engineering Laboratory was modified to be used for drop weight impact tests, as shown in Figure 2. In the existing test set-up, the steel construction was designed to provide desired support conditions at both ends of the column. The west support point, where the axial load was applied by hydraulic jack and cylinders (60 t capacity), was designed to allow axial translations and rotations. A load cell (100 t capacity) was used to measure the axial load and the axial load was tried to keep constant during the tests. The load cell and the cylinder were clamped to prevent bouncing after the impact. Under the effect of drop weight the specimen could shift laterally or lift up. Therefore column ends were clamped by high strength steel rollers (70 mm in diameter) prevent uplifting and lateral movements. These rollers were placed at the top and the bottom surfaces of both column ends. Thus the supports allowed for some rotation and lateral contraction caused by the axial load application. The steel profiles supporting the whole specimen from the two end points were fixed to prestressed strong floor (120 cm thickness) by 32 mm high strength steel rods. The steel supports were designed to be stiff enough to support the loading without significant deformation.

Figure 2 Test set-up

The drop weight test apparatus (steel frame towers and the impactor) was added afterwards to the existing test set-up. The specimens were placed horizontally in the set-up and the impactor was dropped to the 2/3th length of the column (2 m away from the west support of the specimen). Impact load was induced by a freely dropping impactor from a specific height. Impactor can be dropped from a maximum height of 6.0 meters due to the constraints of the test set-up. The impactor was raised and carried by the crane. It could be moved up and down to a designated height by the crane. When the impactor reached the predefined height, it was released resulting free fall of the weight.

Instrumentation

In impact experiments the major difficulty is to measure and record correct test data in a short duration, which is about 0.010 to 0.100 seconds (10-100 milliseconds). Therefore special care must be given to choose proper sensors to make accurate measurements and high-speed data acquisition (DAQ) system to collect and save the data during the tests. A high speed dynamic acquisition (DAQ) system was used in the present tests to collect data at a 5 kHz sampling rate that means signals from each sensors were read and recorded at a rate of 5000 times per second. Thirteen channels of instrumentation (7 potentiometers, 5 accelerometers, 1 load cell) were provided to examine the impact response of the column by the collected sensor data. DEWE43 and SIRIUS dynamic data loggers manufactured by DEWESoft Company were used for data acquisition during the impact test series.

The specimens and the test set-up were instrumented to measure accelerations, displacements and axial forces. The output from the impact tests of the reinforced concrete columns consisting of deflection time histories at seven locations, as shown in Figure 3 were collected. Resistive linear position transducers (potentiometer) were placed underneath the column along its length to collect the displacements during the test. LPM 100 model potentiometers produced by Opkon were used during the tests. They are capable of measuring displacements up to 100 mm precisely and were connected to allow some rotation to avoid any potential damage to the sensors. Seven potentiometers were attached to measure the distribution of deflection along the length. They were placed in between the two supports with 50 cm spacing from each other.

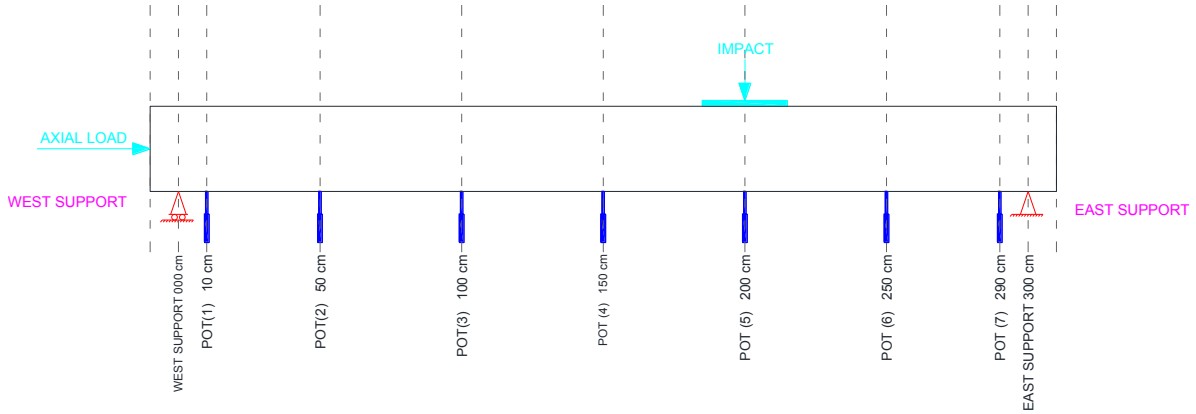

Figure 3 Potentiometer locations from west support

A compression load cell was placed at the east support to measure the axial load. The CLP-100CMP Model load cell, manufactured by Tokyo Sokki Kenkyujo Co. Ltd., with a 1000 kN maximum load capacity was used in the tests.

IMPACT TESTS

Two full-scale RC columns comprising an unretrofitted (control specimen) and a retrofitted column specimen were tested. All the tests were conducted on axially loaded RC members and the impact load was applied by drop weight. The axial load was identical for the specimens, which represented the axial loads on typical frontal ground level columns of low-rise buildings (4-5 story buildings). The axial load level was kept constant at 375 kN which corresponds to approximately 12% of axial load capacity of the cross-section (N_u) or in other words the axial load ratio (n) is 0.12 (Equation 1) where N is the applied axial load, f'_c is the concrete compression strength, b and h are the width and depth of the specimen.

$$n = \frac{N}{bhf'_c} \tag{1}$$

For obtain the responses from different levels of impacts, drop heights were increased gradually. The tested members have identification name. *Imp* denotes impact tests, *R* denotes reference specimens (unretrofitted) and *A* denotes the AFRP retrofitted specimens. The reinforcement details of specimens were planned carefully to avoid shear failure.

Reference Specimen (ImpR1)

The first impacted column, ImpR1 was a control specimen. ImpR1 was subjected to impact load of 585 kg dropped from 3.0 m (17000J). Deflection data at the locations of 10 cm, 100 cm, 200 cm, 250 cm and 290 cm from the west support were accurately collected from the performed test. Deformation versus time curves, recorded by each potentiometer along the specimen length are presented in Figure 4.

Deflection time histories are typical in shape and in period. They act as a half-sine waves with period of 60 ms. The loading point deflection readings (potentiometer at 200 cm, @200cm) indicated that the column deflected a maximum of 47.6 mm. The peak deflection of 47.6 mm occurs at about 20 ms after the impact, and then deflection rapidly drops at the failure and oscillates around 19 mm, which is the permanent deflection. In the time history curve of the potentiometer at 10 cm location (from the west support), negative deflections were recorded 6 ms after the induced impact, which shows the uplifting movement of the specimen. Due to the post vibration of the specimen, deflection at this point ends up with almost zero value deflection, which verifies successfully restrained movement of the end points.

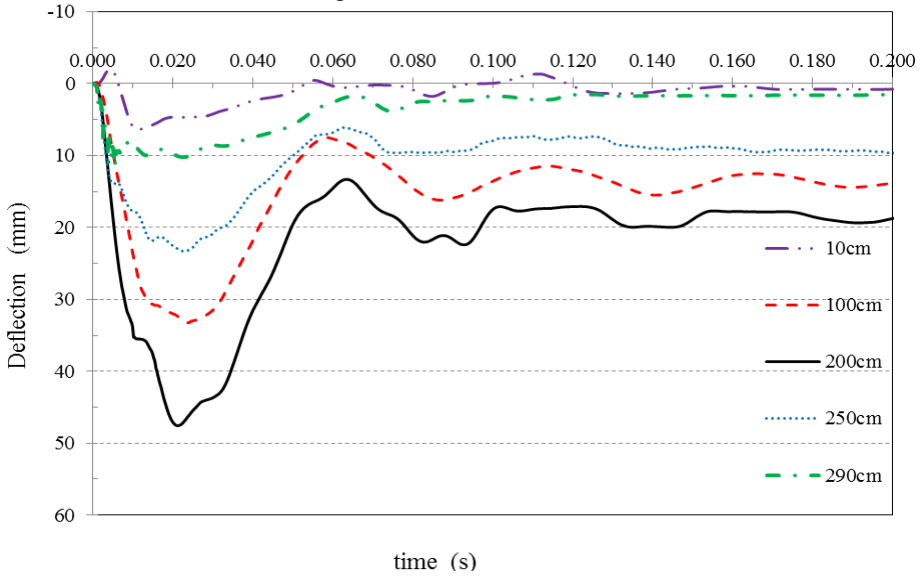

Figure 4 Deflection time history of ImpR1

Damage after the induced impact is presented in Figures 5-6. Concrete crushed and the concrete cover spalled at the top face just near the impactor and extended in the direction of the west support. This damage at the top concrete was due to the compression stresses caused by the impactor and the flexure effect. The concrete cover was extensively damaged that the top longitudinal reinforcement exposed, Figure 5.

Figure 5 Concrete cover disintegration and concrete crushing at the top next to the contact surface

Inclined shear cracks at both sides of the loading zone and minor flexural cracks just under impactor at the tensile zone indicated the formation of the shear-flexure type failure of the specimen (Figures 5-6) and no cracks

were observed close to the support points. The shear-flexure failure was demonstrated by the widening of diagonal shear and vertical flexural cracks. The shear cracks started from the outer side of loading surface and extended towards the bottom face of the specimen. However the shear crack that extended towards the west support was more inclined (Figure 6a) while the crack that extended to the east support was steeper (Figure 6b). Damage was dominated by shear with little flexure involved. Visible excessive permanent damage and residual deflection associated with shear was observed after the impact.

a. steeper cracks close to east support b. inclined cracks close to the west support

Figure 6 Inclined shear cracks

Cracks were marked and the crack widths were measured after the impact test. The widths of the residual cracks are presented in the crack map of ImpR1, Figure 7. The maximum crack width was 3 mm and cracks were mostly close to the loading zone of the specimen. The inclined crack widths varied from 1.8 mm to 3.0 mm and travelled the full depth of the specimen diagonally.

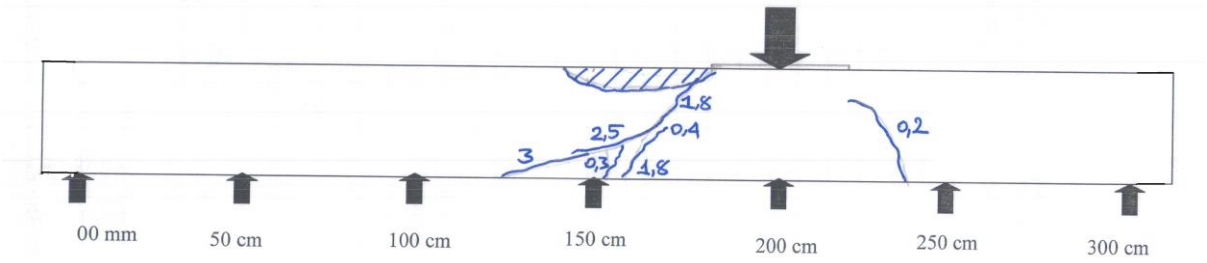

Figure 7 Crack map of ImpR1 (crack widths are in mm)

Aramid Retrofitted Specimen I (ImpA1)

ImpA1 was the retrofitted specimen that was externally confined with by 2 plies of unidirectional AFRP sheets in the transverse direction. By this application method, the shear capacity of the reference columns was aimed to be improved considering the dominant shear-flexure failure under impact.

The retrofitted specimen was impacted twice using different drop heights. In the first impact, the drop weight was constant as 585 kg and height was 3.5 m (20000J). This impact, which was higher than the impact applied to reference specimen, did not cause damage as severe as the damage of the reference specimen. Therefore, the drop height was increased to 4.5 m in the second impact. By this way the impact energy was increased to 26000 J with the increased drop height.

1st Impact: 585 kg, 3.5 m (20000J)

Deflection time history of the ImpA1 specimen obtained by the potentiometers located at 10 cm, 100 cm, 200 cm (loading point), 250 cm and 290 cm from the west end of the specimen are given in Figure 8. The maximum deflection is 50.3 mm, which occurred at 20 ms after the induced impact. The total period of the deflection wave is about 60 ms and the permanent deflection value is 13 mm. It is interesting to note that while the maximum

deflection is higher with respect to reference specimen due to increased impact energy, the residual displacement and damage are significantly less due to enhancement provided by AFRP retrofit.

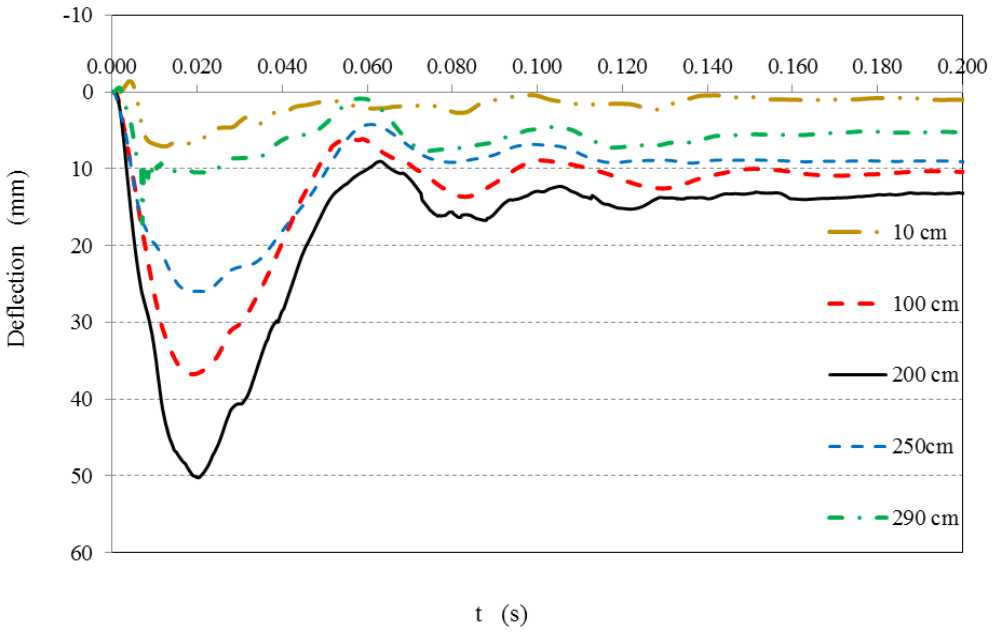

Figure 8 Deflection time history of ImpA1, after the first impact

After the first impact, the crack formation of ImpA1 between the distances 150 cm to 200 cm (under impact zone) from the west support is presented in Figure 9. Two vertical minor flexure cracks initiated at the outermost bottom tension zone. No visible damage/rupture was seen on the AFRP sheets. The formed damage was like a matrix cracking. Impact load is short in duration and causes high stress concentration at the loading region and forms cracks that expand along limited impacted area.

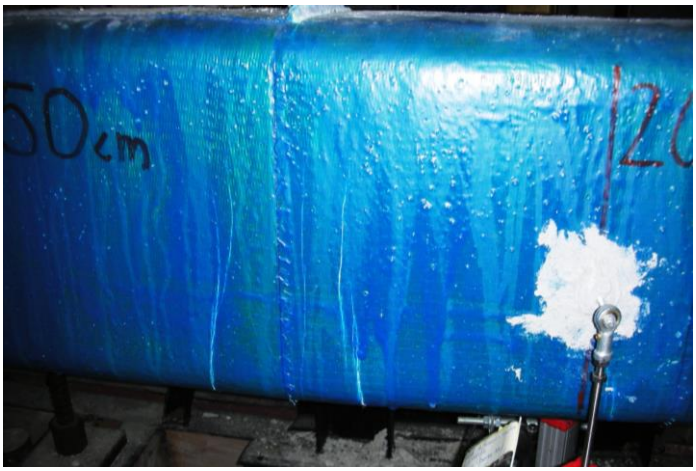

Figure 9 Cracks of ImpA1 after the first impact

Cracks were marked and the crack widths were measured after the first impact, which are presented in the crack map given in Figure 10. Minor vertical flexure cracks formed with a residual width of up to 0.8 mm.

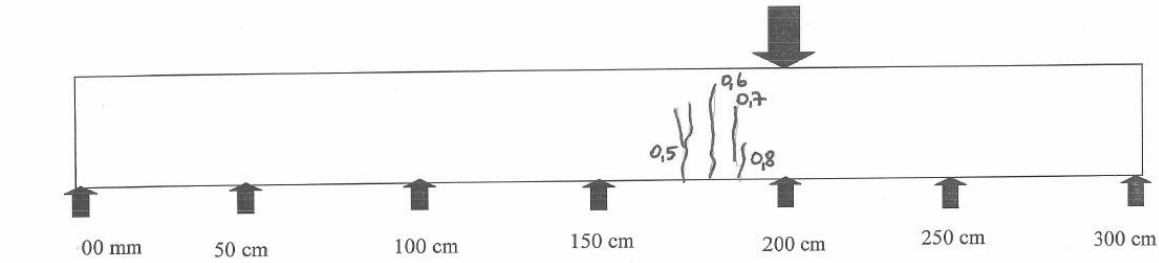

Figure 10 Crack map of ImpA1, after the first impact

2nd Impact: 585 kg, 4.5 m (26000J)

After the second impact, the previous vertical flexure cracks (marked as A) at bottom tension zone propagated further up (marked as B), as in Figure 11. Additionally, new vertical flexure cracks formed as a result of the second impact. AFRP sheets ruptured at the top surface next to the impact region, Figure 11. Aramid fibers ruptured at the top face due to the local effect of the impact loading.

a. Vertical cracks at the loading region b. Rupture of the Aramid fibers at the top surface

Figure 11 Damage of ImpA1, after the second impact

The general crack pattern of the impacted retrofitted specimen was characterized by vertical flexural cracks located around the impact zone. The width of the vertical flexural cracks formed on either side of the loading region had a range of 0.2-3.0 mm. The widths of the residual cracks after the second impact are presented in the crack map of ImpA1, Figure 12.

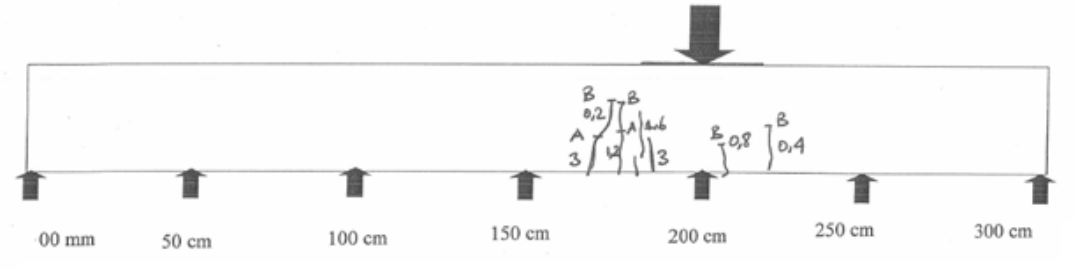

Figure 12 Crack Map of ImpA1, after the second impact (crack widths are in mm)

By the end of the impact test, the aramid jacket was removed from the concrete surface in order to observe the failure/damage mechanism closely. The general crack pattern of the impacted area is presented in the autopsy photo given Figure 13. After the first impact, vertical flexure cracks formed on the AFRP as matrix cracks then the cracks were widened and spread into the concrete surface of the specimen during the second impact. These damages on concrete were flexural cracks formed on tension side of the region with no significant crushing on the top concrete. Since the concrete damage on the top compression zone was limited, the AFRP fibers ruptured due to the local impact effect of the drop weight. The failure mode of retrofitted RC specimen subjected to impact load can be categorized as flexural failure.

Figure 13 Autopsy of ImpA1, after the second impact

RESULTS AND DISCUSSION

Results from impact tests on RC columns before and after retrofitting with AFRP are compared. These results enable the evaluation of the effectiveness of AFRP retrofitting based on its ability to increase impact load carrying capacity as well as transforming the failure mode from shear to flexure.

Failure Mode

The failure mode of the reference specimen, which was designed to be flexure-critical under static loading conditions, differs significantly under impact loads from pure flexure to an undesirable brittle shear-flexure failure due to change of material properties under the higher loading rates, as it was also indicated by Saatci and Vecchio (2009). Similar results were drawn by Remennikov and Kaewunruen (2006) where they indicated that the impact performance of the column was limited by its shear strength.

Reference specimen reached the ultimate state by the formation of major diagonal shear cracks, significant spalling of concrete cover and minor flexural cracks located near the impact area. No cracks occurred near column supports in the tests. Since impact loading is a fast dynamic load, column could only respond during very short time duration by formation of cracks and permanent deflections over a local area.

The observed failure mode in the retrofitted specimen differs significantly compared to reference specimen. The shear strength of the specimen ImpA1 was increased by the application of AFRP retrofitting so that no shear damage was detected after the impulse. While at the first low impact test of the retrofitted column just minor flexural cracks were detected under the loading zone, as the impact level increased in the second stage these former cracks widened and the aramid fibers ruptured at the top face. The AFRP jacket was removed after the test and the observed vertical flexural cracks and minor concrete crushing at the top demonstrated clearly the flexural failure of the retrofitted specimen.

Effect of Retrofitting

ImpR1 was heavily damaged under the impact of 585 kg dropped from 3.0 m; however, ImpA1 had minor cracks under the impact of 585 kg dropped from 3.5 m, which had a higher impulse than that on the first specimen. Additionally, the retrofitted column ImpA1 could stand for a second impact of 585 kg dropped from 4.5 m. This finding clearly revealed that, strengthening with AFRP sheets increased the shear strength, and accordingly the performance of column specimens under impact loads as it was also indicated by Tang and Saadatmanesh (2003) and Ferrier and Hamelin (2005).

The residual deflection values of ImpR1 and ImpA1 (after first impact) are measured as 19 mm and 13 mm, respectively. The residual deformation in the ImpA1 was reduced since no shear deformation was formed in case of ImpA1. Moreover concrete crushing at the top loading surface was limited by the application of the AFRP retrofitting.

The stiffness of the specimen retrofitted by the AFRP jacket had not changed. The periods of the deflection waves were about 60 ms for both specimens.

CONCLUSIONS

Following conclusions can be formed from the results of the drop weight tests of axially loaded RC columns before and after AFRP retrofitting in shear.

* Reference specimen exhibited a shear-critical behavior under impact loads even though it was designed as flexure-critical under static loading conditions.
* The main observed damage of the reference specimen was shear failure with flexure.
* The damage caused by the impact loading was located around the loading zone and no damage was observed close to the column supports.
* The failure mode the column under impact loading was transferred from a brittle shear failure to a more ductile flexural failure by the application of the AFRP retrofitting.
* The impact capacity of the retrofitted columns under drop weight impact test, significantly increased and the residual deflection is decreased compared to the unretrofitted specimens.

CFRP STRENGTHENED CFST COLUMNS UNDER VEHICULAR IMPACT

Md Iftekharul Alam[1,*], Sabrina Fawzia[1] and Chamila Batuwitage[1]
[1]School of Civil Engineering and Built Environment, Science and Engineering Faculty, Queensland University of Technology, QLD, Australia.

ABSTRACT

Concrete filled steel tubular (CFST) columns are increasingly used in bridge piers and high-rise buildings due to their excellent axial load bearing capacity. These columns may experience severe damage or failure due to transverse impact of vehicle collisions. In this study, numerical investigation is carried out to evaluate the effect of carbon fibre reinforced polymer (CFRP) strengthening CFST columns under vehicular impact. The CFRP composites damage mechanisms are simulated to account four different failure criteria. The cohesive elements are introduced as interface element to properly simulate the adhesively bonded regime. Simplified vehicle model is also developed to represent real vehicle behaviour. The FE analysis results show that externally bonded CFRP composites improve the impact resistance capacity compared to bare CFST column.

KEYWORDS

CFST columns, CFRP, vehicular impact, numerical simulation.

INTRODUCTION

Concrete filled steel tubular (CFST) columns provide enhanced structural capacity compared to RC or hollow steel tubular columns. In recent years, these columns are widely used in bridge piers. The early researches have shown that the vehicular or ship impact to the axial load bearing members of bridges is one of the major causes of bridge failure in USA (Wardhana and Hadipriono 2003; Briaud and Hunt 2006). Thus, strengthening/retrofitting of CFST columns may require minimising the damage and failure of bridge columns subjected to accidental vehicular collision. Strengthening of RC structures with externally bonded carbon fibre reinforced polymer (CFRP) is already a proven smart technique over conventional options. However, in recent years, researches are focusing on strengthening/retrofitting metallic structures with CFRP wrapping. Extensive experimental tests and numerical analyses are conducted to explore the potentiality of CFRP strengthened steel members subjected to static loadings (Fawzia *et al*. 2006; Fawzia *et al*. 2007; Shaat and Fam 2009; Fawzia 2013; Kabir *et al*. 2014; Fawzia and Shahanara 2014; Kabir *et al*. 2015). However, research is very limited on the behaviour of CFRP strengthened steel and CFST structures under dynamic loadings such as transverse impact loading (Chen *et al*. 2014; Alam and Fawzia 2015; Alam *et al*. 2014; Alam *et al*. 2015). This study attempts to evaluate the performance of CFRP strengthened full scale bridge column subjected to realistic vehicle impact. Simplified vehicle model is developed and validated with early study. Initially CFRP strengthened CFST column models are validated with available test results in the literature (Chen *et al*. 2014). The validated models are extended to full scale bridge column models and the impact simulation is performed using spring-mass system vehicle model. Both column and vehicle deformations are considered during the simulation as observed in practical situation. The results are presented in terms of impact force and maximum lateral displacement of columns.

SPRING-MASS SYSTEM VEHICLE MODEL

The simplified spring-mass vehicle model proposed by Al-Thairy 2012 is modelled in ABAQUS/ Explicit and validated with experimental, analytical and, early FE analysis. The spring-mass vehicle model consists of a massless rigid surface, a nonlinear spring and a solid mass to represent vehicle weight as shown in Figure 1. The detail of modelling procedure has been discussed in Al-Thairy 2012. The nonlinear spring is modelled to define the load-deformation behaviour of vehicle during impact simulation. The validation of spring-mass vehicle model is conducted by comparing maximum contact force-displacement results with vehicle full frontal impact tests data available in US National Highway Traffic Safety Administration (NHTSA, 2011) and previous FE analysis (Al-Thairy 2012). The contact forces of vehicle frontal crush tests are estimated by Al-Thairy (Al-Thairy 2012) using the proposed equations (Campbell 1974; Jiang *et al*. 2004) and vehicle frontal crush data from NHTSA. The estimated impact force-displacement curves are used as input parameters to simulate nonlinear spring behaviour. Figure 2 shows the contact force-displacement graphs of three different vehicles used to model spring-mass vehicle model. The validation of spring-mass vehicle models are presented in Table

1 by comparing maximum impact force and vehicle crush distance with test results (NHTSA, 2011) and previous FE simulation (Al-Thairy 2012). The spring displacement values in Table 1 represent the vehicle crush distance of frontal impact tests. Good agreements are found for all three vehicles with similar contact forces and spring displacements compared to estimated impact forces and vehicle crush distances.

The validated spring-mass system model is used to represent full scale numerical vehicle model. The Chevrolet C2500 Pick-Up properties will be used in spring-mass system model to simulate impactor vehicle. The early study has shown (Al-Thairy 2012) that impact force-vehicle crush displacement characteristics of Chevrolet C2500 Pick-Up impacted on rigid column is bilinear as shown in Figure 3. The stiffness of vehicle is low until the vehicle front crushes to engine box which is K_1 in Figure 3. Once the engine box is in contact with the rigid column, stiffness is very high (K_2) due to the stiffer engine box. Al-Thairy has shown that the stiffness K_1 of the bilinear vehicle model is mainly depends on the contact width of the column (Al-Thairy 2012). In this current study, full scale numerical column with outer diameter 300 mm is considered which is very similar to the width of column UC 305 x 305 x 118 used in Al-Thairy study. Therefore in this work, K_1 and K_2 values are selected as 510 kN/m and 46.8×10^3 kN/m respectively obtained from the Chevrolet C2500 Pick-Up and rigid UC 305 x 305 x 118 column simulation (Al-Thairy 2012).

FE MODELLING OF FULL SCALE COLUMN

Model Validation

Numerical models of bare CFST columns and one layer CFRP strengthened CFST columns are first developed and validated with experiments conducted by Chen *et al*. (Chen *et al*. 2014). The length of the CFST column is 1700 mm with inner diameter 107 mm and wall thickness 3.5 mm. The detail of specimens and experimental set-up can be found elsewhere (Chen *et al*. 2014). Figure 4 shows the FE model of strengthened CFST column subjected to transverse impact loading. The core concrete is modelled considering the confinement effect and strain-rate effects as discussed in the literature (Richart and Brandzaeg 1928; Mander *et al*. 1988; CEB-FIP 1990; Hu *et al*. 2003). The steel tube is modelled using isotropic classic metal plasticity model by considering elastic-plastic behaviour and strain rate effects of steel material. Cohesive elements are used to model epoxy adhesive between the CFRP layer and steel tube outer surface. Traction-separation law available in ABAQUS (SIMULIA 2011) is deployed to define the failure behaviour of cohesive elements. The continuum shell elements are selected to model CFRP sheet. Well known "Hashin" failure criteria are considered to define the failure of CFRP materials (Hashin and Rotem 1973; Hashin 1980). The material properties provided in Chen *et al*. (Chen *et al*. 2014) are used to model steel, core concrete and CFRP sheet. The adhesive properties are selected after a sensitivity analysis as no adhesive properties are mentioned in experimental study (Chen *et al*. 2014). The validation of bare CFST and CFRP strengthened CFST columns subjected transverse impact loading is shown in Figure 5. Good agreement is found between initial peak impact forces for both columns (Figure 5(a) and (b)). Good matching between the lateral displacement-time curves of both bare and strengthened columns are noticed as presented in Fig. 5.

Figure 5 Validation of FE models

Full Scale Column Model

The validated CFST and one layer CFRP strengthened CFST column models are converted to full scale columns by increasing the column outer diameter 300 mm and length 4000 mm as shown in Figure 6. The validated spring-mass vehicle model representing Chevrolet C2500 Pick-Up is used as an impactor to simulate real vehicle-column interaction subjected to accidental impact (Figure 6(c)). The bottom end of column is fixed boundary condition where the top end is pinned to represent a bridge columns. The impact height is selected as 750 mm from the bottom of the column which is fairly similar to the actual height of Chevrolet C2500 Pick-Up front bumper. Only half of the column length is strengthened in this study to investigate the effects of CFRP strengthening subjected to accidental vehicular impact as shown in Figure 6(b).

RESULTS AND DISCUSSIONS

The structural responses of bare and strengthened CFST columns are investigated in terms of impact force-time histories and maximum lateral displacement-time curves. The speed of vehicle is varied from 60 to 90 Km/h. Figure 7(a) depicts the impact force-time curves comparison of bare CFST (CFST in Figure 7) and strengthened CFST (CFRP-CFST in Figure 7) columns subjected to 60 and 90 Km/h impact velocities. It is noticed that initial impact force is very low until 36 milliseconds impact time for columns due to 60 Km/h impact velocity. This is due to the low initial stiffness of spring-mass vehicle model as shown in Figure 3. Once the spring displacement reaches to the distance of engine box of vehicle then the peak impact force rises sharply due to the stiff material behaviour of engine box. In case of 90 Km/h speed, the sharp increase of peak impact force occurs at 20 milliseconds due to the higher speed of vehicle. The peak impact forces of strengthened columns are higher than the bare CFST columns as shown in Figure 7(a). This may be due to the increase of the global stiffness of CFRP strengthened columns than the bare CFST columns. Figure 7(b) shows lateral load-time histories of bare and strengthened columns under 60 and 90 Km/h impact velocities. CFRP strengthened CFST columns pose improved impact resistance capacity by minimising maximum lateral displacement 18.7% and 21.35% subjected to 60 Km/h and 90 km/h impact velocities respectively. It is also observed that the externally bonded CFRP wrapping system also delaying the maximum lateral deflection by shifting the peak deflection point at higher impact time compared to bare CFST columns.

CONCLUSIONS

In this work, realistic simplified spring-mass vehicle model is developed and validated with earlier study. The three dimensional full scale bare and CFRP strengthened CFST column models are developed to investigate the CFRP wrapping effects under vehicular impact loading. The core findings from this current study are as follows:

- Simplified vehicle model is developed and validated successfully to simulate the realistic vehicle behaviour. The accuracy of this model is acceptable and the computation time is very low compared to full scale FE vehicle model.
- The bare and CFRP strengthened CFST column models are developed and validated with the experimental tests. The results show good agreements in impact force-time histories and maximum lateral displacement-time histories.
- The full scale column models are presented to represent real bridge columns. The transverse impact analyses results show that the peak impact force of strengthened columns increase significantly compared to bare CFST columns.
- The reduction of maximum lateral displacements of strengthened columns has been noticed due to strengthening effects. Thus, CFRP strengthening of CFST columns can be a promising strengthening/retrofitting technique to prevent failure or minimise damage of CFST bridge columns subjected to accidental vehicular impact.

ABSTRACT

Fiber-reinforced polymer (FRP) confining jackets offer an attractive solution for the seismic retrofit of reinforced concrete (RC) columns. For an accurate prediction of the strength and ductility of FRP-confined RC columns, it is necessary to understand the interaction between the FRP jacket and the RC column at all deformation levels under seismic loading. In particular, when widely-spaced steel stirrups/spirals are used as the transverse steel reinforcement, the longitudinal steel bars are likely to develop buckling deformations, which are however restrained by the FRP-confined concrete cover. This paper presents a "beam-on-elastic foundation" model for simulating the buckling behavior of longitudinal steel reinforcing bars laterally supported by FRP-confined concrete using the finite element (FE) approach. In addition, a curved beam approximation is proposed to evaluate the stiffness of the lateral springs that are used to represent the restraining effect offered by the FRP-confined concrete cover. The proposed FE model is verified through comparisons between the predicted and the experimental average stress-strain relationships of steel reinforcing bars, the latter of which were obtained from compression tests of FRP-confined RC columns. The proposed FE model provides an effective method for simulating the buckling behavior of laterally supported longitudinal reinforcing bars for a more accurate analysis of the behavior of FRP-confined RC columns.

INTRODUCTION

Old reinforced concrete (RC) columns, particularly those built prior to the 1970s, often have inadequate transverse steel reinforcement details. As a result, the longitudinal steel reinforcing bars (referred to as steel rebars or rebars for brevity) may buckle at a critical level of compressive strain due to insufficient lateral support. Buckling of rebars can lead to the spalling of concrete cover and a significant loss of the load-carrying capacity of RC columns. The ability of external fiber-reinforced polymer (FRP) jackets (with fibers oriented in the hoop direction to provide confinement to the column) in enhancing the buckling resistance of steel rebars in FRP-confined RC columns has been proven by previous researchers (e.g., Priestley et al. 1996； Hollaway and Teng 2008; Bournas and Triantafillou 2011). In FRP-confined RC columns, the concrete cover is confined by the external FRP jacket and provides much stronger support to the steel rebars, while in conventional RC columns the cover can easily spall when the steel rebars experience significant buckling deformations. Therefore, the buckling of steel rebars in FRP-confined RC columns is generally postponed to a higher strain level due to FRP-confinement, which, however, may not completely eliminate the possibility of rebar buckling (Tastani et al. 2006; Bournas and Triantafillou 2011), particularly when the column section is non-circular and FRP confinement is not so effective. If buckling of rebars does occur, the growth of inelastic buckling deformation of rebars may lead to additional strains in the FRP jacket, causing its premature rupture (Tastani and Pantazopoulou 2004; Pellegrino and Modena 2010; Rousakis and Karabinis 2012, Bai et al. 2015). This interaction between the steel rebars and the external FRP jacket through the concrete cover is an important mechanism governing the behavior of FRP-confined RC columns.

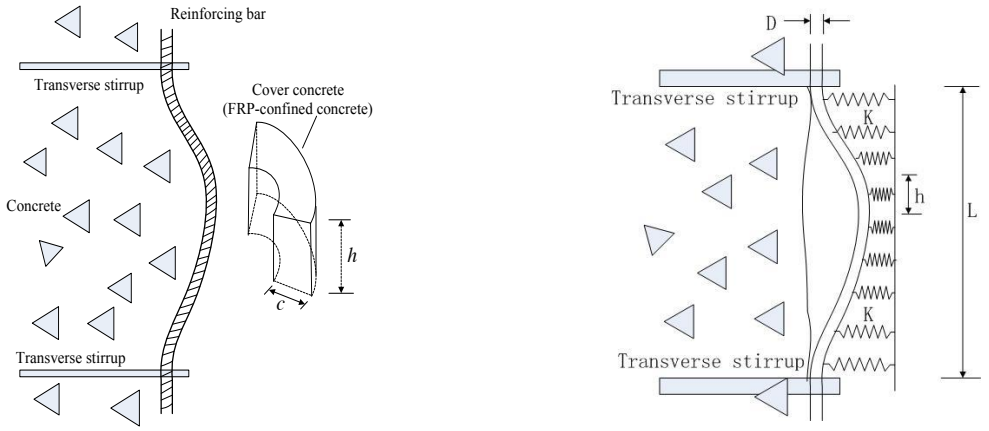
For the accurate prediction of strength and post-peak behavior of FRP-confined RC columns under seismic loading, it is important to understand the above-mentioned interaction mechanism between steel rebars and FRP-confined concrete at all deformation levels. Although a large amount of research has been conducted on the strength and ductility of FRP-confined concrete (e.g., Lam and Teng 2003; Dai et al. 2011), there has been rather limited work on the effect of FRP confinement on the buckling of steel rebars (e.g., Tastani and Pantazopoulou 2004; Pellegrino and Modena 2010; Megalooikonomou et al. 2012); this is contrast with the situation concerning

conventional RC columns, for which steel rebar buckling has received extensive research attention (e.g., Priestley et al. 1996).

Against the above background, this paper presents a finite element (FE) method for the full-range compressive stress-strain behavior of steel rebars in FRP-confined circular RC columns. The interaction between the steel rebars and the FRP jacket is represented using a beam-on-elastic-foundation model, in which the stiffness of the Winkler springs, which are used to represent the lateral support offered by the FRP-confined concrete cover, is derived from a curved-beam approximation of the FRP-confined concrete cover layer.

DESCRIPTION OF THE MODEL CONCEPT

When an RC member is subjected to flexure, the cover concrete in the compression zone may spall at the ultimate state, leading to a sudden loss of the load-carrying capacity (e.g., Dhakal and Maekawa 2002). In FRP-confined RC columns, the cover concrete is kept in position until the rupture of the external FRP jacket due to the confinement in the hoop direction; this rupture usually signifies the ultimate state of the column. A few researchers (e.g., Tastani and Pantazopoulou 2004; Tastani et al. 2006; Bournas and Triantafillou 2011) have paid special attention to the dilation behavior of the core concrete and the cover concrete which is accompanied by the buckling of steel rebars before the rupture of FRP jacket. It can be expected as the axial strain increases, the steel rebars expand together with the core concrete, but this propensity to move away from the column center is restrained by the concrete cover layer which is in turn supported by the FRP jacket. During this process, the FRP jacket provides increasing confining pressures through the cover concrete to restrain the steel rebars from buckling. Figs.1a and 1b illustrate a beam-on-elastic foundation model to describe this interaction mechanism: the steel rebar functions as a beam supported by a set of Winkler springs representing the lateral support from the FRP-confined concrete cover layer. The stiffness of the Winkler springs can be determined based on a curved-beam approximation as described in the next section. This idealized curved beam is composed of two materials: the confined concrete and the FRP jacket. It is important to realize that the FRP jacket has two important functions in the curved-beam approximation: as tensile reinforcement for the curved beam and as the confining device to modify the properties of the concrete.



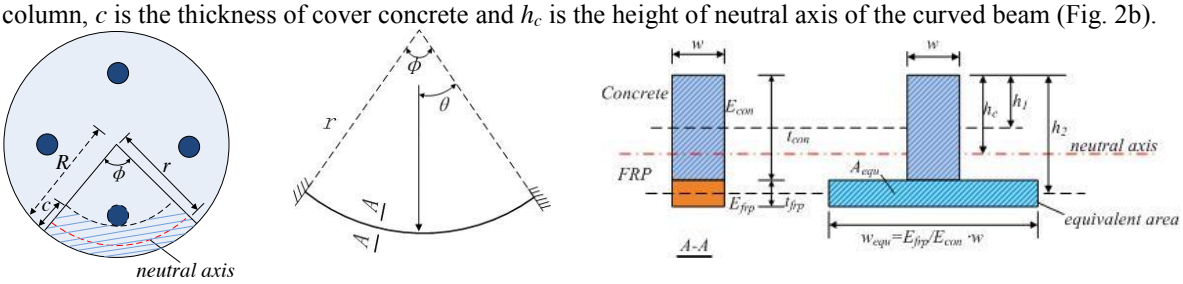
(a) Physical model (b) Simplification of the interaction mechanism

Fig. 1 Description of model concept

EVALUATION OF THE SPRING STIFFNES: CURVED BEAM APPOXIMATION

A simple curved beam model is proposed to estimate the stiffness of the springs between the longitudinal steel reinforcing bar and the FRP jacket. In the model, the circular column section can be divided into several equivalent domains according to the number of longitudinal reinforcing bars due to the symmetry (Fig. 2a). If the middle point of the curved beam is subjected to a concentric load P, the stiffness of the spring (i.e., the cover concrete) can be obtained using $K=P/\Delta$, where Δ is the resultant displacement over there, which can be solved using the flexibility (force) method and the principle of virtual work in structural mechanics (e.g., Laible 1985; Leet 1988). [please refer to Bai (2014) for details]. The boundary conditions of the two ends of the curved beam can be defined as fixed due to the symmetry even though the cover concrete and longitudinal reinforcing bars move outward simultaneously due to the dilation of concrete with the axial shortening of FRP-confined RC column. This is an approximation by which only the relative displacement between the longitudinal steel reinforcing bars and FRP-confined concrete is considered. The simultaneous lateral movement caused by the

dilation of core concrete has a marginal effect on the relative movement. The angle φ formed by the two ends of the curved beam (Fig. 2b) can be determined using $2\pi/n$, where n is the number of reinforcing bars in the whole column section. The radius of the curved beam r has the value of $(R\text{-}c+h_c)$, where R is the radius of the circular column, c is the thickness of cover concrete and h_c is the height of neutral axis of the curved beam (Fig. 2b).



(a) Column section (b) Curved beam model

Fig. 2 Curved beam model

SECTION PROPERTIES OF THE CURVED BEAM

As mentioned before, the curved beam is a beam of two materials: FRP-confined cover concrete and FRP jacket. It is well known that the compressive stress-strain curve of FRP-confined concrete with effective confinement stiffness can be described as a combination of two significant portions: a parabolic portion first and a linear ascending portion afterwards. The slope of the linear ascending portion E_2 can be determined by the following equation (Lam and Teng 2003):

$$E_2 = \frac{f_{cc}^{'} - f_{co}^{'}}{\varepsilon_{cu}} \tag{1}$$

where $f_{cc}^{'}$ is the compressive strength of confined concrete, $f_{co}^{'}$ is the compressive strength of unconfined concrete, and ε_{cu} is the ultimate strain of confined concrete (Lam and Teng 2003). During the loading process, FRP-confined concrete enters into the second linear portion of the compressive stress-strain relationship once the strength of unconfined concrete is reached, after which the FRP confinement effect is activated. Since the buckling of steel reinforcement is unlikely occur before the strength of unconfined concrete is reached, for the buckling analysis of reinforcing bars FRP-confined concrete can be assumed to lie in the second linear portion of the compressive stress-strain curves. Thus, for the buckling analysis of reinforcing bars in FRP-confined concrete, the equivalent elastic modulus of the FRP-confined cover concrete E_{con} is assumed for simplicity as:

$$E_{\text{con}} = E_2 \tag{2}$$

This is an approximation by which the FRP-confined cover concrete is regarded as elastic isotropic material, as E_2 is originally defined for the axial direction. The application of E_2 for the transverse direction of the confined concrete cover layer may need further justifications when more test data are available.

For a composite section the position of the neutral axis is determined as follows (Kaw 1997; Altenbach et al. 2004; Daniel and Ishai 2006; Chen et al. 2009),

$$\begin{aligned} h_c &= \frac{A_{con}\cdot h_1 + A_{equ}\cdot h_2}{A_{con} + A_{equ}} \\ &= \frac{t_{con}\cdot w\cdot h_1 + t_{frp}\cdot w_{equ}\cdot h_2}{t_{con}\cdot w + t_{frp}\cdot w_{equ}} \\ &= \frac{t_{con}\cdot w\cdot h_1 + t_{frp}\cdot E_{frp}/E_{con}\cdot w\cdot h_2}{t_{con}\cdot w + t_{frp}\cdot E_{frp}/E_{con}\cdot w} \end{aligned} \tag{3}$$

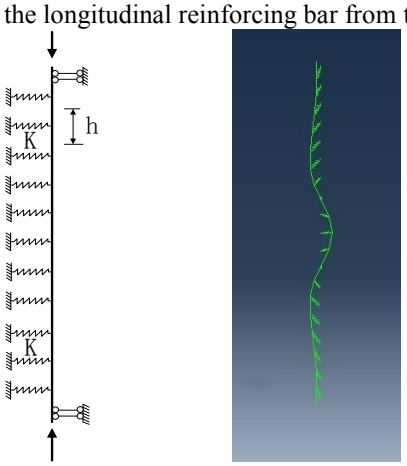
where w is the width of the curved beam; t_{frp} and t_{con} are the thickness of FRP jacket and cover concrete, respectively (Fig. 2b); E_{frp} is the elastic modulus of FRP; h_1 and h_2 are the height of the centroid of the concrete area and the FRP area, respectively. It should be noted that the FRP area is transformed to an equivalent area with the same elastic modulus of concrete. Thus, the centroid of the composite section can be calculated based on an inverse "T" section (Fig. 2b). Once the neutral axis of the composite section is determined, the section properties of the composite beam can be determined as follow:

$$
\begin{aligned}
E_{CB}I_{CB} &= E_{con}(wt_{con}{}^3/12 + wt_{con}(h_c - t_{con}/2)^2) \\
&\quad + E_{frp}(wt_{frp}{}^3/12 + wt_{frp}(t_{con} + t_{frp}/2 - h_c)^2) \\
E_{CB}A_{CB} &= E_{con}wt_{con} + E_{frp}wt_{frp} \\
G_{CB}A_{CB} &= G_{con}wt_{con} + G_{frp}wt_{frp}
\end{aligned} \tag{4}
$$

where G_{con} and G_{frp} are the shear moduli of the FRP-confined concrete and the FRP jacket, respectively.

BEAM-ON-ELASTIC FOUNDATION MODEL

Once the stiffness of the springs is known, the compressive behaviour of longitudinal reinforcing bars in an FRP-confined RC column can be simulated using the "Beam-on-elastic foundation" model as shown in Fig. 3a. The role of springs is to provide lateral support to the longitudinal reinforcing bars, whose behaviour is simulated using the FE approach based on the software ABAQUS (2008). In the FE model, the reinforcing bar is modelled as an assemblage of 2-node Timoshenko beam elements (B21 element) with appropriate cross-section integration. The elastic springs are modelled using an elastic spring element (i.e. the "Spring2" element) with one end connected to the adjacent beam element node and the other end fixed. For the two end nodes of the reinforcing bar, both rotational and translational degrees of freedom are fixed, except for the axial direction. To initiate lateral deformation, a tiny initial imperfection is imposed by cosine-shaped offset satisfying boundary conditions with a mid-length amplitude, which is in the range of 0.001~0.005% of the length of the longitudinal reinforcing bar model (Zong et al. 2013). The axial compression is applied on the steel bar by imposing displacements of equal magnitude but opposite direction at the two ends. Fig.3b shows the deformation shape of the longitudinal reinforcing bar from the FE analysis.



(a) FE model (b) Deformed shape

Fig. 3 Beam-on-elastic foundation model

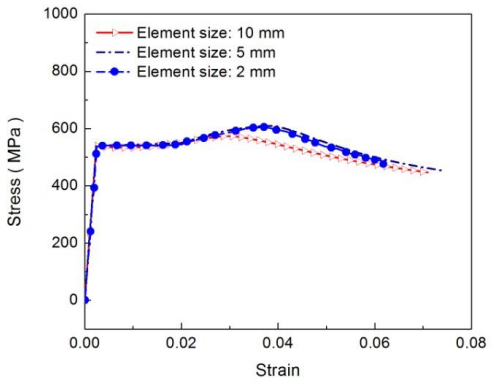


Fig. 4 Convergence study

The stress and strain values obtained from the FE analyses represented the average response. The average stress was calculated by dividing the axial force by the cross section area of the longitudinal reinforcing bar and the average strain was measured by dividing the axial displacement of one end node by the half length of the model due to the symmetry of the load and geometry.

A convergence study was also conducted to investigate the effect of element size on the global compressive behaviour of the longitudinal reinforcing bar. Beam elements with the lengths of 10 mm, 5 mm and 2 mm were used in the convergence study and the analytical stress-strain curves are plotted in Fig. 5. It can be seen that when the element length is shorter than 5 mm, the stress-strain curves reached convergence. Therefore an element size of 5 mm was used in all subsequent analyses.

FE PREDICTIONS VS. TEST RESULTS

In this paper, three cases of stress-strain curves of reinforcing bars in FRP-confined RC columns as reported in Bai (2014) were used here to verify the proposed FE model. Details of the experiment can be referred to Bai (2014). The spring stiffness values for the three cases calculated based on the flexibility method and the principle of virtual work were 39.4 N/mm, 104.7 N/mm, 272.8 N/mm per unit height, respectively. Figures 5a~5c show the comparisons of FE predictions and test results of the compressive stress-strain curves of longitudinal

reinforcing bars in FRP-confined RC columns. The compressive stress-strain curves of the reinforcing bars without buckling effects are also presented for reference. In general, the FE model predictions agree well with the test results. The analytical stress-strain response follows exactly the same path with the reference curve until a certain strain value, where the buckling initiates. Afterwards, the compressive stress decreases gradually with the increase of the strain. The main differences between the FE predictions and the test results are their yield stresses: in the experimentally observed compressive stress-strain curves, the longitudinal reinforcing bars in FRP-confined RC columns in the tests yielded before the actual material yield strength of steel, while the stress-strain curves obtained from the FE analyses exhibited the same yield point as the actual one. This is mainly because the compressive stress-strain relationships obtained from the tests reflected the average response of the longitudinal reinforcing bars over the whole measured height (i.e., 250 mm). The observed premature yielding of reinforcing bars was due to the strain localization mechanism. In other words, the yielding of reinforcing bars always occurs at a local position rather than the whole height in the tests, leading to a lower average yield stress of the reinforcing bar when the yielding occurred locally.

Figures 5b and 5c show that the FE predictions tend to underestimate the compressive stress of longitudinal reinforcing bars, particularly when the axial deformation becomes large (Fig. 5c). This was mainly because that the experimental stress-strain curves of reinforcing bars were obtained from the compressive tests on FRP-confined RC columns and represent the average response of four longitudinal reinforcing bars in the columns. In reality, it was less possible that four reinforcing bars buckled simultaneously and then proceeded with the same rate. Usually, one or two bars buckled relatively earlier than others (Bai 2014). As a consequence, the buckling response of the reinforcing bars might be postponed in terms of the average stress-strain relationships. It should be also noted that the interaction between the longitudinal reinforcing bars and the external FRP jacket in FRP-confined RC columns is very complicated. The assumptions adopted in the present study, such as the use of equivalent elastic modulus of FRP-confined concrete (e.g., Eq. 2) and the linear characteristics of the lateral spring, need further experimental verifications. Fig. 5 also presents FE predicted compressive stress-strain response of a bare bar (i.e., without lateral support, $K = 0$) for comparison purposes. It is very clear that the existence of lateral support influences significantly the compressive stress-strain response of longitudinal reinforcing bars.

CONCLUDING REMARKS

This paper has presented an FE model to simulate the compressive stress-strain response of longitudinal reinforcing bars in FRP-confined RC columns with the incorporation of a "Beam-on-elastic foundation" model. In the model, the longitudinal reinforcing bars is simulated as an assembly of beam elements and the confinement effect provided by external FRP jackets is modelled as a series of elastic Wrinkle springs to provide lateral support. A simple curved beam model has been proposed to approximate the stiffness of the springs through the flexibility method and the principle of virtual work. The curved beam is treated as a composite beam accounting for the contributions from both the external FRP jacket and the FRP-confined cover concrete. Once the spring stiffness is determined the FE model with the employment of the "beam-on-elastic foundation" concept can be used to quantify the compressive stress-strain response of laterally supported longitudinal reinforcing bars. Comparisons between the FE predictions and test results have validated the suitability of using the "beam-on-elastic foundation" model for simulating the compressive stress-strain response (i.e., progressive buckling.) of reinforcing bars in FRP-confined RC columns.

ABSTRACT

Fibre reinforced polymer (FRP) anchors made from rolled or folded fibres have been shown to be an effective technology for delaying or even preventing premature debonding failure in concrete structures strengthened with externally bonded FRP. It would naturally be expected that the use of FRP anchors can improve the earthquake-resistance of FRP strengthened structures by increasing its loading capacity and ductility especially the latter. This study explores the application of FRP anchors in seismic strengthening of clay brick walls. One unique feature of such a system is that the brick unit has smaller dimensions compared to common concrete specimens. This paper reports an experimental pull out study of these FRP anchors. Test parameters included anchor construction, the diameter of the anchor, and the size of predrilled holes in clay brick. The experimental results indicate that FRP anchors can be designed to achieve high loading capacities and hence can be effectively used to prevent or delay FRP debonding failure. The results also indicate that the geometry of the anchor system has a significant effect on its loading capacity.

FRP anchor, masonry, anchorage strength, experiment.

INTRODUCTION

There has being an explosive increasing demand for retrofitting existing structures to improve their performance, especially to enhance their earthquake-resistance. The use of FRP strengthening system has recently emerged as one of the advanced retrofitting techniques. Although this technique has been proved to be a convenient and effective approach, existing studies have also demonstrated that externally bonded FRP tends to exhibit premature debonding from the substrate, prior to the development of full material strength (Smith, et al., 2011), leading to reduced seismic performance of FRP strengthened structures due to the brittleness and low energy dissipation capacity.

One effective and rational approach for preventing or delaying debonding is the use of proper anchor technologies, commonly including metal anchors to mechanically fasten the FRP sheet to substrate and FRP anchor to be embedded into a predrilled hole in substrate using epoxy (Ozbakkaloglu and Saatcioglu, 2009, Smith, et al., 2011, Zhang, et al., 2012). The former often results in bearing failure of the FRP due to stress concentrations around the anchor. FRP anchors can usually avoid or minimise this problem because the fibres from the anchor are spread out and bonded to the FRP sheet. It has an added advantage of being the same corrosion-resistant material of the strengthening FRP. A FRP anchor consists of a rolled or folded FRP strip embedded into a predrilled hole in substrate using adhesive. Existing research has demonstrated that the utilization of FRP anchors can effectively improve the seismic performance in terms of loading carry capacity and energy dissipation capability.

The vast majority of existing studies of FRP anchors has been concerned with concrete structures. Little research has been conducted on the pullout behaviour of FRP anchors installed into masonry, especially clay brick masonry. One feature of such a system is that brick units have smaller dimensions compared to common concrete specimens.

This paper reports an experimental study on the pullout behaviour of FRP anchors embedded into clay bricks. The effects of important parameters, including brick strength, hole diameter, anchor embedment (hole) depth, and anchor fiber content on the pullout behaviour were examined. An anchorage strength model is proposed which may be adopted for design use. This study forms part of a project on seismic strengthening of masonry structures using a hybrid FRP grid-FRP anchor system.

EXPERIMENTAL STUDY

A total of 42 CFRP anchors were manufactured and tested under pullout action. The test parameters included the anchor construction, embedment depth, hole diameter, fibre content and brick strength.

FRP anchor construction

FRP anchors can be formed either dry or wet and both were explored in this study: the former uses dry FRP strips to form a bar for the embedded portion whilst the latter uses wet FRP strips. FRP anchors are then constructed commonly by rolling the pre-cut FRP sheet, either dry or wetted. However, the rolling usually leads to fibre congestion at the centre of the anchor leading to difficulties in wetting the fibres in the centre in the dry process. An alternative method is to prepare the anchor by folding the sheet in order to have more uniform wetting of the fibres.

To investigate the performance of the different FRP anchor construction methods, three types of FRP anchors were explored in the present study: anchors made by rolling dry FRP strips, folding dry FRP strips, and folding wet FRP strips. For both rolling and folding dry FRP anchors, a FRP strip with the desired size was cut from a large FRP sheet, which was then rolled or folded to form an anchor. For impregnated (wet) FRP anchor, a thin layer of epoxy was used to wet the area of the FRP strip which would be embedded into bricks after folding.

The material properties of the CFRP and epoxy resin used to manufacture the FRP anchors are summarized in Table 1. The two critical parameters in determining the width of FRP strip were: (1) the tensile capacity of FRP anchors, and (2) the content of FRP and epoxy inside the predrilled hole. As the interested failure mode was the pullout failure of FRP anchors, the anchors were thus designed to have sufficient amount of fibres to prevent the rupture anchor failure in pullout test.

Table 1 Properties of CFRP sheet and epoxy used in manufacturing FRP anchors (from manufacturer)

Material	Nominal thickness (mm/ply)	Ultimate tensile strength (MPa)	Elastic modulus (MPa)	Rupture strain (%)
CFRP sheet	0.167	3400	230000	1.7
Epoxy resin	-	30	4500	0.9

Brick specimens

Two types of solid clay bricks were used in this study: one had compressive strength and bending tensile strength of 21.7 MPa and 3.16 MPa respectively and the other had compressive strength and bending tensile strength of 31.1 MPa and 5.35 MPa respectively. All the bricks had nominal dimensions of 240×115×53 mm^3. The strengths were tested following the Chinese standard GB 5101-2003 (2003).

Anchor installation

A rotary hammer drill was used to drill the holes to a depth equal to the designed embedment length of anchors in the clay bricks. The holes were cleaned using compressed air. They were then filled with a two component epoxy adhesive using a syringe. Two 0.9mm diameter steel wires were bound together and used to stir the adhesive in order to make it uniform and consistent and eliminate air pockets. The anchors were then inserted into the holes perpendicular to the brick face. The free end of FRP anchors were adhesively clamped using two aluminium plates after 2 days of installing the FRP anchors. All specimens were cured at room temperature for 3 days prior to testing.

Test setup

All specimens were tested using a 300 kN universal testing machine. The test set up is shown in Figure 1. The pullout tests were conducted under displacement control at a loading rate of 2 mm/min. In addition to the load, the displacement of FRP and bricks were monitored using both LVDTs and the PIV technique (Figure 1 (b)).

TEST RESULTS AND DISCUSSION

The pullout behaviour of FRP anchors were analysed as follows. Table 2 summarises the key test parameters and results.

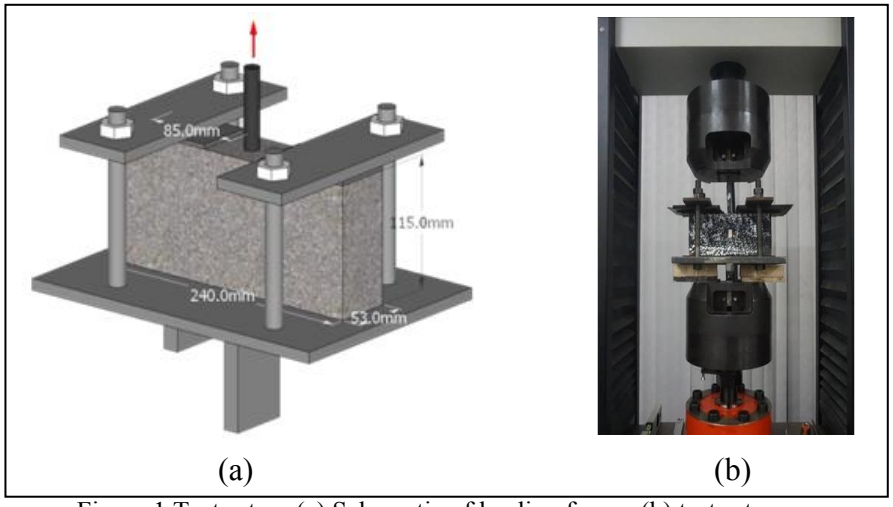

Figure 1 Test setup: (a) Schematic of loading frame, (b) test setup

Failure modes

The failure modes may be classified into four types: Type A - mixed mode with a triangular prism detached from and a unsymmetrical splitting crack into the brick [Figure 2 (a)], Type B - a triangular prism detached from the brick [Figure 2 (b)], Type C– mixed mode with a triangular prism detached from and a symmetrical splitting crack into the brick [Figure 2 (c)], and Type D – mixed mode with a triangular prism detached from the brick with a splitting crack along the embedded FRP anchor within the detached prism [Figure 2 (d)]. All failures are brittle. A brick triangular prism or similar shape is evident in all modes. Compared to the failure modes of FRP anchors embedded in concrete substrate, an important distinction is that a triangular prism is detached from the tested clay bricks whilst a cone occurs in concrete (Figure 3). This may be attributed to the smaller dimensions of the adopted bricks compared with the common concrete specimens. Existing analytical models developed for concrete cone failures may therefore not be applicable to brick anchorage failures because the projected area of the failure prism is rectangle in the bricks instead of a circular area in concrete specimens.

Optimization of FRP anchors

Three types of FRP anchors were used in this study, namely, rolling dry FRP strip (J type in Table 2), folding dry FRP strip (Z type in Table 2), and folding wet FRP strip (ZJX type in Table 2). Figure 4 illustrates the effect of anchor type on the average ultimate pullout load. It is shown that the folding wet FRP anchors provided the highest ultimate pullout load among the three types of anchors, because this anchor has good bond between the anchor and the brick as well as between fibres. The pullout behaviour of this anchor was thus investigated further.

Influence of key variables of FRP anchor

This section analyses the effects of key parameters of the ZJX type FRP anchors on the anchorage strength. The pullout strength versus anchor hole diameter is shown in Figure 5. It is seen that the ultimate pullout loads are very similar for hole diameter =10 and 12mm. Note that the average equivalent diameter of the folding wet FRP anchors was 9.1 mm, which means that there was only a very small amount of adhesive around the anchor in the holes and little working space when the hole diameter is small. When the hole diameter was increased to 14 mm, the ultimate pullout load was significantly improved, probably because improved bond between the anchor and masonry due to increased working space and bond area. Eight out of the nine specimens failed in modes exhibiting splitting cracks (Figures 2a, c, d) when the hole diameter was increased to 14 mm, only specimen ZJX-10 failed with a single brick chunk broken off (Figure 2b).

The pullout strength versus the anchor hole depth (anchorage length) is shown in Figure 6. It is clear that the deeper the hole the greater the ultimate pullout strength for a given hole diameter. The specimens with smaller hole depths (~20 mm) usually failed in modes without splitting cracks extending to the full height of brick (Figures 2b and d).

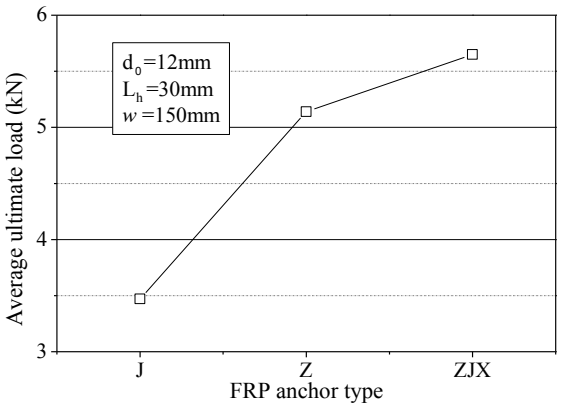

Figure 4. Effect of FRP anchor type on ultimate pullout load

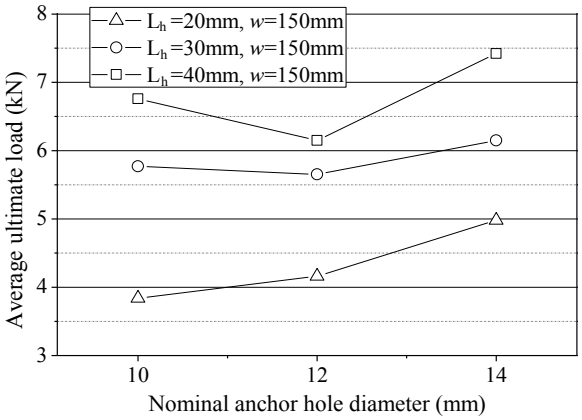

Figure 5. Effect of anchor hole size on ultimate pullout load (ZJX anchor)

The FRP strip width, also referred as equivalent anchor diameter converted from the perimeter of finish FRP anchors, versus the ultimate pullout load is plotted in Figure 7. It is interesting to note that the highest ultimate pullout load is experienced by anchors with a width of 100 mm (equivalent anchor diameter of 7.4 mm). The loading capacity was lower for specimens with 150mm FRP strips may be because less adhesive was used for the same hole diameter leading to weaker bond.

The lower brick strength led to a weaker pullout ultimate load as expected, e.g., the pullout strength from ZJX-ii-34 to 36 was lower than that from ZJX-i-7 to 9 as only brick strength were different in the two groups. All three low strength brick specimens (ZJX-ii-34 to 36) failed in the type D mode (Figure 2). That can be contributed to the pullout of FRP anchor due to cracks in the brick.

PULLOUT STRENGTH MODEL FOR FRP ANCHORS IN CLAY BRICK

It was observed that a triangular prism was detached from the brick in all ZJX specimens. This failure pattern may thus be used as the base case for deriving the pullout capacity of FRP anchor in clay bricks. Compared with the cone failure of FRP anchor in concrete (Figure 3(a)), the triangular prism failure in clay bricks shared the similar failure manner but a different projected area due to the smaller dimensions of bricks. Assuming a cone angle (α) of 45 º based on a statistical analysis, Ozbakkaloglu and Saatcioglu (2009) proposed the following concrete cone capacity model based on the ACI 349-85 (1997) cone model:

$$F_{cone} = f_{ct} A_N = f_{ct} \cdot (\pi L_c^2 + \pi L_c d_a) \quad (1)$$

In which f_{ct} is the concrete tensile strength, A_N is the projected area of stress cone which consists of a circular area for the basal plane of the cone and the surface area of the bond, L_c is the depth of the concrete cone, and d_a is the diameter of the anchor as shown in Figure 3(a).

Equation 1 cannot be applied directly to the clay brick triangular prism failure for several reasons. Firstly, there is an apparent difference in the failure shapes. Secondly, the test results showed in this study that the pullout strength is influenced by not only the diameter of the anchor (d_a) but also that of the hole (d_0). Thirdly, it is found from the test that the triangular prism angle (α) (Figure 3b) varied with the anchor geometry. A new strength model is thus required for the triangular prism in bricks. By examining the failure prisms in detail, the projected failure area of the brick failure prism $(A_N)_{brick}$ (Figure 3(b)) may be expressed as

$$(A_N)_{brick} = w_b S_b + \pi L_c d_a = 2 \cdot w_b \cdot \frac{L_c}{\tan\alpha} + \pi L_c d_a \quad (2)$$

where w_b is the width of the brick, L_c is the depth of the triangular failure prism in the anchor direction, S_b is the length of the projected area, and α is the triangular angle.

Apart from the desired parameters w_b and d_a, the parameters related to the triangular prism failure pattern, such as, L_c and α, were measured in the experiment and recorded in Table 3. The depth of triangular prism (L_c) and the length of the projected area (S_b) were directly measured from the two sides of the brick as shown in Figure 8. It can found from Table 3 and Table 2 that the depth of triangular prism (L_c) was approximately equal to the hole depth (L_h). In order to develop a prediction model, the depth of triangular prism (L_c) in equation 2 is replaced by the hole depth (L_h) because it is a pre-defined parameter.

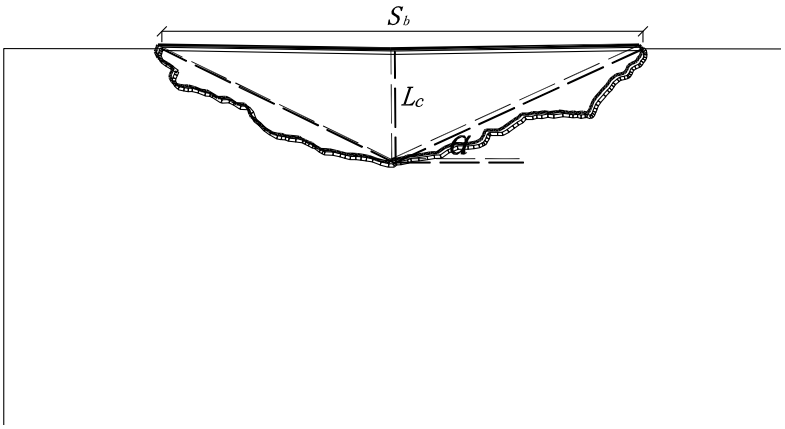

Figure 8. Brick triangular prism failure pattern

An approximation was adopted in calculating the triangular angle (α) in Table 3 by assuming that the triangular prism was symmetrical. A regression analysis of the test results shows that α can be closely related to the hole depth (L_h) and the hole diameter (d_0) as follows

$$\tan\alpha = 0.18\frac{L_h}{d_0} \tag{3}$$

The pullout strength model should consider all the critical parameters identified in the experiments, including hole depth (L_h), hole diameter (d_0) and diameter of anchor (d_a). The ratio of diameter of hole to the anchor (d_0/d_a) was chosen as an additional term to jointly consider the effects from both parameters. The pullout strength model was thud developed by a regression analysis as follows

$$(F)_{brick} = 0.115 \cdot f_{bt} \cdot \left\lfloor \frac{2hL_h}{\tan\alpha} + \pi L_h d_a \left(1 + \frac{d_0}{d_a}\right) \right\rfloor \tag{4}$$

where f_{bt} is the tensile strength of the brick.

Substituting equation (3) into equation (4) yields

$$(F)_{brick} = 0.115 \cdot f_{bt} \cdot \left\lfloor \frac{2hd_0}{0.18} + \pi L_c d_a \left(1 + \frac{d_0}{d_a}\right) \right\rfloor \tag{5}$$

It is clear that this new model is a prediction model because all parameters are pre-defined.

The statistical performance of the proposed model was examined by comparing its predictions with the test data as listed in Table 3. It is clear that the predictions of the proposed pullout strength model are in close agreement with the test data. However, the experimental data presented are limited, more test data are required to further validate the proposed model.

CONCLUSIONS

This paper has presented a study on the behaviour of FRP anchors embedded into clay bricks. Three types of FRP anchors were explored to optimize the FRP anchor manufacture approach. The influences of key parameters of the optimal FRP anchor, made by folding wet FRP strips, were investigated. It has been found that the geometry of the anchor system has a significant effect on the its loading capacity. An increase of the brick strength also increases the ultimate pullout strength. Finally, a new simple pullout strength model has been developed. This new model considers all the critical parameters based on the present test results and its prediction has been shown in close agreement with the test results.

ABSTRACT

It is well known that strengthening/seismic retrofit with fiber-reinforced polymer (FRP) confinement is highly effective for circular reinforced concrete (RC) columns but much less effective for rectangular columns (including square columns as a special case). As a result, FRP-confined concrete in rectangular columns often exhibits a softening stress-strain response (i.e., a stress-strain response with a descending branch), leading to a softening sectional moment-curvature response. For such cases, localization of inelastic deformation occurs at the column ends, which presents a significant challenge for numerical simulations to obtain objective results. Existing studies on the numerical simulation of FRP-confined rectangular RC columns under cyclic/seismic lateral loading have however overlooked this issue. In the present paper, an objective numerical approach for FRP-confined square RC columns under cyclic/seismic lateral loading is presented, in which the force-based beam-column element with the modified Scott and Fenves integration scheme in OpenSEES (Open System for Earthquake Engineering Simulation) is employed. To use this element properly, the development and use of an equivalent plastic hinge length model for such columns is carefully examined. The objectivity and accuracy of predictions from the proposed numerical approach are demonstrated using numerical examples.

KEYWORDS

FRP-confined RC column, square column, non-objectivity problem, plastic hinge, OpenSEES, force-based beam-column element.

INTRODUCTION

Fiber-reinforced polymer (FRP) jacketing offers an effective means to enhance the seismic performance of reinforced concrete (RC) columns (Xiao and Ma 1997; Teng *et al*. 2002; Teng *et al*. 2015). The effectiveness of this seismic retrofit method has been demonstrated by many researchers through experimental studies, but there has been relatively limited research on the numerical simulation of such columns. Teng *et al*. (2015) recently proposed the first reliable numerical approach for the simulation of FRP-confined circular RC columns under combined axial compression and cyclic/seismic lateral loading using the fiber-section force-based beam-column element with the Gauss-Lobatto integration scheme available in OpenSEES (2009) (Open System for Earthquake Engineering Simulation). Their approach was based on the uniaxial stress-strain model of Lam and Teng (2009) for FRP-confined concrete subjected to cyclic axial compression and a hysteretic moment-rotation model to account for the effect of strain penetration of longitudinal steel bars in the column footing (i.e., effect of fixed-end rotations) (Teng *et al*. 2015). Close agreement between the predictions and the test results was achieved by this approach.

The approach developed by Teng *et al*. (2015) however cannot be directly applied to FRP-confined rectangular RC columns (including square RC columns as a special case) under seismic/cyclic lateral loading. This is because FRP confinement is much less effective for rectangular columns than for circular columns, so FRP-confined concrete in rectangular columns often exhibits a softening stress-strain response (i.e., the stress-strain curve possesses a descending branch), leading a softening sectional moment-curvature response. For such cases, localization of inelastic deformation occurs at the column ends, which presents a significant challenge for numerical simulations using beam-column elements to obtain objective results. More specifically, if Teng et al.'s (2015) approach is directly employed to simulate the response of these columns, the element response changes with the number of integration points adopted for the element (referred to as the non-objectivity problem or localization problem) (Coleman and Spacone 2001; Scott and Fenves 2006; Valipour and Foster 2009). This issue, however, is not so significant in circular columns where a relatively thin FRP jacket leads to a

hardening (i.e., monotonically ascending) stress-strain response. The present paper presents a numerical approach that provides objective predictions of FRP-confined square columns under cyclic/seismic lateral loading through the development and use of a model for the equivalent plastic hinge lengths of such columns.

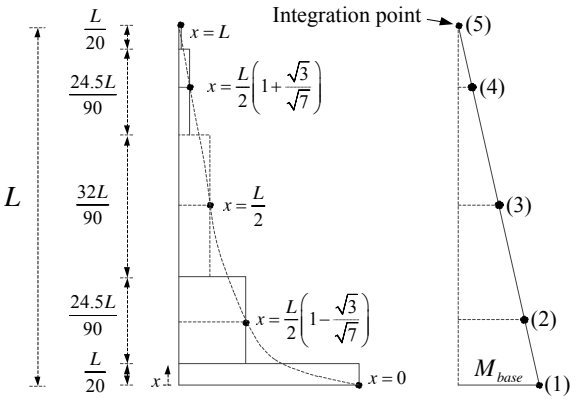
Figure 1 Curvature and moment distributions in a cantilever column



(a) Curvature distribution (b) Moment distribution

Figure 2 Curvature and moment distributions assumed for a force-based beam-column element with 5 Gauss-Lobatto integration points

PLASTIC HINGE LENGTHS OF RC COLUMNS

Unless otherwise stated, the discussions in the remainder of the present paper are limited to cantilever columns of length *L* bent in single curvature (Figure 1) due to a constant axial load and a varying lateral load at the free end. A fixed-end column bent in double-curvature can be represented as two cantilever columns meeting at the point of contraflexure. In a cantilever RC column, the moment increases linearly down the column height, and large inelastic deformations are concentrated in the vicinity of the column end/base (the plastic hinge region). The distance from the column base to the section where the curvature equals the yield curvature (Figure 1) is referred to as the physical plastic hinge length (Hines *et al*. 2004; Jiang *et al*. 2014) and denoted by l_{pr}.

For hand calculation of lateral displacements of a column, a simplified curvature distribution, which has the same profile area over the column as the actual curvature distribution (Figure 1), has commonly been used. This simplified curvature distribution is composed of a linear elastic variation due to elastic deformation along the full-height of the column plus a rectangular plastic hinge region at the column base (Park and Paulay (1975). The height of this assumed plastic hinge zone, denoted by l_p, is referred to as the equivalent plastic hinge length. The curvatures within the equivalent plastic hinge length are expected to reflect all the effects that contribute to the lateral displacement of the column other than the linear elastic deformation. For an RC column with a column aspect ratio $L/\left(4r_g\right)$ (where r_g = radius of gyration, which is $D/4$ for circular columns with a diameter equal to *D*) larger than 3.0, shear deformation is negligibly small and may be ignored (Priestley *et al*. 2007). Based on the simplified curvature distribution in Figure 1, the ultimate lateral displacement at the tip of the column can be calculated as:

$$\Delta_u = \Delta_y + \Delta_p = \frac{\kappa_y L^2}{3} + \left(\kappa_u - \kappa_y\right) l_p \left(L - 0.5 l_p\right) \tag{1}$$

where κ_y and κ_u are the yield curvature and the ultimate curvature of the column section respectively.

The equivalent plastic hinge length of the column can be related to the physical plastic hinge length via the following equation by assuming that the plastic curvature varies linearly over the physical plastic hinge length (Figure 1) (Hines *et al*. 2004; Jiang *et al*. 2014):

$$l_p = \frac{l_{pr}}{2} + 0.022 d_b f_y \tag{2}$$

where d_b and f_y are the diameter and yield stress of the longitudinal steel bars respectively.

NON-OBJECTIVITY ISSUE IN FORCE-BASED BEAM-COLUMN ELEMENTS

Force-Based Beam-Column Elements

Force-based beam-column elements have drawn much attention since their first appearance (Taucer *et al*. 1991) and have since been used extensively in the simulation of seismic performance of RC structures (Spacone *et al*. 1996a, 1996b). Force-based beam-column elements allow the nonlinear deformation of structural members in frames to be captured with a very coarse discretization. These elements have also been used in the simulation of cyclic/seismic performance of FRP-confined circular RC columns in recent years (Shao *et al*. 2006; Zhu *et al*. 2006; Mosalam *et al*. 2007; Teng *et al*. 2010; Teng *et al*. 2011; Lin *et al*. 2012; Liu *et al*. 2013; Hu and Barbato 2014; Teng *et al*. 2015).

In a force-based element, the force field is interpolated along the element instead of the displacement field in a traditional displacement-based element; as a result, element equilibrium is satisfied in a strict sense. The integrals of a force-based beam-column element formulation are generally evaluated by numerical integration. Typically, only one element is needed to represent a structural member in a frame when distributed member loads do not exist. Therefore, the Gauss-Lobatto integration scheme is commonly used as it has two integration points at the element ends where the bending moments are typically the largest. A schematic diagram of the five-point Gauss-Lobatto integration scheme for the sectional curvature of a cantilever column is shown in Figure 2. In this numerical integration scheme, the actual curvature distribution is approximated by that of five rectangles along the element length (Figure 2). In order to accurately represent the deformation of the member, four to six Gauss-Lobatto integration points are typically used (Neuenhofer and Filippou 1997).

Based on the Gauss-Lobatto integration scheme illustrated in Figure 2, the free-end lateral displacement of the cantilever column can be found using the principle of virtual forces as follows (Taucer *et al*. 1991; Scott 2004):

$$\Delta = \sum_{i=1}^{n} b(x_i)\kappa(x_i)w_i \tag{3}$$

where x_i is the location of the *i*th integration point; $b(x_i)$ is the virtual moment at the *i*th integration point due to a unit lateral load at the free end; $\kappa(x_i)$ is the curvature at the *i*th integration point; w_i is the weight of the *i*th integration point (Figure 2).

Non-Objectivity of Predictions

For a hardening sectional response, inelastic deformations spread along the element as the load increases and the solution does not depend on the number of integration points. By contrast, for a softening sectional response, inelastic deformations will localize at a single integration point, causing the predictions to depend on the number of integration points. For the cantilever column shown in Figure 2, which employs the five-point Gauss-Lobatto integration scheme, localization of inelastic deformations will occur at the integration point at the column base over a length of $L/20$ [referred to as the characteristic length (Scott 2011)]. If a different number of Gauss-Lobatto integration points is used, this characteristic length will be different. As a result, a unique solution does not exist and the element response changes with the number of Gauss-Lobatto integration points (Coleman and Spacone 2001; Scott and Fenves 2006).

To avoid the non-objectivity issue mentioned above, several techniques have been proposed by researchers (Coleman and Spacone 2001; Scott and Fenves 2006; Addessi and Ciampi 2007; Scott and Hamutçuoğlu 2008; Valipour and Foster 2009). Among these techniques, the Scott and Fenves (2006) integration scheme strikes a good balance between reliability and simplicity. In this integration scheme, the characteristic length is set to be equal to the equivalent plastic hinge length of an RC column. The inner sections (i.e., sections away from the end sections) however are assumed to be elastic, making it inapplicable to RC members with a hardening sectional response. In OpenSEES (2009) (Version 2.4.2), the Scott and Fenves (2006) integration scheme was modified (referred to as the modified Scott-Fenves integration scheme) by adding a two-point Gauss quadrature integration in the element interior to capture the inelastic deformations of the inner sections; as a result, the modified Scott-Fenves integration scheme is applicable to RC members with both hardening and softening sectional responses. Therefore, the modified Scott-Fenves integration scheme in OpenSEES was chosen in the present study to simulate the response of FRP-confined square RC columns under cyclic/seismic lateral loading.

Characteristic Lengths for the Modified Scott-Fenves Integration Scheme

To achieve objective responses, two fixed characteristic lengths are used in the modified Scott and Fenves (2006) integration scheme for the two ends of the element. This characteristic length was taken to be equal to the equivalent plastic hinge length by Scott and Fenves (2006), but this approximation may cause significant errors. To achieve accurate predictions, the relationship between the characteristic length and the equivalent plastic hinge length is derived herein using a cantilever column subjected to a lateral load at the free end. The curvature distribution of the column used by the modified Scott and Fenves integration scheme is shown in Figure 3. The lateral displacement at the free end, based on this curvature distribution, can be calculated in Eq. (3) to be:

$$\begin{aligned}\Delta &= \kappa_{base} L l_p^{SF} + \left(L - 8/3\, l_p^{SF}\right) \cdot \frac{L - 8/3\, l_p^{SF}}{L} \cdot \frac{M_{base}}{EI} \cdot 3 l_p^{SF} \\ &+ \frac{\left[L - 4l_p^{SF} - \frac{1}{2}\left(L - 4l_p^{SF}\right)\left(1 - \frac{1}{\sqrt{3}}\right)\right]^2}{L} \cdot \frac{M_{base}}{EI} \cdot \frac{1}{2}\left(L - 4l_p^{SF}\right) \\ &+ \frac{\left[L - 4l_p^{SF} - \frac{1}{2}\left(L - 4l_p^{SF}\right)\left(1 + \frac{1}{\sqrt{3}}\right)\right]^2}{L} \cdot \frac{M_{base}}{EI} \cdot \frac{1}{2}\left(L - 4l_p^{SF}\right) \\ &\approx \kappa_{base} L l_p^{SF} + \frac{M_{base}}{EI}\left(\frac{L^2}{3} - L l_p^{SF}\right)\end{aligned} \tag{4}$$

where κ_{base} is the curvature at the base section of the column; *EI* is the effective cross-sectional stiffness outside the plastic hinge region. At the ultimate state, the ultimate lateral displacement at the column free end can be approximated as:

$$\Delta_u \approx \kappa_u L l_p^{SF} + \kappa_y \left(\frac{L^2}{3} - L l_p^{SF}\right) = \frac{\kappa_y L^2}{3} + \left(\kappa_u - \kappa_y\right) L l_p^{SF} \tag{5}$$

By equating Eq. (5) with Eq. (1) for the ultimate lateral displacement at the column free end, the characteristic length l_p^{SF} can be expressed as a function of the equivalent plastic hinge length l_p:

$$l_p^{SF} = \left(1 - \frac{l_p}{2L}\right) l_p \tag{6}$$

It is obvious that the characteristic length l_p^{SF} in the modified Scott-Fenves integration scheme can be significantly smaller than the equivalent plastic hinge length l_p.

Figure 3 Modified Scott and Fenves integration scheme in OpenSEES for a cantilever column

EQUIVALENT PLASTIC HINGE LENGTH MODELS

Although a significant number of plastic hinge length models have been developed for conventional RC columns, only a few studies have been conducted on FRP-confined columns, leading to only two plastic hinge

length models for these columns (i.e., Gu *et al*. 2012; Jiang *et al*. 2014). Gu *et al*. (2012) modified the equivalent plastic hinge length model of Paulay and Priestly (2009) for conventional RC columns by adding the effect of FRP confinement. This model was developed based on the ultimate lateral displacements of 29 FRP-confined circular RC columns under cyclic lateral loading that failed by FRP rupture due to hoop tension. In this model, the equivalent plastic hinge length increases to a peak value and then decreases with the FRP confinement ratio [$\lambda_f = 2E_f t_f \varepsilon_f / (Df'_{co})$, where E_f, ε_f, and t_f = the elastic modulus, ultimate hoop tensile strain and thickness of FRP jacket respectively; D is the diameter of the column section; and f'_{co} is the unconfined concrete strength] (Figure 4). It should be noted that the database of 29 columns used for developing this model included both hardening and softening sectional responses, which may have introduced some errors to the equivalent plastic hinge model which should be used in modeling columns with a softening sectional response. Jiang *et al*. (2014) tested seven FRP-confined square RC columns under monotonic lateral loading, and the equivalent plastic hinge lengths of these test columns also exhibited an ascending and then a descending trend with the FRP confinement ratio, but these were much smaller than those of corresponding circular columns with the same FRP confinement ratio based on the definition of Eq. (8). Therefore Jiang *et al*. (2014) modified the equivalent plastic hinge length model of Gu *et al*. (2012) by introducing the corner radius ratio ($2r/b$) to reflect the reduced FRP confinement effectiveness in square columns. As this modification was based on their own test columns which all had the same corner radius ratio of 0.20, their model is unable to reflect closely the effect of corner radius ratio for square columns. A more robust equivalent plastic hinge length model (Lin 2015) has recently been proposed based on a test database of 18 FRP-confined square RC columns under monotonic/cyclic lateral loading, in which the corner radius ratio ranges from 0.10 to 0.20. This model (Lin 2015), which is similar in form to Jiang *et al*.'s (2014) model, is given by:

$$l_p = 0.08L + 0.022 f_y d_b + \left(\frac{2r}{b}\right)^{\lambda} \begin{cases} 3.028\lambda_f L & \text{when} \quad 0 \le \lambda_f \le 0.1 \\ \left(0.51 - 2.30\lambda_f + 2.28\lambda_f^2\right) L & \text{when} \quad \lambda_f > 0.1 \end{cases} \tag{7}$$

where $\lambda = 1.22$ was obtained based on a regression analysis to minimize the errors between the predictions of Eq. (7) and the test results (Figure 4); r is the radius of the rounded corners; b is the width of a square section; and λ_f is the equivalent FRP confinement ratio for square columns:

$$\lambda_f = \frac{f_l}{f'_{co}} = \frac{2E_f \varepsilon_f t_f}{b f'_{co}} \tag{8}$$

This equivalent plastic hinge length model (Lin 2015) [Eq. (7)] was therefore adopted in the present study to determine the characteristic length l_p^{SF} of the modified Scott-Fenves integration scheme.

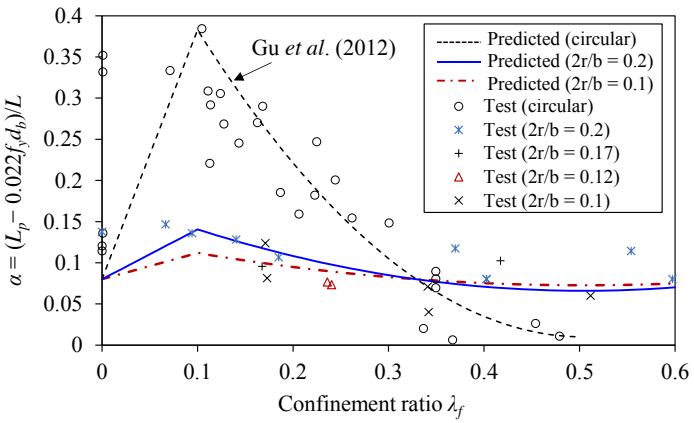

Figure 4 Test results versus predictions of a new model for equivalent plastic hinge lengths (Lin 2015)

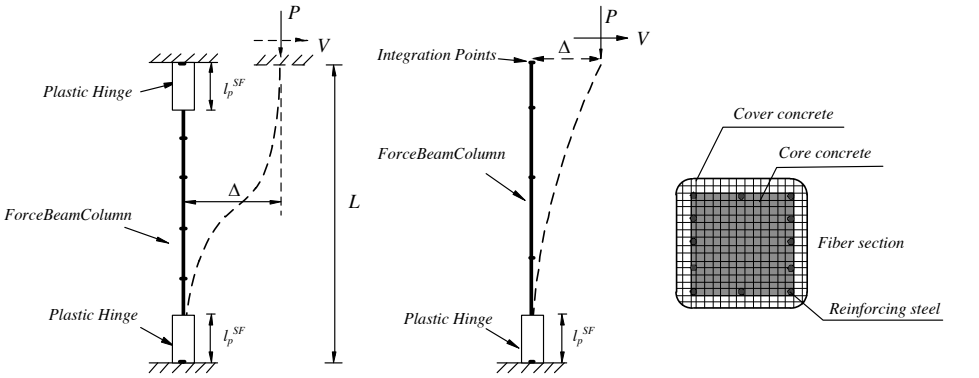
NUMERICAL SIMULATION OF FRP-CONFINED SQUARE RC COLUMNS

Numerical Modelling

As indicated in Figure 5, a cantilever column was modelled using a single force-based beam-column element with the modified Scott and Fenves integration scheme, as was implemented in OpenSEES (2009). Each fixed-end section was assigned with a characteristic length calculated using Eqs. (6) and (7) [Figure 5(a)]. The sectional response at each integration point was predicted by the fiber section method (i.e., the section was

divided into many small fiber elements instead of layers due to the default choice of OpenSEES). The fiber discretization of the square column section is shown in Figure 5(c). The steel fibers were assumed to follow the same cyclic stress-strain model for steel reinforcement as was used by Teng *et al*. (2015). The cover concrete was confined solely with an FRP jacket while the core concrete [i.e., the concrete enclosed by the transverse steel reinforcement (TSR)] was confined with both the FRP jacket and the TSR. Therefore, the concrete core and the concrete cover were assumed to follow two different cyclic stress-strain models respectively as explained in the next sub-section. The cover concrete was divided into two layers in the cover thickness direction and 17 layers along the section side; the core concrete was divided into 14 × 14 equally distributed layers. This level of discretization has previously been shown to lead to converged results (Lehman and Moehle 2000).



(a) Double-curvature bending (b) Single-curvature bending (c) Fibre discretization of cross section

Figure 5 Numerical model for an FRP-confined square RC column

Stress-Strain Models for FRP-Steel-Confined Concrete and Steel

The model used in the present study to predict the envelope curve of concrete in FRP-confined square RC columns under cyclic axial compression is that proposed in Lin (2015). This stress-strain model is applicable to both FRP-steel-confined concrete (the core concrete) and FRP-confined concrete (the cover concrete, which is treated as a special case of FRP-steel-confined concrete). For cases with a softening stress-strain response, the model consists of a cubic first portion, a linear descending second portion, and a horizontal third portion (Figure 6) and is described by the following equations:

$$\sigma_c = \begin{cases} f'_{cc}\left[r\frac{\varepsilon_c}{\varepsilon_{cc}} + (3-2r)\left(\frac{\varepsilon_c}{\varepsilon_{cc}}\right)^2 + (r-2)\left(\frac{\varepsilon_c}{\varepsilon_{cc}}\right)^3 \right] & 0 \le \varepsilon_c \le \varepsilon_{cc} \\ f'_{cc} + E_2\left(\varepsilon_c - \varepsilon_{cc}\right) & \varepsilon_{cc} < \varepsilon_c \le \varepsilon_{rsd} \\ f'_{cu} & \varepsilon_{rsd} < \varepsilon_c \le \varepsilon_{cu} \end{cases} \tag{9}$$

$$r = \frac{E_c}{E_c - E_{\text{sec}}} \tag{10}$$

$$E_{\text{sec}} = \frac{f'_{cc}}{\varepsilon_{cc}} \tag{11}$$

where σ_c and ε_c are the axial compressive stress and strain of confined concrete; E_c is the modulus of elasticity of unconfined concrete; f'_{cc} and ε_{cc} are the peak axial stress and the corresponding axial strain of confined concrete; ε_{cu} and f'_{cu} are the ultimate axial strain and the axial stress at ultimate axial strain of confined concrete; ε_{rsd} is the axial strain at the initiation of the horizontal third portion; and E_2 is the slope of the linear second portion of the stress-strain curve. Further details of the stress-strain model (including equations for f'_{cc}, ε_{cc}, f'_{cu}, ε_{cu}, ε_{rsd}, and E_2) can be found in Lin (2015). These equations take into account the confinement effects of both FRP and TSR, as well as the strain gradient effect due to combined axial compression and bending.

The hysteretic stress-strain behavior of FRP-confined or FRP-steel-confined concrete within the compressive stress-strain domain is described using the unloading/reloading rules from Lam and Teng (2009) (Figure 6). Readers can refer to Lam and Teng (2009) and Teng *et al*. (2015) for more details of the model. For the concrete

in cyclic tension, the modified cyclic stress-strain model of Yassin (1994) for unconfined concrete was used (Teng *et al*. 2015). The "ReinforcingSteel" stress-strain model available in OpenSEES was adopted to represent the hysteretic behavior of steel reinforcement. This model has been shown to be superior to other stress-strain models of steel reinforcement in OpenSEES (2009) (Teng *et al*. 2015).

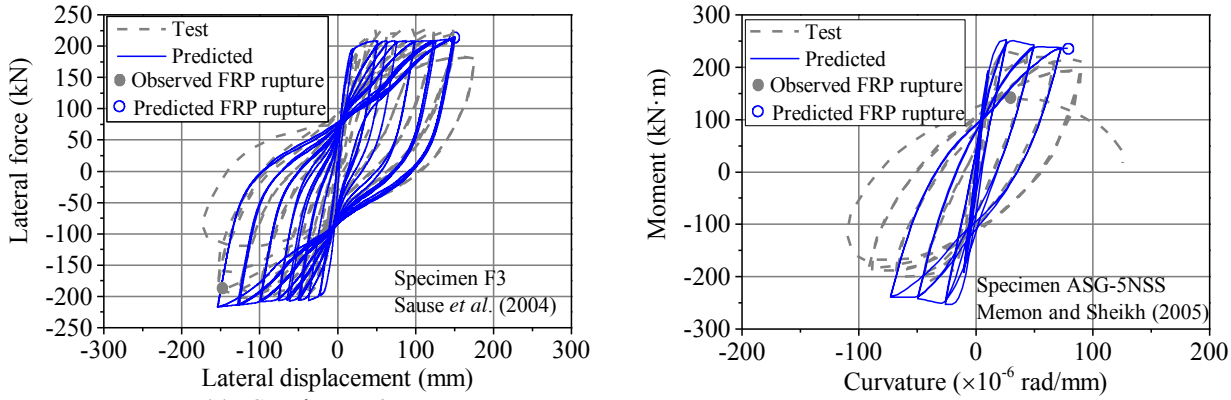
Figure 7 Numerical results for Specimen F3 tested by Sause *et al*. (2004)



(a) Specimen F3 (b) Specimen ASG-5NSS

Figure 8 Cyclic lateral load-displacement curves: test results versus numerical predictions

Numerical Results

Figure 7 shows the numerical results obtained using a single force-based beam-column element with 4, 5, 6, and 7 Gauss-Lobatto integration points for Specimen F3 tested by Sause *et al*. (2004). The sectional moment-curvature curve obtained from a conventional section analysis is shown in Figure 7(a); it is obvious that this specimen has a softening sectional response. The predicted monotonic lateral force-lateral displacement curves

are shown in Figure 7(b). It can be seen that the numerical results vary significantly with the number of integration points, demonstrating the non-objectivity of numerical results.

The numerical results using the force-based beam-column element with the modified Scott and Fenves (2006) integration scheme are shown in Figure 8 for specimen F3 and specimen ASG-5NSS from Sause *et al*. (2004) and Memon and Sheikh (2005) respectively. It can be seen that the responses of the test columns can be reasonably closely predicted using this approach given the complexity of the problem. In particular, the ultimate lateral displacement and ultimate curvature are reasonably well predicted by the proposed approach.

CONCLUDING REMARKS

FRP-confined concrete in rectangular columns often exhibits a softening stress-strain response due to the much lower effectiveness of FRP confinement in these columns compared with that in circular columns. For such cases, localization of inelastic deformation occurs at the column ends, which presents a significant challenge for numerical simulations to obtain objective results. This paper has presented an objective numerical approach for FRP-confined square RC columns under cyclic/seismic loading, in which the force-based beam-column element with the modified Scott and Fenves integration scheme in OpenSEES (Open System for Earthquake Engineering Simulation) is employed. To use this element properly, the development and use of an equivalent plastic hinge length model for such columns was carefully examined. The objectivity and accuracy of predictions from the proposed numerical approach have been demonstrated using numerical examples.

ABSTRACT

The pull-out test of near-surface-mounted (NSM) FRP (fiber-reinforced plastics) rod from concrete was performed using engineered cementitious composites (ECC) as bonding materials. The feasibility of cementitious materials in NSM FRP strengthened concrete was then analyzed. Carbon FRP (CFRP) rods and Basalt FRP (BFRP) rods with spiral surfaces and diameters of 8 mm were used in the test. The bonding lengths are 5 times and 10 times of the FRP diameter, respectively. Results show that the failure modes of all the specimens using ECC as bonding materials are pull-out of FRP rods with ductile behavior. Moreover, specimens with NSM FRP rods using epoxy are prepared as control specimens to evaluate the feasibility of ECC. For CFRP rods, the pull-out load-bearing capacity of specimens using ECC is 70% and 50% of that in specimens using epoxy for 5 times and 10 times of the FRP diameter, respectively. For BFRP rods, the load-bearing capacity of specimens using ECC is 75% and 55% of that in specimens using epoxy for 5 times and 10 times of the FRP diameter, respectively. Thus, ECC can be applied in NSM FRP strengthened concrete structures as the bonding materials.

INTRODUCTION

Fiber-reinforced plastics (FRP) have been widely used in civil engineering in the form of FRP rods, FRP sheets or FRP plates because they have high strength, low density, high resistance to corrosion, and can be transported easily compared to steel plates. A new technique known as NSM (near-surfaced-mounted) FRP rod or plate strengthening concrete structure appears in the field of retrofitting and has been extensively studied in the past decade. The FRP rod or plate in this technique is inserted into a groove cut in the surface of concrete using bonding materials, and improves the bending-resistance and shear capacity of the concrete structure.

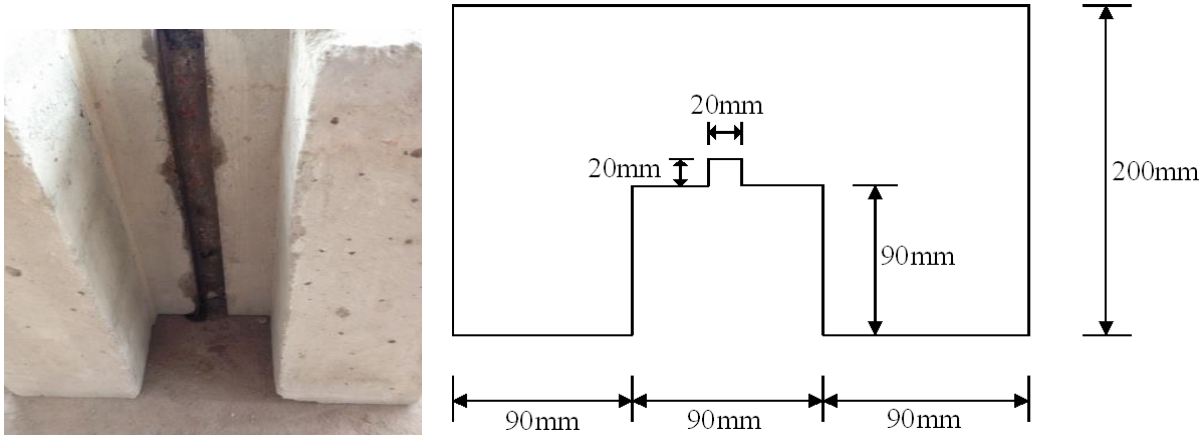
The method of NSM FRP strengthening has many advantages over that of externally bonded FRP plate or sheet. The FRP is embedded in the concrete cover and the effect of abrasion and impact on FRP can be then avoided. The bonded area of NSM FRP to concrete is increased and the strengthening efficiency is improved. Cement-based materials can be used as bonding materials instead of epoxy. Thus, the technique of NSM FRP strengthening can be adopted under the condition of high temperature and humidity. It becomes a hot topic in concrete strengthening since the new technique was first used in Sweden in 1940s (Asplund 1949). Large amount of theoretical and experimental work were performed, including bond performance between NSM FRP and concrete (De Lorenzis et al. 2002, 2007; Galati and De Lorenzis 2009; Soliman et al. 2011; Yang et al. 2009) , study on flexural strengthening (Al-Mahmoud et al. 2012; Capozucca 2009; Kotynia 2012; Kreit et al. 2011; Oehlers et al. 2008; Oudah and EI-Hacha 2012; Wahab et al. 2011; Wang et al. 2011; Yao et al. 2008) and shearing strengthening (Dias and Barros 2013) of concrete structures with NSM FRP.

Epoxy is usually used as bonding materials and the interfacial failure mode between FRP rod and concrete is splitting of epoxy layer which is significantly brittle. Moreover, the performance of epoxy is very sensitive to high temperature and humidity. Therefore, it is necessary to adopt a new type of cementitious materials instead of epoxy as bonding materials and change the brittle interfacial failure to ductile behavior. Engineered cementitious composites (ECC) may be an alternative, which were first designed by Li and Leung (1992) based on micro-mechanics and fracture mechanics and express ductile and strain-hardening behavior. Researchers have carried out much theoretical and experimental work on the optimal designed fiber-reinforced concrete and gain a lot of significant findings (Li et al. 2001, 2007; Xu et al. 2008, 2009; Gao and Xu 2007; Zhang et al. 2010,

2011). The intention of this paper is to study the feasibility of ECC used as bonding materials in NSM FRP rod strengthened concrete structure. Pull-out test of NSM FRP rod from concrete was performed and the failure mode was observed to determine the ductile behavior.

EXPERIMENTAL PROGRAMME

C-type concrete specimen was prepared in Fig. 1 to eliminate the eccentric effect in the pull-out test. The sizes of cross-section of specimen are seen in Fig. 1(b). The groove has sectional sizes of 20 × 20mm^2. The height of specimen is 300 mm.



(a) (b)

Figure 1 C-type concrete specimen

Commercially available premixed concrete was used in the experiment with the mix proportion and basic mechanical parameters in Table 1. Two types of FRP rods with spiral wound surfaces and diameters of 8 mm, i.e., CFRP (carbon FRP) rod and BFRP (basalt FRP) rod, are used in the test. The basic mechanical parameters are shown in Table 2.

Table 1 Mix proportion and basic mechanical parameters of concrete

Mix proportion water : cement : sand : gravel	28-day cubic compressive strength (MPa)	28-day elastic modulus (GPa)
0.47:0.7:1.9:2.52	33.86	30.65

Table 2 Basic mechanical parameters of FRP rods

Type of FRP rod	Density (g/cm^3)	Tensile strength (MPa)	Elastic modulus (GPa)	Fracture elongation (%)
CFRP rod	1.5-1.6	3200	140	1.5
BFRP rod	1.9-2.1	1200	50	1.6

ECC are used as bonding materials and the detailed mix proportion is seen in Table 3. Herein, the cement is P. O. 42.5 common Portland cement (Chinese Standard GB 175 2007). Ultra-fine fly ash is adopted partially instead of cement and quartz sands are used as fine aggregates in the test. Polycarboxylate-based high-range water reducer is utilized as admixture. Reinforcing materials used in the test are Polyvinyl Alcohol (PVA) fibers with diameters of 39 μm and lengths of 12 mm. A four-point-bending test as shown in Fig. 2 is carried out to study the mechanical properties of the ECC. The load-displacement at mid-span curve is seen in Fig. 3.

Table 3 Mix proportion of ECC in the test

Binding materials			Water-to-binder ratio	Sand-to-binder ratio	High-range water reducer	Volume of PVA fiber
Cement	Fly ash	Silica fume				
0.5	0.4	0.1	0.26	0.8	1.8%	1.7%

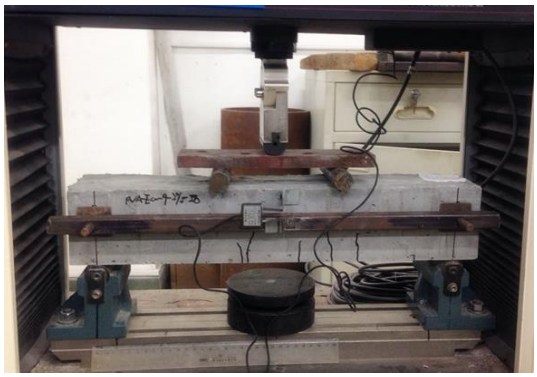


Figure 2 Four-point-bending test for ECC

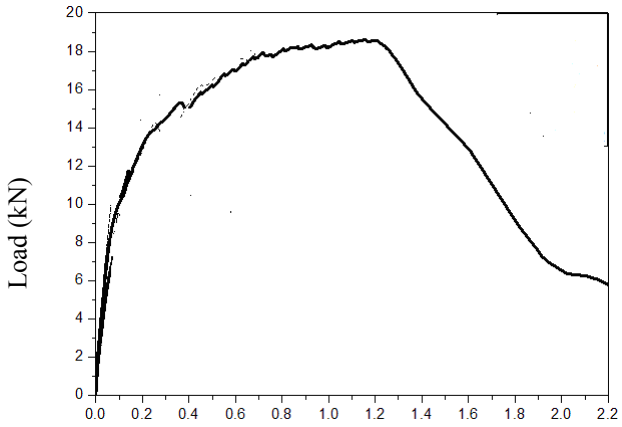

Figure 3 Load-displacement at mid-span curve for ECC

The bonding lengths L are 5 times and 10 times of the rod diameters d, respectively, for both CFRP and BFRP rods. Thus, four groups of specimens are tested. Moreover, epoxy is adopted as another type of bonding materials for reference and then four groups of control specimens are prepared in the experiment. The basic properties of the epoxy are shown in Table 4. All the specimens are tested using an Electrical Universal Testing System with a maximum range of 100 kN after 28-day curing. The test setup is seen in Fig. 4. An extensometer with the maximum range of 50 mm was used to measure the relative slip between the rod and the concrete block at the loaded end. One arm of the extensometer was fixed on the rod and the other arm touched a short column adhering on the top of the load-bearing plate but very near to the rod. The pull-out load P was measured using a load cell set in the testing machine. The rate of loading was controlled by the displacement of the loading head, and fixed at 0.2 mm/min. The readings from the load cell and the extensometer were collected in a data acquisition system.

Figure 4 Photo of test setup

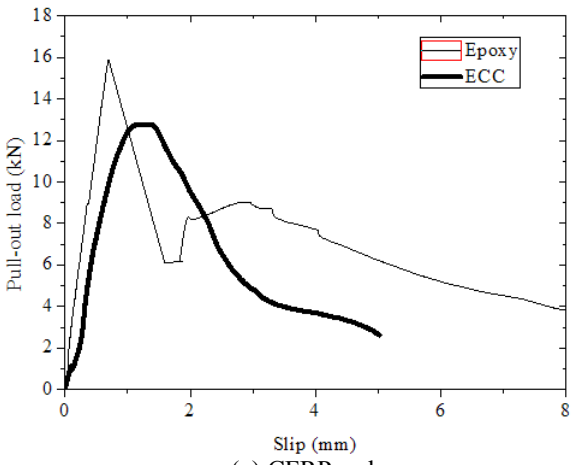
RESULTS AND DISCUSSION

When the bonding materials are ECC, all the specimens are in failure by pull-out of FRP rods from concrete blocks without splitting as shown in Fig. 5(a). Very thin cracks can be detected in the ECC layer but the crack propagation is apparently delayed by the PVA fibers due to the high crack-resistance and toughness of ECC. Ductile failure mode can be obtained by using ECC as bonding materials. However, the specimens with epoxy as bonding materials fail by splitting failure of epoxy layer as shown in Fig. 5(b) which is significantly brittle. Fig. 6 shows typical load-slip curves for the two types of FRP rods. There is a slowly descending part in the curve for ECC as bonding materials but a sharply reduction is observed for epoxy as bonding agent when the peak load is exceeded. After the point B, the epoxy layer is actually split and only residual friction remains between the FRP rod and epoxy. Therefore, the ductile behavior can be evaluated based on the stage from the beginning of loading to the start of frictional part. Obviously, the better ductility is observed in the specimens using ECC as bonding materials.

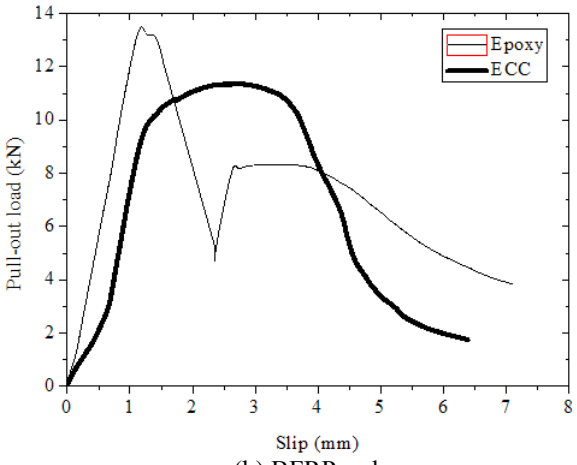
(a) ECC

(b) Epoxy

Figure 5 Failure modes of specimens using different bonding materials



(a) CFRP rod



(b) BFRP rod

Figure 6 Typical load-slip curves

The maximum pull-out load is lower when ECC is used as bonding materials. For CFRP rods, the pull-out load-bearing capacity of specimens using ECC is 70% and 50% of that in specimens using epoxy for L=5d and

L=10*d*, respectively. For BFRP rods, the load-bearing capacity of specimens using ECC is 75% and 55% of that in specimens using epoxy for *L*=5*d* and *L*=10*d*, respectively. But the ductility of specimens with ECC is significantly improved. Thus, ECC can be applied in NSM FRP strengthened concrete structures as the bonding materials.

CONCLUSIONS

The technique of NSM FRP strengthening concrete structures has been gradually applied in civil engineering. Epoxy is usually used as the bonding materials, and then the failure mode is always splitting of the epoxy layer which is significantly brittle. Thus, it is necessary to select a type of cementitious materials with good ductility as bonding materials instead of epoxy. Engineered cementitious composites (ECC) have been adopted in structural retrofitting due to the high strength and high toughness. The intention of this paper is to study the feasibility of ECC used as bonding materials in NSM FRP rod strengthened concrete structure. The pull-out test of NSM FRP rod from concrete was performed using ECC as bonding materials. The feasibility of cementitious materials in NSM FRP strengthened concrete was then analyzed. CFRP rods and BFRP rods with spiral surfaces and diameters of 8 mm were used in the test. The bonding lengths *L* are 5 times and 10 times of the FRP diameters *d*, respectively. Results show that the failure modes of all the specimens using ECC as bounding materials are pull-out of FRP rods with ductile behavior. Moreover, specimens with NSM FRP rods using epoxy are prepared as control specimens and brittleness is most significant in these specimens. For CFRP rods, the pullout load-bearing capacity of specimens using ECC is 70% and 50% of that in specimens using epoxy for *L*=5*d* and *L*=10*d*, respectively. For BFRP rods, the load-bearing capacity of specimens using ECC is 75% and 55% of that in specimens using epoxy for *L*=5*d* and *L*=10*d*, respectively. Thus, ECC can be applied in NSM FRP strengthened concrete structures as the bonding materials.

CYCLIC BOND BEHAVIOUR OF FRP-TO-STEEL BONDED JOINTS

Hao Zhou, Yashar Doroudi, Dilum Fernando *

ABSTRACT

Cyclic behaviour of the FRP-to-steel bonded interfaces is a key issue to be addressed in modelling the long-term performance of FRP-to-steel bonded joints. However, compared to extensive experimental and theoretical study on the bond-slip behaviour between two adherents, either FRP-to-steel or FRP-to-concrete under monotonic loading, so far only few research have been carried out on the cyclic behaviour of such bonded joints. This paper presents a new bond-slip model to model the behaviour of FRP-to-steel bonded joints under quasi-static cyclic loading. In addition, an analytical model to model the load-displacement behaviour and interfacial shear stress distributions is also presented. The results from the proposed model and the results from another existing model are compared with the experimental results from two FRP-to-steel bonded joints tests under cyclic loading. Results from the proposed model show a better agreement with the experimental load-displacement behaviour, shear stress distribution and the bond-slip behaviour.

KEYWORDS

FRP-to-steel bonded joints, cyclic behaviour, interfacial shear stress distribution, bond-slip model.

INTRODUCTION

In flexurally strengthened steel structures using externally bonded FRP laminates, the interfacial shear stress transfer in the adhesive layer that bonds the steel and FRP together is crucial to the performance of the strengthened structure (Teng *et al*. 2012). Therefore proper understanding of the bonded interfaces is of critical importance in determining when the failure will occur and how effectively the FRP is utilized. Many studies have been carried out on understanding and modelling the interfacial failures in FRP-to-steel bond joints (Yu *et al*. 2012, Fernando *et al*. 2015, Teng *et al*. 2015). Pull tests on simply bonded joints, where the adhesive layer is primarily subjected to interfacial shear stress, have been commonly used to study the bond behaviour under interfacial shear loading. Interfacial shear behaviour is an important basis for understanding the behaviour of FRP-to-steel interfaces subjected to combined shear and peeling stresses. A bond-slip model, which depicts the relationship between the local interfacial shear stress and the relative slip between the two adherents, is of fundamental importance to understand and model the behaviour of FRP strengthened steel structures. Many studies have been carried out to determine the bond-slip behaviour of FRP-to-steel bonded joints (Yu *et al*. 2012, Fernando *et al*. 2010); and different bond-slip models with different levels of sophistications have been proposed. Most commonly used are the bi-linear bond-slip models. In such models, when defining damage, linear unloading to zero stress at zero slip is assumed. Thus, any inelastic deformations are ignored. This assumption means, the applicability of such a bond-slip model is limited to static monotonic loading conditions. While no studies have been carried out on the bond-slip behaviour of FRP-to-steel bond joints under cyclic loading, some works have been done on FRP-to-concrete bonded joints under cyclic loading. In FRP-to-concrete bonded joints, debonding failure often occurs closer to the bonded interfaces few millimetres within the concrete, while debonding failures in FRP-to-steel bonded joints are unlikely to occur within the steel substrate due to the relatively high strength of steel. Due to this difference in debonding failure, direct application of the bond-slip models of FRP-to-concrete bonded joints to FRP-to-steel bonded joints is not possible. Nevertheless, underlying concepts such as interfacial fracture energy and effective bond length are still applicable to the FRP-to-steel bonded joints.

In the existing bond-slip models for FRP-to-concrete and FRP-to-steel bonded interfaces under quasi-static monotonic loading, damage parameter is calculated assuming linear unloading to zero load at zero stress. However, experimental results on the bond-slip behaviour of FRP-to-concrete bonded joints under cyclic loading showed remarkable hysteresis loops, indicating inelastic deformations occurred during the cyclic loading. In addition, experiments showed that the residual slip (i.e. slip at zero loading) at the loading end increased with the increase in loading cycles (Ko and Sato 2007). These observations clearly indicate that the commonly used approach of calculating the damage parameter in bond-slip models for quasi-static monotonic loading, i.e. assuming linear unloading to zero load at zero slip, is not accurate for cyclic loading. Based on the experimental

observations, several analytical approaches were proposed to define the bond-slip behaviour of the FRP-to-concrete bonded joints under cyclic loading (Ko and Sato 2007, Diab *et al*. 2009, Martinelli and Caggiano 2014, Carrara and De Lorenzis 2015). Except Ko and Sato (2007), the other existing models assume bi-linear bond-slip behaviour with a linear ascending branch followed by a linear descending branch, as commonly assumed in FRP-to-concrete bond-slip models under quasi-static monotonic loading. The essential difference between the different bond-slip models proposed for cyclic loading is in the approach used to define the damage parameter under cyclic loading. In the most advanced of these models (Martinelli and Caggiano 2014, Carrara and De Lorenzis 2015), damaged parameters is either related to the ratio between inelastic and total fracture energy (Martinelli and Caggiano 2014) or negative slip increments (i.e. reversal of the residual slip at zero shear stress) (Carrara and De Lorenzis 2015). Martinelli and Caggiano (2014) model assumes negative shear stresses to be possible during the unloading process while Carrara and De Lorenzis (2015) model assumes negative shear stresses are not possible. Negative shear stresses could occur due to the reversal of plastic deformations, friction or interlocking that are assumed to be negligible by Carrara and De Lorenzis (2015) in deriving their model. However, so far this assumption is not experimentally verified.

This paper presents an analytical model to model the behaviour of FRP-to-steel bonded joints under cyclic loading. The proposed model is similar to that proposed by Martinelli and Caggiano (2014), but different in terms of the damage parameter used. The analytical models are compared with preliminary experimental results from FRP-to-steel bonded joints carried out by the authors group.

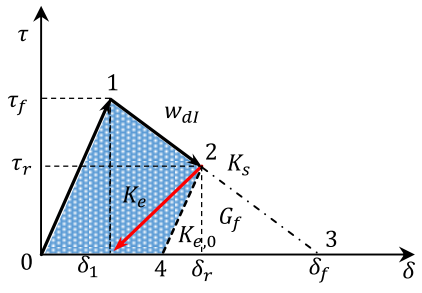
ANALYTICAL MODEL

In deriving the analytical solution presented below, few simplifying assumptions were made. It was assumed that the adhesive layer is subjected to only shear deformations. Previous experimental observations have found this assumption to be reasonable for a bond in a single shear pull off test (Fernando 2010). It is further assumed that the adhesive layer is subjected only to shear stresses which are constant across the adhesive layer thickness and that both adherents (i.e. the CFRP plate and the steel substrate plate) are subjected to uniformly distributed axial stresses. These assumptions have also been commonly adopted in the development of similar analytical solutions for CFRP-to-steel bonded joints under quasi-static monotonic loading (Fernando *et al*. 2014). With these assumptions, the governing differential equation well established for a bonded joints in a single-lap pull test is given by Fernando *et al*. (2014):

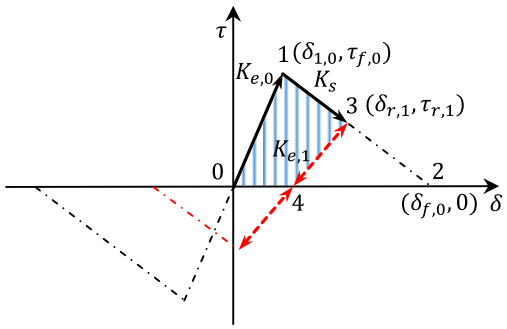
$$\frac{d^2\delta}{dx^2} - \left(\frac{1}{E_p t_p} + \frac{b_p}{E_s b_s t_s}\right) f(\delta) = 0 \qquad (1)$$

Where δ is the slip between the two adherents. E_p, t_p, b_p is the elastic modulus, thickness and width of the FRP plate respectively. Likewise, E_s, t_s, b_s is the elastic modulus, thickness and width of the steel plate respectively. $f(\delta)$ represents the relationship between the shear stress (τ) and the slip (δ). Eq. 1 can be solved if the bond-slip model, $f(\delta)$ is known. The bi-linear model under cyclic loading adopted in this study is illustrated in Figure 1.

a)



b)



c)

d)

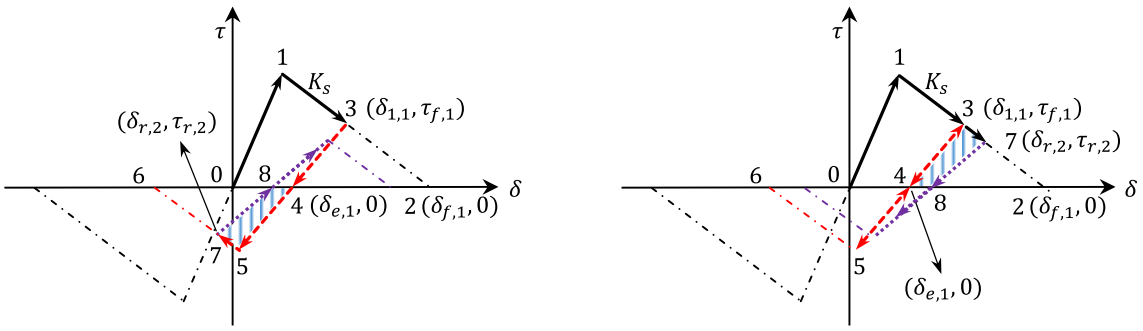


Figure 1. Local bond-slip model under cyclic loading: a) Martinelli and Caggiano's (2014) model; b): The proposed model in the first unloading (in softening range); c): The proposed model which subsequent unloading/reloading is in the negative softening range; d): The proposed model which subsequent unloading/reloading is in the positive softening range.

The local bond-slip model presented in Figure1 can be mathematically described as:

$$f(\delta)=\begin{cases} K_{e,i}\left(\delta-\delta_{e,i}\right) & \text{when } \left|\delta-\delta_{e,i}\right|\le\left|\delta_{1,i}-\delta_{e,i}\right| \\ K_{e,i}\left(\delta_{1,i}-\delta_{e,i}\right)+K_s\left(\delta-\delta_{1,i}\right) & \text{when } \left|\delta_{1,i}-\delta_{e,i}\right|<\left|\delta-\delta_{e,i}\right|\le\left|\delta_{f,i}-\delta_{e,i}\right| \\ 0 & \text{when } \left|\delta-\delta_{e,i}\right|>\left|\delta_{f,i}-\delta_{e,i}\right| \end{cases} \quad i=0,1,\cdots,n \tag{2}$$

Where notation i means the i^{th} unloading/reloading step. δ is the slip, $\delta_{e,i}$ is the plastic slip, and $\delta_{1,i}$,$\delta_{f,i}$ is the slip value corresponding to the peak shear stress and debonding initiation respectively. $K_{e,i}$ is the damaged elastic stiffness which is given by:

$$K_{e,i+1}=\left(1-D_{i+1}\right)K_{e,i} \qquad i=0,1,...,\mathrm{n} \tag{3}$$

When i=0, $K_{e,0}$ represents the initial elastic stiffness. It is also assumed that when unloading/reloading occurs in the elastic range, no damage would be caused. Otherwise, the damage parameter D is used to indicate the stiffness degradation.

The plastic slip is calculated as:

$$\delta_{e,i}=\delta_{1,i}-\frac{\tau_{f,i}}{K_{e,i}} \qquad i=0,1,...,\mathrm{n} \tag{4}$$

In which $\tau_{f,i}$ is the peak shear stress value in the ith unloading/reloading step, which is also the shear stress value when unloading happens in the previous step, assuming unloading happens in the softening range. Otherwise, it might keep unchanged.

In terms of the damage parameter, Martinelli and Caggiano (2014) defined the damage parameter as a function of the ratio between the inelastic energy and the total fracture energy, i.e.

$$D_I=\left(\frac{w_{dI}}{G_f}\right)^{\alpha_d} \tag{5}$$

Where α_d is a damage coefficient, which is taken to be a unit in the subsequent analysis. In Figure 1a, w_{dI} is indicated by the area enclosed by the bond-slip curve and the line with slope of the initial stiffness, i.e. A_{01240}. However, with this definition of the damage parameter, when damage parameter value is closer to zero, negative slip may result at zero shear stress during the unloading. The negative residual slip means total fracture energy may increase, which is not possible. In the current study an alternative damage parameter is defined as follows,

$$D_{II,i+1}=\left(\frac{w_{dII,i+1}}{G_i}\right)^{\alpha_d} \tag{6}$$

As graphically shown in Figures 1b-d, the calculation of the damage parameter can be explained as follows. Since no damage is considered when unloading happens in the elastic range, only the situation that unloading/reloading in the softening range is illustrated.

In Figure 1b, assuming the first unloading occurs, therefore

$$w_{dII,1} = A_{01340} = A_{013240} - A_{4324}$$
$$G_0 = A_{013240} \tag{7}$$

In Figure 1c, if the reloading happens in the negative softening range,

$$w_{dII,2} = A_{45784} = A_{4576084} - A_{87608}$$
$$G_1 = A_{4576084} \tag{8}$$

Or as shown in Figure 1d, reloading/unloading in the positive softening range,

$$w_{dII,2} = A_{43784} = A_{437284} - A_{8728}$$
$$G_1 = A_{437284} \tag{9}$$

Note $A_{4324} = A_{4576084}$ in Figure 1c and $A_{4324} = A_{437284}$ in Figure 1d, when it comes to failure, the total energy dissipated in the cracks and plastic deformation is equal to the total fracture energy which is the area under the initial bond-slip relationship (Bažant 1996), i.e.

$$\sum_{i=1}^{n} w_{dII,i} = G_f = A_{013240} \tag{10}$$

In a particular unloading/reloading case, $w_{dII,i}$ can be expressed implicitly as:

$$w_{dII,i+1} = G_i - \frac{1}{2}\left[\delta_{f,i} - \delta_{r,i+1} + \tau_{r,i+1}/K_{e,i+1}\right]\tau_{r,i+1} \tag{11}$$

Substituting Eq. 4 into Eq. 6, it is straightforward to get an implicit expression of the damage parameter, i.e.

$$1 - D_{II,i+1} = \frac{1}{2G_i}\left\{\delta_{f,i} - \delta_{r,i+1} + \tau_{r,i+1}\Big/\left[\left(1 - D_{II,i+1}\right)K_{e,i}\right]\right\}\tau_{r,i+1} \tag{12}$$

It can be found that the damage parameter is the only variable, which can be calculated given a slip value. Obviously, the damage parameter and the unloading/reloading stiffness is a function of the slip value while unloading/reloading occurs in both models. Meanwhile, it is assumed that when the slip is reversed, the bond-slip model is antisymmetric respect to the point where the shear stress is zero at the elastic range, i.e. point 0 in the initial bond-slip model and point 4 in the unloading one. Besides, the stiffness in the softening range keeps constant. The difference between these two prediction models will be explained and discussed in the case study.

EXPERIMENT

Series of single-shear pull off test on CFRP-to-steel bonded joints were carried out at the University of Queensland (UQ) structures laboratory. Two of these tests are used in this study for the comparison with analytical results. Both specimens were made using 1.4mm thick, 50mm wide CFRP plates bonded to steel substrate with 1mm thick Sika 30 adhesive layer. The elastic modulus of CFRP in the fiber direction was 170GPa. Details of the specimens and the test setup are given in Figure 2.

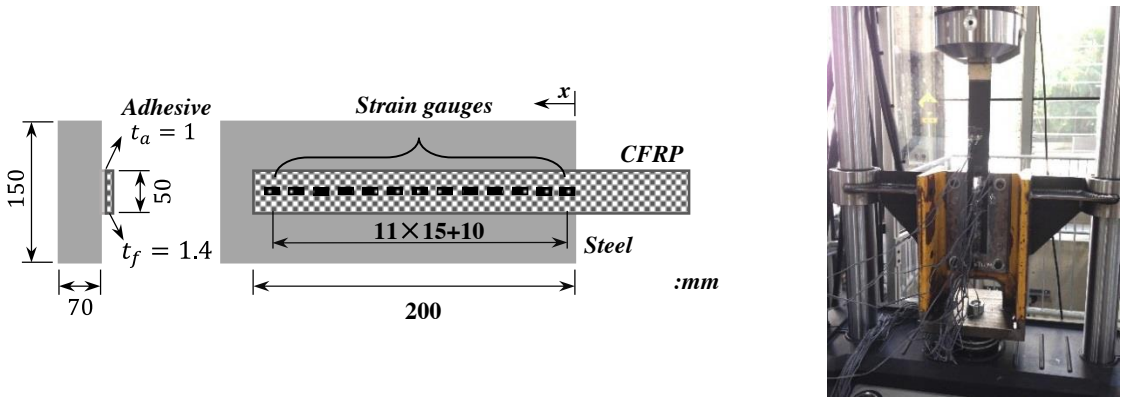

Figure 2 Test set-up and instrumentation

Both specimens were nominally identical and varied only in the applied loading scheme. For the first specimen (Specimen I), fully reversed load cycles were applied, while for the second specimen (Specimen II) partially reversed load cycles were applied. The loading schemes for specimen I and II are given in Table 1. These loading schemes were designed based on the analytical full range behaviour models (Fernando *et al*. 2014) to obtain; (1) several loading cycles within the ascending branch of local bond-slip models, (2) several load cycles within the descending branch of local bond-slip models, (3) several cycles with shear stress zero (or below zero) during unloading (for fully reversed load cycles only), and (4) several cycles with positive shear stress at

reloading (for partially reversed loading cycles only). A number of strain gauges were attached to the top surface of the CFRP plate at intervals of 15mm except for the first strain gauge (counted from the loaded end of the steel substrate, see Figure 2, which was at 5mm from the loaded end of the steel substrate plate and the second one was 10mm interval.

Based on a series of monotonic test, the parameters associated with the bond-slip model were identified as $\delta_1 = 0.04mm$, $\delta_f = 0.13mm$, $\tau_f = 23MPa$. Using these values in the bond-slip model presented in Eq. 2, the governing equation, i.e. Eq. 1 was solved numerically to get the load-displacement curve under cyclic loading, the shear stress distribution along the bonding length and the local bond-slip relationship under cyclic loading.

Table 1 The loading scheme

Loading step	Fully reversed mm→mm→mm	Partially reversed kN→mm→kN
1	0→0.042→0(0.002)	0→0.043→2.6
2	0(0.002)→0.062→0(0.005)	2.6→0.077→18
3	0(0.005)→0.082→0(0.008)	18→0.221→28

12	N/A	28→0.587→38

Note: The slip value in the bracket is the minimum slip reached in the test while unloading.

RESULTS AND DISCUSSION

The experimental load vs displacement curves for both specimens are compared with the analytical predictions in Figure 3. Results from the Martinelli and Caggiano (2014) model are shown as Prediction-I, while the results from the proposed model in this study are shown as Prediction-II. Both Prediction-I and Prediction-II generally agree well with the experimental curves. Hysteresis loops while unloading and reloading can be observed from the test results. Such hysteresis loops are ignored in the simplified analytical models presented in this study.

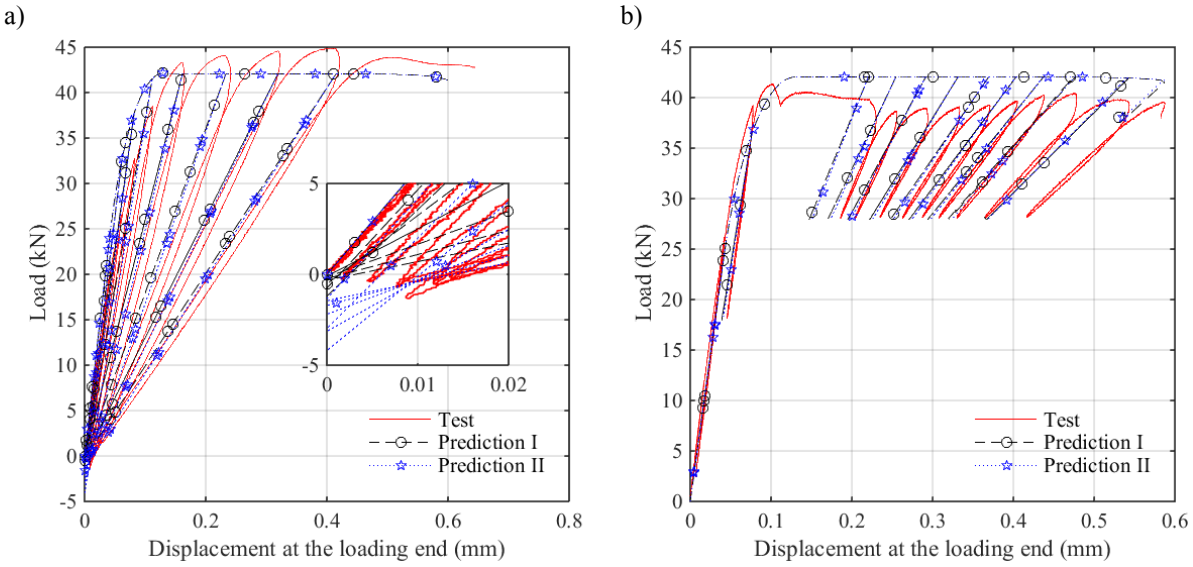

Figure 3 The comparison between the theoretical and experimental results: (a) fully reversed cyclic loading ; (b) partially reversed cyclic loading

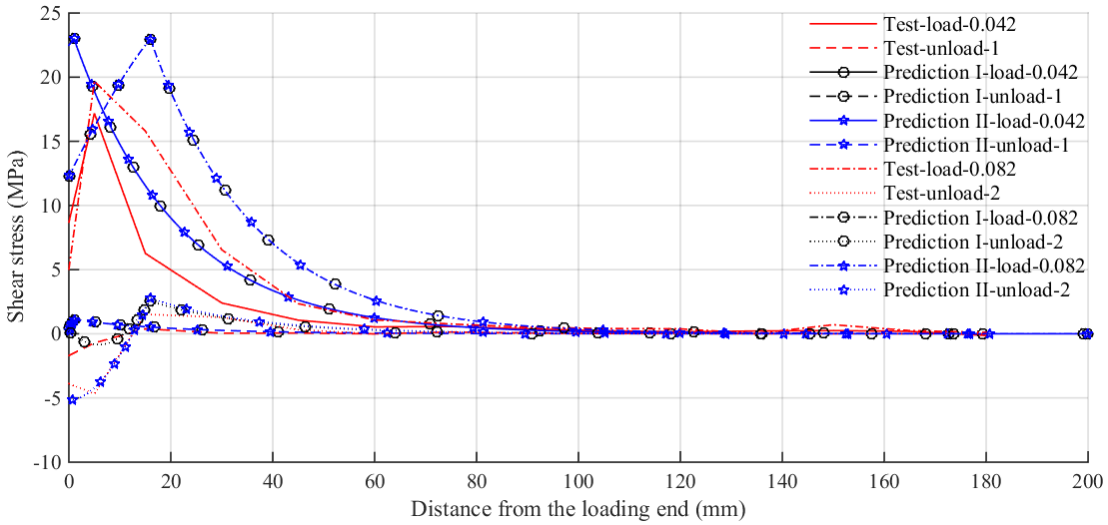
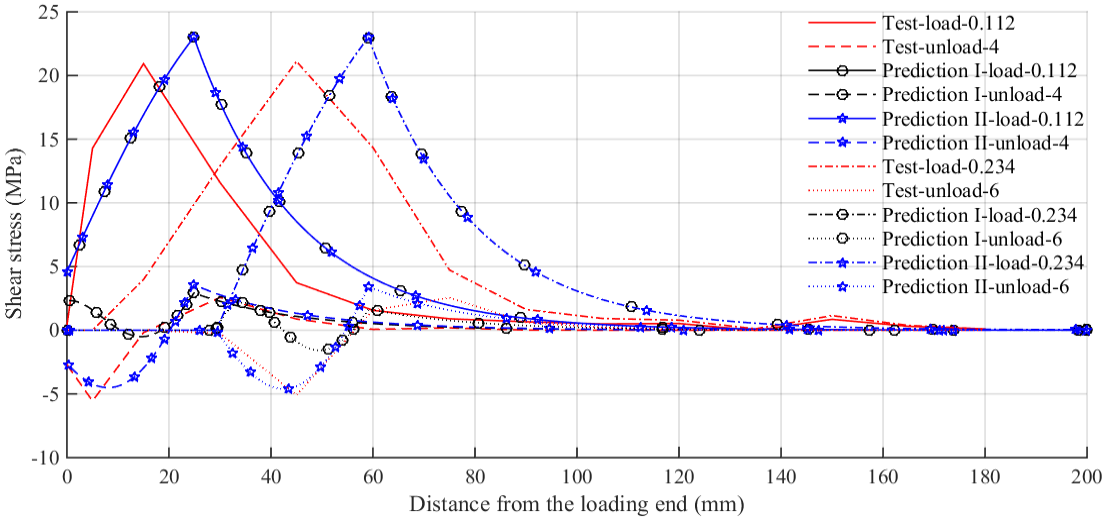
A detailed illustration of the load-displacement curve close to the origin is presented in Figure 3a. Results show that the external force is negative when the displacement at the loaded end approaches zero. Due to the reduced stiffness of the unloading path in damaged regions, a residual slip can be expected at zero load. Further reduction in the displacement at the loaded end will result in negative loading. In this negative load region, Prediction-II gives a better agreement with the experimental results than the Prediction-I (Figure 3a). Occurrence of the negative loading can be further explained by the shear stress distribution along the bond length as shown in Figure 4.

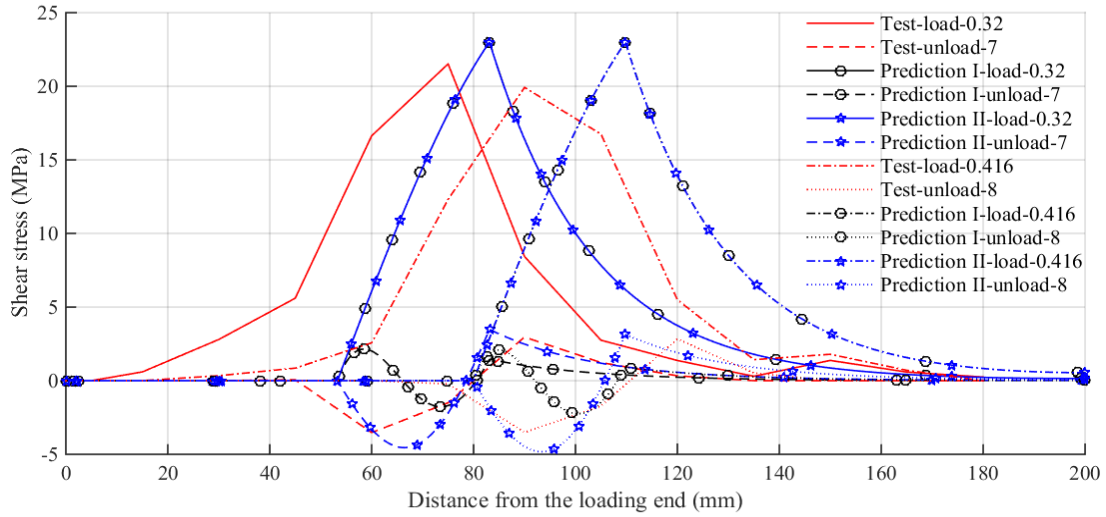
a)



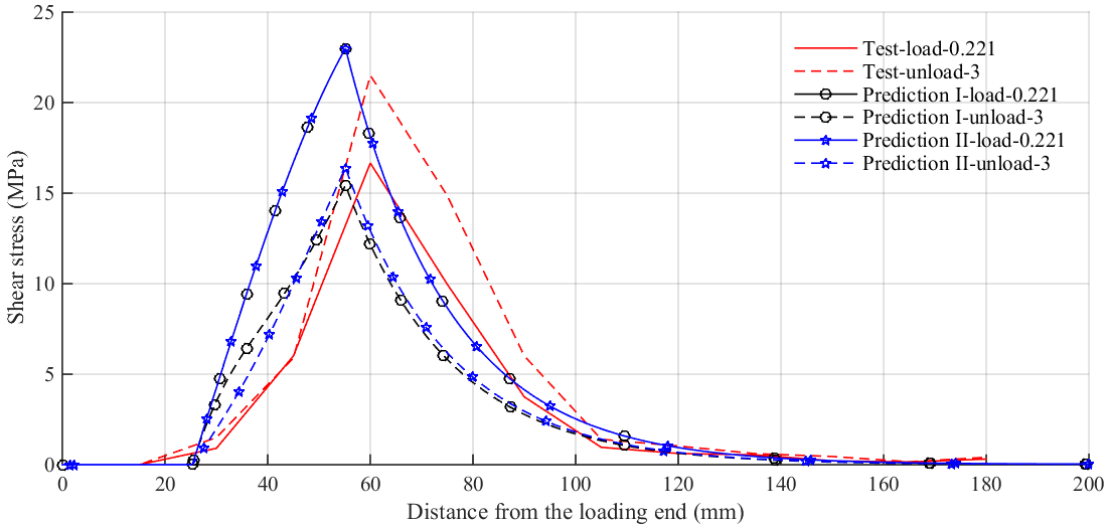
b)



c)



d)



e)

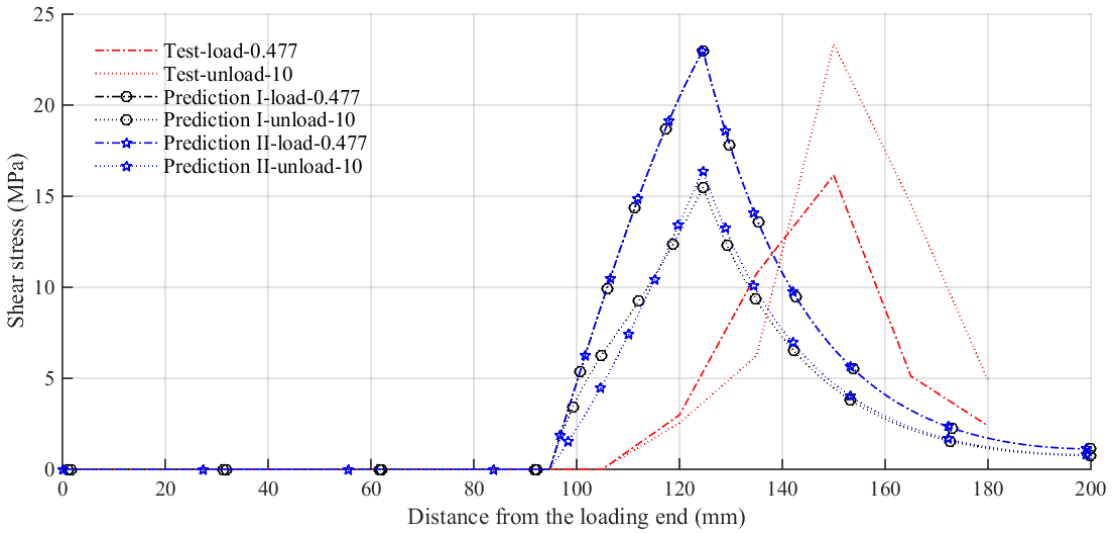


Figure 4 The shear stress distribution comparison between test and both predictions: a) to c) comparison based on the fully reversed cyclic loading test results; d) to e) comparison based on the partially reversed cyclic loading test results

The experimental interfacial shear stress distributions of fully reversed cycle loading test show negative shear stresses at the loaded end and positive shear stresses in the region following the negative shear region (Figures 4a-c) at full unloading (according to the slip in the test). Negative shear stresses mean that the direction of the

shear has reversed, which is due to the reversal of the plastic slip in the region closer to the loaded end. It is also seen that closer to the zero loading, the area of negative shear stress region is larger than the positive shear stress region, thus agreeing with the negative loading observed in the load displacement curve at the reversal of residual displacement. The difference between the negative stress region and positive stress region becomes more pronounced as the load increases. Prediction-II captures this negative stress region effectively while prediction-I always predicts positive stresses closer to the loaded end (Figures 4a-c) except in the initial loading cycles. During the positive loading, both models give similar predictions and agree well with the experimental results at lower loads. As the load increases, predicted interfacial shear stress distributions are found to be shifted towards the unloaded end compared to the experimental interfacial shear stress distributions. For the partially reversed cyclic loading test, both prediction-I and prediction-II give similar predictions (Figure 4d). As negative shear stresses does not exist, both models appear to agree well with the experimental results. Load displacement curve of the specimen I shows that experimental load to be slightly higher than the predicted load, and initial stiffness of the load displacement curve to be slightly lower than the initial stiffness of the predicted curve. These differences could be explained through the comparison of local bond-slip models.

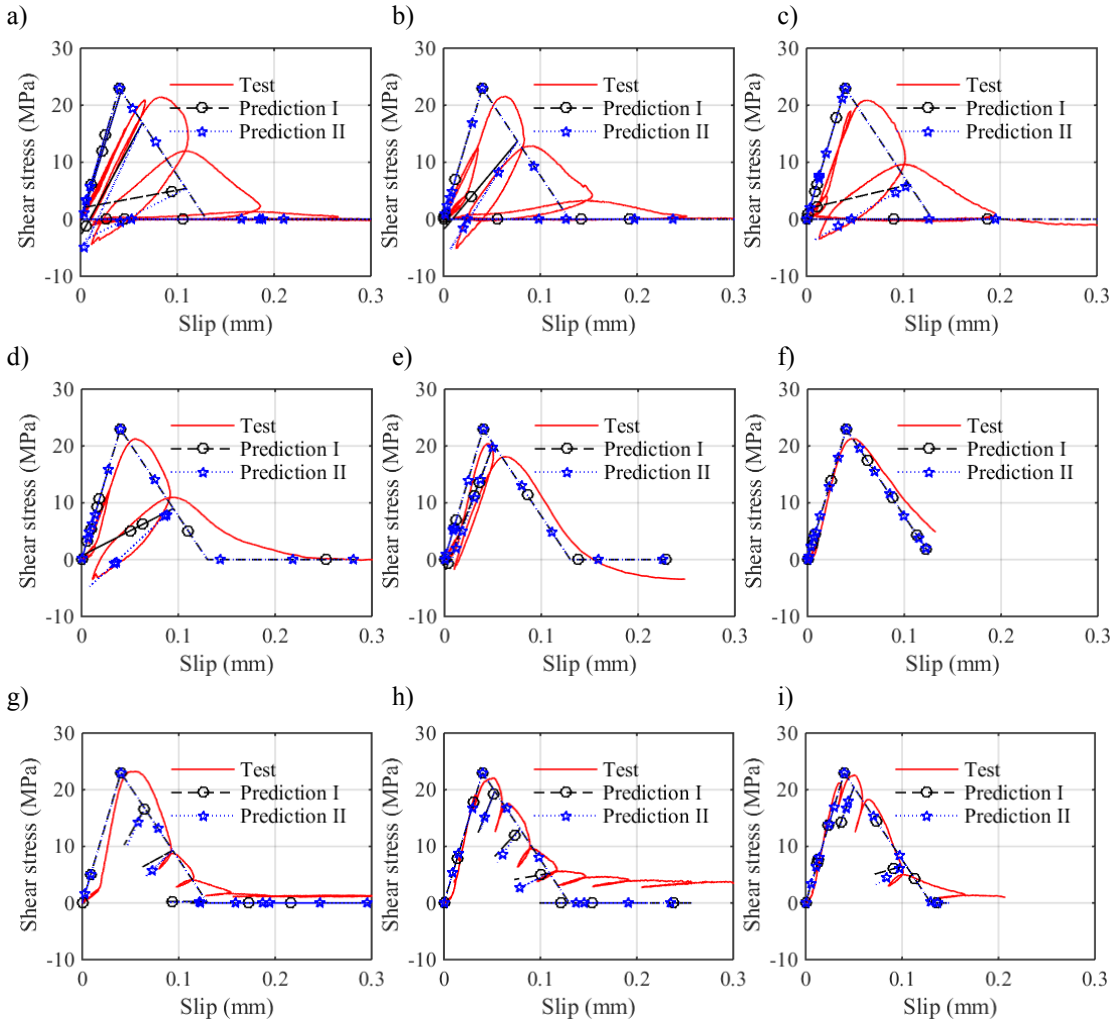

Figure 5 The evolution of local bond-slip model at different points along the bonding length: i.e. fully reversed cyclic loading: a) *l*=15mm; b) *l*=45mm; c) *l*=60mm; d) *l*=90mm; e) *l*=105mm; f) *l*=135mm; partially reversed cyclic loading: g) *l*=45mm; h) *l*=90mm; i) *l*=120mm

A comparison between the predicted and experimental bond-slip curves at different locations along the bond length for specimen I is given in Figures 5a-f, while those for specimen II are given in Figures 5g-i. Significant hysteresis loops can be seen in the experimental bond-slip curves of specimen I, compared to the specimen II. Such hysteresis behaviour is neglected in the prediction models. Both prediction models over-estimat the initial stiffness of the bond-slip curves. This over estimation results in the overestimation of load-displacement behaviour. In addition, it can also be seen that the maximum slip, where the debonding initiation occurs, is significantly under estimated by the bond-slip models. This under-estimation of the maximum slip result in early debonding in the prediction models compared to the experimental result, which is demonstrated by the shift in

interfacial shear stress distributions in Figure 4. Compared to prediction-I results, prediction-II results give a much better agreement with the experimental bond-slip behaviour under cyclic loading, especially after the damage initiation. After the damage initiation, during unloading, prediction-I is shown to give negative slip at zero stress, which is thermodynamically not possible. Prediction-II does not show such errors, and always results in a positive residual slip at zero shear stress.

CONCLUSIONS

This paper has presented an analytical bond-slip model for FRP-to-steel bonded joints under quasi-static cyclic loading. An analytical model to model the behaviour of FRP-to-steel bonded joints under quasi-static cyclic loading is also presented. Results from the proposed mode and Martinelli and Caggiano (2014) model are compared with the experimental results from two FRP-to-steel bond joints tests under cyclic loading. Based on these comparisons, some conclusions can be drawn as follow: 1). both prediction models show a good agreement of the load-displacement relation of FRP-to-steel joints under both full and partial cyclic loading, but proposed model is superior to the existing model in terms of predicting the behaviour when slip at the loaded end is closer to zero during the unloading. 2) the results from the proposed model show a good agreement of the shear stress distribution, compared to an opposite distribution trend in Martinelli and Caggiano (2014) model. 3) more research is required to construct the constitutive model of such kind of bonding joints under cyclic loading, with regard to the bond behaviour at the interface level.

ABSTRACT

Overweight trucks are common on the highways in China, which presents fatigue damage problem for the reinforced concrete (RC) bridges. Externally bonding CFRP sheets is increasingly being used to repair the damaged bridges. The degradation of adhesive bonding in a wet-dry environment, however, may have a significant adverse effect on the long term durability of the repaired bridges. This paper presents an experimental study on the flexural capacity of damaged RC T-beams strengthened with CFRP sheets subjected to the wet-dry cycles. A total of 19 specimens in 8 series were tested. The specimens were damaged by constant fatigue loading which were equivalent to the repetitive loadings caused by the overweight trucks across a bridge in one year. The specimens subjected to wet-dry environment were exposed to a period of 3 months or 6 months. A wet-dry cycle was 24 h including a wet cycle (salt water) of 10 h and a dry cycle (hot air at 40 ℃) of 14 h. The experimental results showed that a slight reduction in stiffness was observed for the strengthened beams due to overloading damage or wet-dry exposure. The residual deflection and cracks caused by overloading damage reduced the effect of CFRP strengthening. The wet-dry cycles induced degradation to bond at the concrete/FRP interface. Only in the first 3 months, however, the wet-dry environmental exposure can obvious reduce the strength of the retrofitted beams.

Flexural capacity, RC beams, fatigue overloading, wet-dry cycles.

INTRODUCTION

Reinforced concrete (RC) bridges in highway are subjected to an increasingly heavy traffic. Depending on the type of highway, components in decks can experience up to 7×10^8 stress cycles (Mays and Tilly 1982). Consequently, fatigue damage, especially caused by the overweight trucks, is one of the main problems that occur in highway bridges. Externally bonding carbon fibre reinforced polymer (CFRP) sheets to the tension face has been accomplished to repair the damaged bridges (Hollaway and Head 2001). However, the degradation of adhesive bonding in a hygrothermal environment may have an adverse effect on the mechanical behaviour of the repaired bridges. Therefore, specific research is needed to understand the durability of the repaired bridges under the environmental conditions.

To study the problem of the overload of vehicles, Yu et al. (2013) proposed a real-time overload monitoring system of bridges and roads based on the structural response. Ye et al. (2012) developed a stress spectra for fatigue life assessment of steel bridges with use of long-term monitoring data dynamic strain. The predicted fatigue life of Tsing Ma Bridge is varying slightly when using more than 10 daily strain data and keep almost the same when using more than 20 daily strain data. A damage model for the determination of damage caused by traffic was developed and applied on three RC bridges (Pircher et al. 2013). The results show that heavy trucks can cause high damage for all three bridges. Zhu (2011) developed an *S-N* curve of RC T-beams to predict the residual service life of highway RC simply-supported girder bridges. In addition, an *S-N* curve was developed from the test results to predict the fatigue life of the steel beams reinforced with CFRP plate (Deng and Lee 2009).

Choo el al. (2007) presents a study on a CFRP retrofitted RC bridge subjected to extreme vehicular loads. The increase in flexural capacity provides an adequate margin of safety against further overloading. The capacity and rigidity of the RC beams damaged by static loading were highly enhanced by CFRP strengthening (Benjeddou et al. 2007). The durability of RC beams reinforced with GFRP laminates were investigated by Almusllam (2006). The test results showed that none of the environmental conditions have a noticeable influence on the flexural strength of the retrofitted beams. The experimental tests on the durability of the concrete elements strengthened with near surface mounted CFRP laminates showed a decrease of around a 12% in the maximum pull-out force due to the wet-dry cycles (Garzon-Roca et al. 2015).

From above, the previous research has shown that heavy trucks may cause high damage in the RC bridges and CFRP externally bonding technique can restore their capacity. The influence of the wet-dry environmental exposure on the retrofitted RC members had investigated as well. However, the knowledge on the combined effects of overweight truck damage and wet-dry exposure on the retrofitted RC bridges is absent. In this paper, an experimental study on overloading damaged RC T-beams strengthened with CFRP sheets subjected to wet-dry environmental exposure was conducted. A total of 19 specimens in 8 series were tested. Fatigue loading cycles to damage the beams was equivalent to the repetitive loadings caused by the overweight trucks across a bridge in one year. The retrofitted beams were subjected to salt environments in a wet/dry environmental chamber for 3 or 6 months.

VEHICLE OVERLOADING SPECTRA

A weigh-in-motion system was installed on a simply-supported RC T-girder bridge of Guangzhou Round City Highway which is a typical highway bridge in south China. The weight of every vehicle across this bridge was recorded. The maximum stresses and stress ranges of the tensile longitudinal steel bars in the main girders were obtained based on the recorded vehicle weigh-in-motion and finite element analysis using MIDAS/Civil (2010). The rainflow cycle counting technique was used to transfer the complex irregular stress time histories into a set of constant stress range frequency data, which is listed in Table 1. The AASHTO (2002) allowable service moment is based on 60% of yielding stress of the steel bar which is 310 MPa in Chinese bridge standard (JTG D60-2004). Therefore, only the trucks with more than 100% allowed weight were considered in Table 1, of which the corresponding stresses of the steel bars were 173.7 MPa. In Table 1, the specified number of cycles per month for the *i*th overload rate or stress range was the average values in three typical months.

To calculate the number of cycles to failure for the *i*th stress range, an *S-N* curve for RC T-beams (Zhu 2011) was adapted, which is expressed as:

$$logN = 12.9047 - 3.2402 log\Delta\sigma \quad (1)$$

The methods of fatigue design and assessment are based on the Miner's rule for fatigue damage accumulation, which is expressed by

$$D = \sum_{i=1}^{k} D_i = \sum_{i=1}^{k} n_i / N_i \quad (2)$$

where D is the fatigue damage accumulation index. From the above equation, the fatigue damage accumulation indexes D_i was obtained and recorded in Table 1.

Table 1 Vehicle overloading spectra

Overloading rate /%	100-110	110-120	120-130	130-140	140-150	150-200	200-250	250-300
Max. stress /MPa	173.7	179.3	185.0	190.7	196.3	202.0	230.4	258.7
Stress range /MPa	113.4	119.0	124.7	130.4	136.0	141.7	170.1	198.4
Number of cycles n_i /cycles	167	110	80	56	42	79	16	2
Fatigue life N_i /10^4 cycles	168	151	128	113	98	85	47	29

EXPERIMENTAL STUDY

A total of 19 specimens distributed in eight series were tested, containing each series one, two or three specimens. Table 2 summarizes the experimental program carried out. All specimens belonging to one series had equal characteristics. The series 'C' indicates control specimens. The references 'D', 'F' and 'H' indicate damage status, strengthening status and wet-dry environmental exposure status, respectively. The suffixed digital 3 and 6 indicate months of wet-dry environmental exposure.

Table 2 Experimental program and results

Series	Damage status	Strengthening status	Age at testing (months)	Number of specimens	Ultimate Loads (kN)	Ultimate Displacement（mm）
C	/	/	/	3	86.02	54.70
D	damaged	/	/	2	89.67	62.56
F	/	strengthened	/	3	159.73	43.69
DF	damaged	strengthened	/	4	155.40	43.28
FH-3	/	strengthened	3	1	146.31	44.76
FH-6	/	strengthened	6	1	149.98	39.25
DFH-3	damaged	strengthened	3	2	149.25	41.90
DFH-6	damaged	strengthened	6	3	154.91	42.30

Specimen

All beams had a T cross-section as shown in Figure 1, reinforced with 2 Φ14 mm steel bars. They are provided with Φ 6 mm diameter steel stirrups at 100 mm center to center spacing and distributed over the span. The mix proportions used to cast all beams were 1:1.81:2.77:4.51 (water: cement: sand: aggregate). The average 28-day compressive strength of the concrete was 36.62 MPa. The yield and ultimate stresses of steel bars were 397 MPa and 535 MPa, respectively, with an elastic modulus of 202 GPa. The CFRP sheet (UT70-30) used was a uni-directional CFRP supplied by Toray Industries. The ultimate strength and the elastic modulus of the CFRP were 3878 MPa and 244 GPa, respectively. The adhesive used was Lica-100 A/B, a two-part thixotropic epoxy resin. It had a modulus of elasticity of 3.2 GPa and a tensile strength of 55.5 MPa. All beams were cast from the same batch in the laboratory and then cured for 28 days.

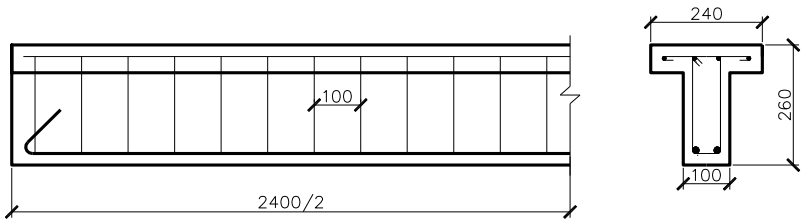

Figure 1 The beam cross-section (mm)

Preparation of strengthened specimens

The specimen series DF, DFH-3 and DFH-6 were overloading fatigue damaged before CFRP strengthening. The tensile concrete surface of each strengthened specimens was ground by a concrete scabbler until exposure of aggregate was achieved, then blown with clean air to remove dust and cleaned by acetone to ensure a good bond between the concrete surface and adhesive. After mixing, the adhesive was applied on to the beam and CFRP sheet. The excess adhesive was squeezed out along the edges of the sheet, assuming complete adhesive coverage. Two layers of CFRP sheet was bonded to the tension face of the strengthened specimens. In order to avoid CFRP sheet debonding at the ends during the testing, they were attached in three U-shapes with 50 mm extension on each side of the beams, as shown in Figure 2.

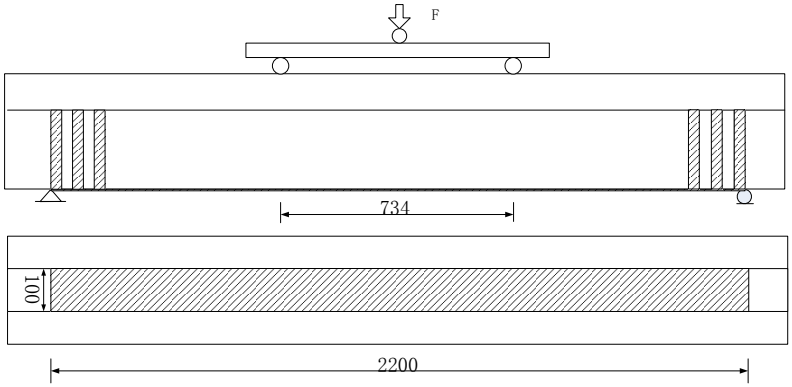

Figure 2 The strengthened beams (mm)

Wet-dry environmental exposure

The wet/dry environmental chamber has a length of 3 m, a width of 2 m and a depth of 1.5 m. The temperature control accuracy is ±1℃. The specimens were subjected to salt environments in which there were alternating wet and dry cycles. Sea water was simulated using 35 g of salt in 1 L of water which is equivalent to the average salinity of the oceans. The temperature of the hot air is 40 ℃. A wet-dry cycle was 24 h including a wet cycle of 10 h and a dry cycle of 14 h. The specimen series FH-3, FDH-3 and FH-6, FDH-6 were exposed for a total of 3 months and 6 months, respectively.

Test set-up and procedures

The tests were carried out in a servo-hydraulic SDS500 test machine with a maximum capacity of 500 kN, subjected to a four-point bending set up as shown in Figure 2. For retrofitted beams, the strain in the middle of the CFRP sheet was measured using two 20 mm long strain gauges. Deflections were measured at middle of the specimens using a potentiometer. All data were automatically recorded by a data logging system (TDS-530). The crack width was observed by a microscope. During loading, the strains, displacements and load were recorded every 1 second.

The specimens were damaged under fatigue loading. Loading was applied sinusoidally, with a frequency of 0.2 Hz. The minimum and maximum cycle loads are 16.8 kN and 73 kN, which convert to stresses σ of 60.3 MPa to 358.0 MPa. The minimum cycle stress 60.3 MPa was determined by the stress of longitudinal steel bars in the bridge main girders under self-weight and secondary permanent load. The maximum cycle stress 358.0 MPa was equal to the 0.9 time of the yield stress of the steel bar 397 MPa. According to Eq. (1), the corresponding number of fatigue cycles N was 69000. From the fatigue damage accumulation indexes in Table 1 and Eq. (2), the fatigue damage accumulation index for the T-girder per year is 55.2×10^{-4} and thereby the number of cycles in the tests is 380.

All specimens were finally tested under static load, by displacement control at a rate of 0.05 mm/sec. Loading was stopped when compressive concrete was crushed in the un-retrofitted specimens or when the CFRP sheet was tensile ruptured in retrofitted specimens.

EXPERIMENTAL RESULTS AND DISCUSSION

A summary of the test results including the ultimate strengths with their associated deflections, and the strain in CFRP sheets are given in Table 2. The un-strengthened beams in series C and D were failed due to compressive concrete crushed. The strengthened beams in other series were failed due to CFRP sheet ruptured.

Fatigue overloading damage

The damage in the RC beams was cumulated with the cyclic overloading. The average deflections at middle of the beams in series D, DF, DFH with the number of cycles were shown in Figure 3. The average curves were used instead of all curves to avoid cumbersome presentation. The figure shows that the deflections increased quickly in the first 60 cycles and varied slightly in the rest cycles. The damage of the specimens was identified by residual deflection and cracks, as shown in Table 3. The average residual deflections of the beams were 0.91, 1.47, 1.11 mm, respectively, which indicates that the fatigue overloading damage weakened the stiffness of the beams. The width of the residual cracks in part of beams was more than 0.2 mm which is the allowed width of cracks in RC beams in Chinese bridge standard (JTG D60-2004). This indicates that these beams need be repaired after one year fatigue overloading damage.

Table 3 The results of overload damage tests

Series	Residual crack width (mm)	Residual deflection (mm)
D	0.11	0.91
DF	0.28	1.47
DFH	0.26	1.11

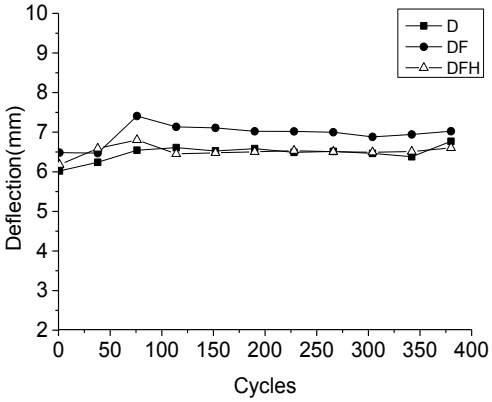

Figure 3 Deflections during the fatigue cycles

Flexural Capacity

All specimens were statically tested to determine ultimate strength and deflections. The test results in the form of load-deflection behaviour are presented in Figure 4. Average curves of each series were used to instead of the curves of all specimens to avoid cumbersome presentation. Two aspects are noted from Figure 4. Firstly, all the strengthened beams showed a strength enhancement over the un-strengthened beams, but the strengthened beams have very little enhancement in stiffness prior to the un-strengthened beams yielding. Secondly, the overloading fatigue damage and wet-dry exposure have only marginally effects on the load-deflection curves.

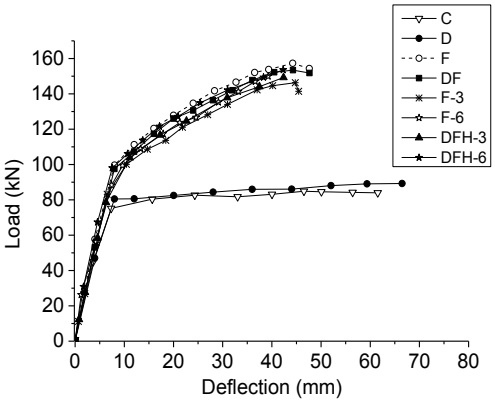

Figure 4 Load-deflection curves

The average ultimate loads and deflections of every series were recorded in Table 2. The comparisons of the average ultimate loads are shown in Figure 5 as well. As shown in the table, the damaged RC beams in series D have a higher strength and lower stiffness than the control beams in series C. This is because that the cyclic overloading increased the strength of the longitudinal steel bar by the effect of cold draw but damaged the concrete. The CFRP strengthening increased the ultimate strength of the undamaged beams in series F by 85.7% and the damaged beams in series DF by 73.3% in comparison with series without CFRP C and D, respectively. It indicates that the CFRP strengthening has less effective for the damaged RC beams due to the residual deflection and cracks. Comparing the specimens in series F and DF, the 3 and 6 month wet-dry cycles reduced the ultimate strength of the strengthened RC beams in series FH-3 and DFH-3 by 6.0% and FH-6 and DFH-6 by 3.7%, respectively. The wet-dry environmental exposure has clearly effect on the mechanical behaviour of the CFRP reinforced concrete members for the first 3 month but this effect is marginal for the next 3 month and even longer period (Huang 2014). The strength of the concrete, meanwhile, increased with the time of immersing in the water. These explain that the strength of the specimens under the wet-dry environmental exposure reduced in the first 3 months and then slightly increased in the next 3 months.

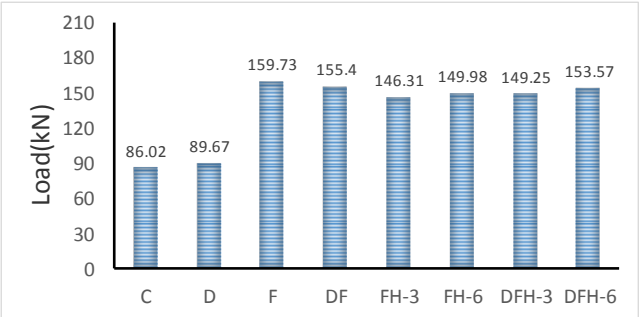

Figure 5 Ultimate loads

The strain in the CFRP sheet at the middle of the beams during the tests was presented in Figure 6, from which the following observation can be made: The specimens had a linear behaviour up to the yielding of the beams. Large deformation occurred and the strains increased rapidly in strain gauge after the beams had yielded. The specimens in all series but series F had the similar load-strain curves. The specimens F without damage and environmental exposure had a slightly smaller strain at the same loads than other specimens. It indicates that the retrofitted beams in series F had better stiffness than others, which can also be observed in Figure 4.

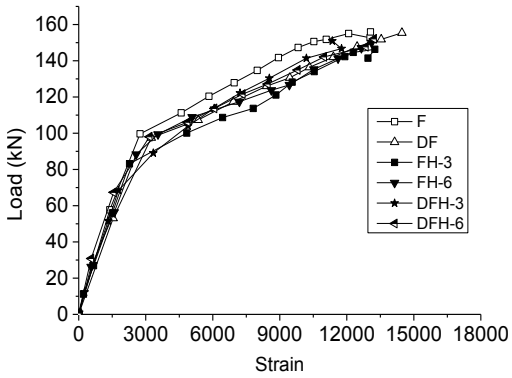

Figure 6 Load-strain curves

The width of the cracks in the middle of the specimens was measured at the load level of 79 kN. The average values of series C, F, DF and DFH-3 are 0.22 mm, 0.12 mm, 0.19 mm and 0.40 mm, respectively. The width of the cracks in the strengthened specimens in series F was about half of that in the control specimens in series C, which indicates the CFRP strengthening effectively restricts the crack opening. Due to the residual cracks caused by the fatigue overloading cycles, the strengthened damaged specimens in series DF have wider cracks than the specimens in series F. The width of the cracks in the specimens in series DFH-3 was about two times than specimens in DF. This is because that the degradation of the bond of FRP sheets with concrete after wet-dry exposure reduced the effect of CFRP strengthening, which was also the reason of the peak load reduction of the strengthened beams after wet-dry cycles.

CONCLUSIONS

This paper has presented an experimental study on overloading damaged RC T-beams strengthened with CFRP subjected to wet-dry environmental exposure. A total of 19 specimens in 8 series were tested. 4 series were damaged under fatigue loading cycles which are equivalent to the vehicle load caused by the overweight trucks on highway bridges during one year. 4 series were exposed under the wet-dry cycles for 3 or 6 months. The following conclusions can be drawn from the experimental results. (1) The residual deflections and cracks in the RC T-beams damaged by the fatigue overloading cycles cannot be ignored and the beams need be repaired. (2) A slight reduction in stiffness was observed for the strengthened beams due to overloading damage or wet-dry exposure. (3) The residual deflection and cracks caused by overloading damage reduced the effect of CFRP strengthenings. (4) The strength of the CFRP retrofitted specimens reduced 6.0% by 3 months wet-dry cycles but only 3.7% by 6 months wet-dry cycles. It indicates that the wet-dry environmental exposure has obvious effect on the strength of CFRP strengthened beams only in the first 3 months. (5) The degradation of the bond of FRP sheets with concrete after wet-dry exposure caused a significant increase of the crack width in the strengthened beams. (6) The pre-damage caused by the fatigue overloading cycles did not show a noticeable influence on the flexural properties of the specimens subjected to wet-dry cycles.

ABSTRACT

Steel plate and concrete composite strengthening (SPCCS) method is developed on the basis of steel and concrete composite girder, the process of which mainly includes welding studs on the reinforcing steel plates, planting rebars in the original concrete, and casting concrete between the original structure and steel plates, thus the new and existing concrete can work together. It can improve both the bearing capacity and stiffness of bridge significantly. In order to investigate the shear resistance of concrete girder reinforced by SPCCS method, two full-scale damaged box girder released from an actual bridge are tested for contrast, one without reinforcement and the other is reinforced by SPCCS method. The shear mechanical behavior and failure mode before and after reinforcement are obtained and analyzed. Furthermore, the shear mechanism and calculation formula of shear capacity for box girder reinforced by SPCCS method are presented. The comparisons show that the calculation results are in good agreement with the test results.

INTRODUCTION

Concrete bridges are widely used for their good bearing capacity and low cost. However, disease of different degrees is inclined to appear on concrete bridges under the action of environment and repeated loads. For instance, various forms of cracks are likely to appear on prefabricated concrete box girder, including longitudinal crack, transverse crack, diagonal crack and u-shaped crack, because of its own section form and tensile strength of material. All of the cracks and other damages will affect the service life and safety of bridges. Therefore, it is critical to reinforce the damaged bridges, restore the use function and prolong the service life (Kasan *et al*. 2014; Ludovico *et al*. 2010).

Traditional reinforcement methods are often accompanied by inevitable defects. For example, section enlargement method has higher requirements for clearance, and the cracks on bottom flange are unavoidable. CFRP strengthening method has limitation in improving the bearing capacity and stiffness of the structure, and so on. Therefore, better reinforcement methods are needed to be explored to meet the different needs of reinforcement. Steel plate and concrete composite strengthening (SPCCS) method is developed on the basis of steel and concrete composite girder, which can increase the bearing capacity and stiffness of bridge through encasing steel plates on the reinforcing concrete, and it makes the reinforcing portion integrally worked together with the original concrete structures by welding studs on reinforcing steel plates, planting rebars in existing concrete, and casting new concrete between the existing structure and steel plates. The reinforcement method has both advantages of section enlargement method and sticking steel plate method. Moreover, compared with section enlargement method, the deadweight of reinforced girder has less increase and the strength of steel plate is effectively used. Compared with sticking steel plate method, the connections in SPCCS method are more reliable, and the reinforced portion can be fully used to improve the bearing capacity largely.

SPCCS method was put forward by Prof. Nie in China, who conducted research on flexural behavior of rectangular beam reinforced by SPCCS method, and applied this method to practical engineering (Nie *et al*. 2001; Nie *et al*. 2007; Nie and Zhao 2008). The research team of Prof. Wang also conducted experiments and theoretical analysis on flexural and shear performance of concrete beam reinforced by SPCCS method (Wang and Gao *et al*. 2010; Wang and Yuan *et al*. 2010; Wang 2011 and Ren 2009). From the researches, it showed that the SPCCS method could significantly increase the flexural and shear bearing capacity of test beams. In this paper, full-scale experiments are carried out on concrete box girders with and without reinforcement by SPCCS method, and the girders are demolished from a real bridge after ten-year service. The shear mechanical

performance and ultimate shear bearing capacity of the girders are analyzed before and after reinforcement, and theoretical formula on shear bearing capacity of box girder reinforced by SPCCS method is presented.

EXPERIMENTS OVERVIEW

Test girder and reinforcement design

The two test girders are of 20m span prestressed concrete box girder released from a freeway viaduct in Yinchuan, China. Field test results showed that there were different degrees of disease on the components of the PC box girder, for example, the longitudinal and lateral cracks appeared in the bottom flange of box girder, vertical, diagonal and vertical cracks were appeared on the web. Shear capacity tests are carried out on test girders, one without reinforcement, and the other is reinforced by SPCCS method.

In the SPCCS reinforcement, in order to prevent the local damage caused by large counteracting force, the supporting parts of the girder are also reinforced by SPCCS method. Considering both the needs of shear reinforcement and economy, the height of concrete and steel is taller at the range of 500cm away from the supports and reduced in mid-span within 733.4cm. The thickness of reinforced concrete is 8cm, and C40 self-compacting concrete is adopted, the grade of which is the same with the original beam concrete. The thickness of reinforcing steel plate is 6 mm, the steel grade is Q235. At the same time, the top flange is also reinforced by a layer of 8cm thick reinforced concrete. Figure 1 shows the test girder before and after reinforcement by SPCCS method, and Figure 2 shows the cross section of the test girder before and after reinforcement.

Loading device

The shear test girders are loaded by one-point loading method, and the distance between loading point to support point is 3m, as shown in Figure 3. Each beam is loaded twice. In the first loading, the calculation span is 19.2m, and then the test girder is turned 180 degrees to the other end, so the second loading is acted on the other end to avoid the damaged part resulted from the first loading, and the calculation span is 14.5m, as shown in Figure 4. The serial numbers of test girders are shown in Table 1.

Arrangement of measuring points

The strain of concrete and steel is tested by strain gauges, and the test contents including the concrete strain of top flange, web and bottom flange, the strain of stirrup and the strain of reinforcing steel plate. The measuring point arrangements of web strain and stirrup strain of SPCCS-S-1 are showed in Figure 5 and Figure 6 respectively.

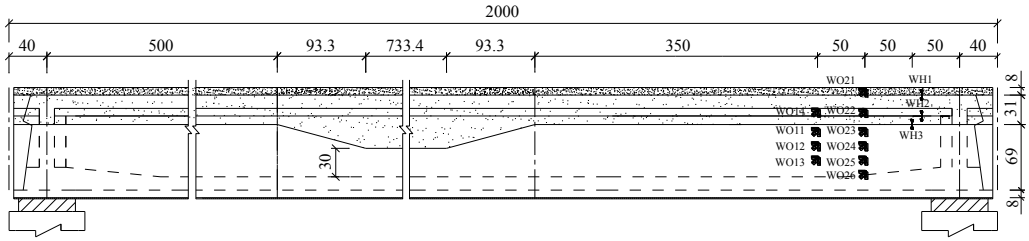

Figure 5 Web strain measuring point arrangement of SPCCS-S-1

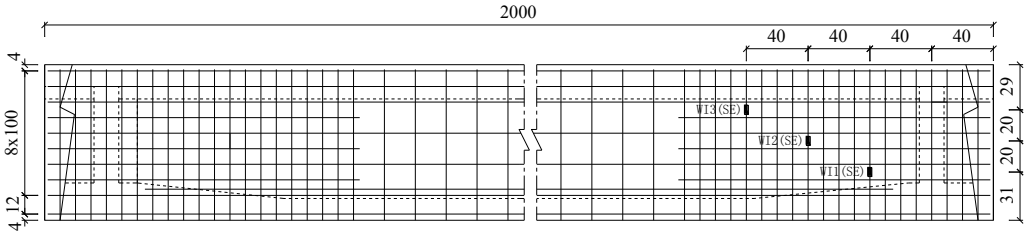

Figure 6 Stirrup strain measuring point arrangement of SPCCS-S-1

Test phenomena and failure mode

(1) Test girders without reinforcement

For test girder N-S-1, when the load is 600kN, the web in shear span has new diagonal cracks, the crack angle is about 50°, and the maximum crack width is about 0.15mm. Then the number of diagonal cracks and crack width

increases with the load. When the load is 800kN, the web under loading point also appears diagonal cracks. The maximum crack width is 0.25mm when the load is 900kN, 0.4mm for 1200kN, and 0.5mm for 1400kN. When the load is 1500kN, the diagonal cracks extend to the haunch, and the maximum crack width is about 0.9mm. The load stops increasing when it reaches to 1815kN, and the test girder starts automatic unloading. When the load reduces to 1742kN, the top flange is crushed, and the load reduces to 533kN suddenly, it shows that the test girder is damaged.

For test girder N-S-2, when the load is 870kN, new diagonal cracks appear in shear span, and the maximum crack width is 0.2mm. When the load is 1000kN, the crack width increases to 0.33mm, and the diagonal cracks has extended to the haunch. When the load is 1240kN, the crack width is 0.5mm. When the load increases to 1400kN, 1600kN and 1800kN, the crack width is 0.7mm, 0.8mm and 1mm respectively. The load stops increasing when it reaches to 2000kN, and the test girder automatically unloads to 1921kN. When the load increases to 1965kN again, the top flange is crushed, and the load automatically drops to 764kN, and the test girder is damaged. Failure modes of the two test girders are shown in Figure 7.

(a) Web cracks of N-S-1

(b) Web cracks of N-S-2

Figure 7 Failure modes of test girders without reinforcement

(2) Test girders with SPCCS reinforcement

Test girder SPCCS-S-1 has no obvious change when the load is less than 1800kN, and stripping crack between reinforcing steel and concrete appears after 1800kN. When the load is 2100kN, cracks extend from the reinforcement concrete of the web. When the load increases to 3260kN, steel plate below the loading point strips from the concrete. The maximum load reaches to 3273kN, then local buckling occurs on the steel plate below the loading point, and the main diagonal crack appears from top flange to the haunch, the deflection of girder increases significantly, the test girder is damaged.

For test girder SPCCS-S-2, cracks extend to the haunch when the load is 2000kN, but the width of crack is smaller, about 0.05mm. When the load is 3100kN, the reinforced concrete starts to strip off from the original girder, and steel plate and reinforced concrete are stripped obviously in shear span zone, steel plate under loading point appears local buckling. When the load is 3270kN, the concrete of top flange starts to fall off, then the steel plate and reinforced concrete strips continuously, accompanied with the sound of concrete crush. When the load is 3290kN, the test girder automatically unloads, and the maximum carrying capacity is reached. After that, the steel plate below loading point strips off from reinforced concrete completely and the maximum crack width in the haunch is 0.2mm. Steel plate appears several local buckling. Failure modes of the two girders are shown in Figure 8.

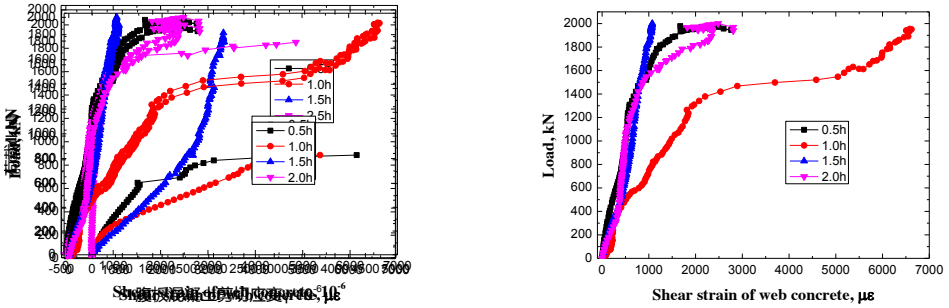
DISCUSSION OF RESULTS

Test girders without reinforcement

Shear strain of web concrete

Figure 9 shows the load-shear strain curves of web concrete in different cross-sections of test girders without reinforcement. For test girder N-S-1, the distances from measuring points to support are 0.5h, 1.0h, 1.5h and 2.5h separately (h means depth of girder). For test girder N-S-2, the distances from measuring points to support are 0.5h, 1.0h, 1.5h and 2h separately. As shown in Figure 9, measuring points at sections of 0.5h and 1.0h in N-S-1 cannot carry more load when the load reaches to 800kN due to the cracks, so that shear force is carried by stirrups and concrete without crack. Other measuring points can carry shear force sustainably until the limit load is close when cracks appear. Shear stress in section of 1.0h is significantly greater than that in other sections.

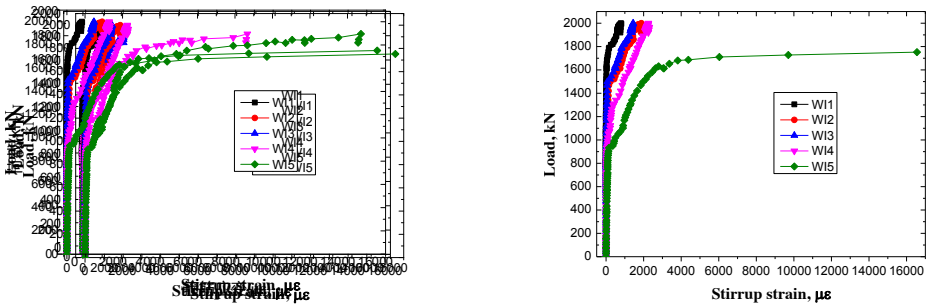


(a) Test girder N-S-1 (b) Test girder N-S-2

Figure 9 Load-shear strain curves of web concrete in different cross-sections

Strain of web stirrup

Figure 10 shows the load-strain curves of web stirrup, measuring points WI1~WI5 are located within shear span of 3m, of which the distance to support increases gradually. It can be seen from Figure 10, when the load is less than 800kN, stirrup strain is very small for there almost has no new cracks. After the appearance of diagonal cracks, shear force redistributes which resulted in sharply increase of stirrup strain, and stirrup turned into elastic-plastic stage quickly. When the limit load is reached, most of the stirrups have entered into yield status.



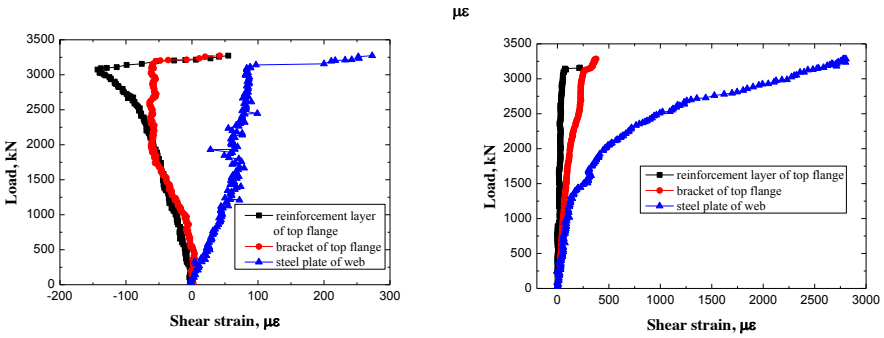
(a) Test girder N-S-1 (b) Test girder N-S-2

Figure 10 Load-strain curves of web stirrup

Steel plate and concrete composite strengthening test girders

Shear strain of web and top flange

Figure 11 draws the load-shear strain curves of web and top flange at different vertical positions in the section whose distance to supports is 1.0h. Figure 11 illustrates the reinforcement layer and haunch of box girder provide small shear capacity, and the web carry the most shear force, so SPCCS method can make full use of steel strength by setting steel plate at the outside of the reinforced concrete of web, and increase the shear carrying capacity of reinforced girders.

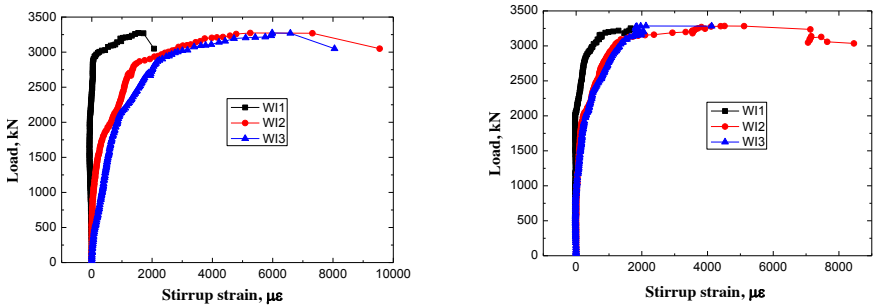


(a) Test girder SPCCS-S-1 (b) Test girder SPCCS-S-2

Figure 11 Load-shear strain curves of web and top flange in section of 1.0h

Strain of web stirrup

Figure 12 shows the load-strain curves of web stirrup. The distances from measuring points to support are 0.4h, 0.8h and 1.2h separately. As shown in Figure 12, when the load is less than 1500kN, stirrup strain is small because there is no new crack. After the load is larger than 1500kN, with the cracks increasing, stirrups carry more and more shear force, stirrup strain increases gradually, so that the slope of the curve grows faster and stirrup turns into elastic-plastic stage gradually. When the limit load is reached, load remains steady while strain continues to grow, and stirrups yield eventually.

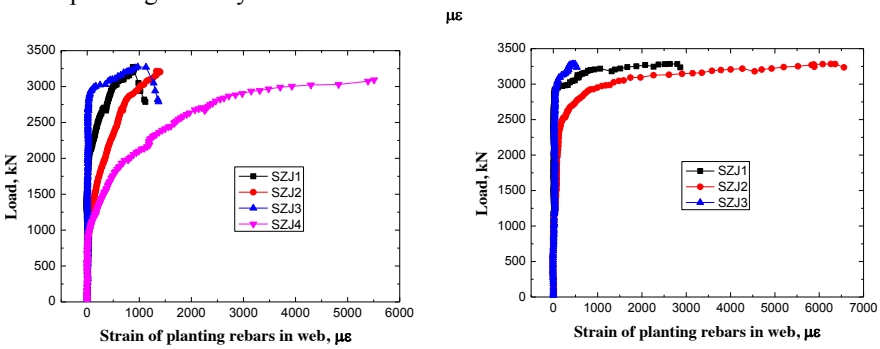


(a) Test girder SPCCS-S-1 (b) Test girder SPCCS-S-2

Figure 12 Load-strain curve of web stirrup

Strain of planting rebars in web

Figure 13 shows the load-strain curves of planting rebars in web, and the measuring points are set at the end of girder web on the loading side. As shown in Figure 13, in the early stage of loading, the stress of the planting rebars is smaller. At this time, shear stress and normal tensile stress of the interface between new and existing concrete is mainly carried by the bonding strength of the interface. Then the strain of the planting rebars grows rapidly with the increase of load, which showed that planting rebars have good force transfer effect, so that the strengthening part and the original girder can carry load together, thus the shear capacity of the original girder is improved. Part of the planting rebars yield when the limit load is reached.



(a) Test girder SPCCS-S-1 (b)Test girder SPCCS-S-2

Figure 13 Load-strain curves of planting rebars in web

Figure 14 shows the relative slip between new and existing concrete of SPCCS-S-2, and measuring points are set at the end of girder on the loading side. As can be seen from Figure 14, there is almost no relative slip

between new and existing concrete before limit load. When limit load is reached, slide grows rapidly and the relative slip up to 6.2mm. Therefore, in the process of loading, the reinforced concrete and the original concrete work together and can bear the load as a whole, and the strengthening effect is good. The regularity in SPCCS-S-1 is similar to that in test beam SPCCS-S-2.

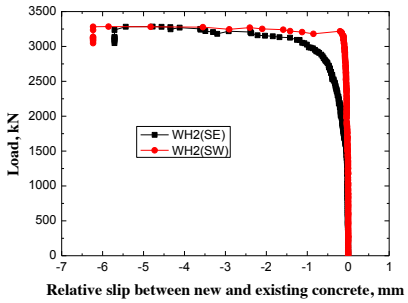


Figure 14 Load-relative slip curves between new and existing concrete

Figure 15 illustrates the load-relative slip curves between new concrete and reinforcing steel plate of SPCCS-S-1, and measuring points are set at the end of girder on the loading side. From Figure 15 we can see that there is basically no relative slip on the interface until limit load is reached. When the load is close to the limit load, the slide has a great increase and the maximum relative slip up to 0.12mm. It is indicated that the reinforced concrete and the steel plate can work as a whole in the process of loading, and the strengthening effect is good. The regularity in SPCCS-S-2 is similar to that in test beam SPCCS-S-1.

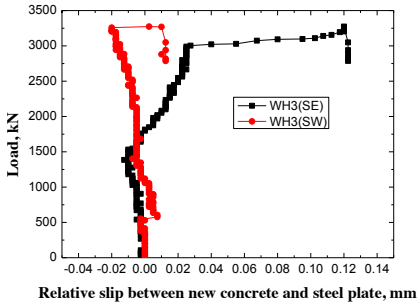

Figure 15 Load-relative slip curves between concrete and steel plate

Comparison of shear carrying capacity

Shear carrying capacity of test girders without reinforcement and reinforced by SPCCS method are shown in Table 2.

Table 2 Comparison of shear carrying capacity

Test girder number	Ultimate shear capacity Vu/kN	Stirrup yield shear force Vy/kN	Increase proportion of shear carrying capacity after reinforcement
N-S-1	1531	1304	——
N-S-2	1588	1207	——
SPCCS-S-1	2761	2185	77.0%
SPCCS-S-2	2605	2230	67.0%

From Table 2, it can be seen that shear carrying capacity of test girders is increased by 67.0% and 77.0% respectively after reinforced by SPCCS method. Obviously, SPCCS method can effectively improve the shear capacity of box girders, and the shear reinforcement effect is great. Moreover, yield shear force of stirrups after reinforcement is greater than that before reinforcement, it is indicated that because of the effect of reinforcing part, the yield time is delayed and the shear capacity of the test girder is improved.

THEORETICAL ANAYLYSIS OF SHEAR CAPACITY

Shear mechanism of steel plate and concrete composite strengthening method

Test results showed that as for box girder reinforced by SPCCS method, before the diagonal cracks appear, the strain of both reinforcing steel plates and stirrups is small. After the diagonal cracks appear, the internal force of girder redistributes, and the strain of both reinforcing steel plates and stirrups increases rapidly. The reinforced part plays a significant role in improving the shear capacity of box girder. Generally, the load transformation system of a girder with diagonal cracks can be compared as a group of tied-arch structure, as shown in Figure 16. It is composed of basic arched-body I upon the critical diagonal cracks and a group of small arched-body II and III below the critical diagonal cracks. SPCCS method improves the shear capacity of girder in the following aspects:

(1) Reinforcing steel plates of web hold on to the small arch system, then the small arch system can carry more shear force. Therefore, the pressure on the basic arched-body I decreases and the propagation of diagonal crack is constrained; at the same time, the strength of reinforcing steel plates is higher than that of concrete, which can carry larger shear force.

(2) Reinforcing steel plates and longitudinal rebars of bottom flange transmit the principle compressive stress of the small arched-body II and III to the support by dowel action; at the same time, steel plate of bottom flange distributes the normal stress of longitudinal rebars, and improves the dowel action of longitudinal rebars.

(3) The reinforcing concrete can increase the shear area of web concrete, and lower the neutral axis of box girder, thus improving the shear capacity of box girder.

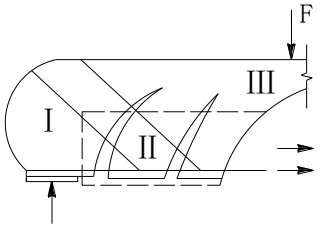

Figure 16 Mechanical model of box girder after diagonal cracks appear

Shear capacity calculation of box girder reinforced by SPCCS method

Shear capacity calculation of box girder reinforced by SPCCS method should take following factors into consideration: cracks on the original structure has effect on shear capacity of the box girder after reinforcement; lateral steel plates have contribution to shear capacity after reinforcement, and the area of steel plates should be transformed into concrete area; shear connection degree between new and existing concrete and that between reinforcing steel plates and new concrete has effect on shear capacity after reinforcement.

On the basis of experimental research, considering the effect of connection degree of shear connectors, Chunsheng Wang and Tengxian Ren put forward the shear capacity calculation formula of reinforced concrete T beam reinforced by SPCCS method (Ren 2009; CCCC Highway Consultants Co. Ltd 2004; Nie and Zhao 2010). Considered the contribution of bent-up rebars and prestressed reinforcement to shear capacity, the formula is revised in this paper, as shown in Equation (1).

$$V_{\mathrm{u}}=\alpha_1\alpha_3(1.964-\frac{0.964}{1+12.807\bar{r}^{2.168}})\sqrt{(2+0.6p)\sqrt{f_{\mathrm{cu,k}}}\rho_{\mathrm{sv}}f_{\mathrm{sv}}}(0.43\times10^{-3}A_0\psi_{\mathrm{cs}}+0.45\times10^{-3}A_{\mathrm{n}})$$
$$+0.75\times10^{-3}f_{\mathrm{sd}}\sum A_{\mathrm{sb}}\sin\theta_{\mathrm{s}}+0.75\times10^{-3}f_{\mathrm{pd}}\sum A_{\mathrm{pb}}\sin\theta_{\mathrm{p}} \quad (1)$$

where α_1 is the opposite sign bending moment coefficient, $\alpha_1=1.0$ when calculating shear capacity of the simple supported beam and segment of continuous beam that near side supports, and α_1=0.9 when calculating shear capacity of the cantilever beam and segment of continuous beam that near middle supports; α_3 is the influence coefficient of compression flange, and $\alpha_3=1.1$; $\bar{r}=r/(r+1)$, r is shear connection degree, $r=n_{\mathrm{d}}/n_{\mathrm{f}}$, n_{d} is the actual amount of shear connectors in shear span, n_{f} is the calculated amount of shear connectors in shear span by plasticity design method, as for box girder reinforced by SPCCS method, r takes the minimum value of studs and planting rebars which has the smaller shear connection degree; p is the reinforcement ratio of longitudinal tensile rebars in diagonal section after reinforcement, $p=100\rho$, $p=2.5$ when $p>2.5$; $\rho=(A_{\mathrm{s1}}+A_{\mathrm{s2}})/(A_{\mathrm{o}}+A_{\mathrm{n}})$, A_{s1} is the total area of longitudinal rebars and prestressed reinforcement

in diagonal section of original girder, A_{s2} is the total area of longitudinal rebars in reinforcing concrete and reinforcing bottom plates, $A_0 = bh_0$, b is the width of the original girder, h_0 is the effective height of the normal section of original girder, A_n is the total area of new concrete and transformed area of reinforcing steel plates; $f_{cu,k}$ is the cube compressive strength of original concrete; ρ_{sv} is the reinforcement ratio of stirrups; f_{sv} is the tensile strength of stirrups; ψ_{cs} is the correction factor related to diagonal cracks of the original girder, $\psi_{cs} = 1.0$ when there is no diagonal crack before reinforcement, $\psi_{cs} = 0.835$ when the width of crack is smaller than 0.2mm, and $\psi_{cs} = 0.78$ when the width of crack is larger than 0.2mm; A_{sb} and A_{pb} are the area of general bent-up rebars and prestressed bent-up reinforcement in the same bending section at the diagonal section respectively; θ_s and θ_p are the intersection angle between longitudinal axis and tangent line of general bent-up rebars and prestressed bent-up reinforcement respectively; f_{sb} and f_{pb} are the tensile strength of general bent-up rebars and prestressed bent-up reinforcements respectively.

The shear capacity of test girders reinforced by SPCCS method is calculated according to Equation (1), and then the calculated value is compared with the test value, as shown in Table 3.

Table 3 Comparison of shear capacity by calculation and test

Test girder number	Test Value V_{exp} /kN	Calculated Value V_u /kN	V_u / V_{exp}
SPCCS-S-1	2761	2844	1.03
SPCCS-S-2	2605	2844	1.09
Average Value	2683	2844	1.06

Table 3 indicated that the difference between test value and calculated value is below 10%, thus the formula proposed by this paper can well reflect shear capacity of box girder reinforced by SPCCS method, as well as can provide reference for calculation in engineering.

CONCLUSIONS

Though experimental and theoretical researches on shear capacity of damaged full-scale concrete box girder before and after reinforced by SPCCS method, following conclusions can be obtained.

(1) SPCCS method can improve the whole working performance of existing structure and new reinforcement part by the shear force transforming through planting rebars and studs. Test results showed that the reinforcement part can carry the loads with the existing girder together, and the shear capacity of PC box girder is improved effectively.

(2) The failure mode of PC box girder reinforced by SPCCS method is that diagonal cracks propagate rapidly, which are caused by stripping between new and existing concrete or new concrete and steel plate, then the stirrups yield and the girder fails eventually. Therefore, it is important to choose the diameter, spacing, and number of planting rebars and studs reasonably.

(3) The shear capacity of PC box girder after reinforced by SPCCS method is improved 67% at least, and this reinforcement method can constrain the development and propagation of cracks effectively as well as delay the yield of stirrups.

(4) The shear mechanism and calculation formula on shear capacity of PC box girder reinforced by SPCCS method are proposed, and the calculated results and experimental results coincide well.

ABSTRACT

Based on the failed criterion of steel reinforcement fracture, an analytical model is presented for predicting the fatigue life of reinforced concrete (RC) beam strengthened with fiber reinforced polymer (FRP) sheets. In this model, the load cycle is divided into some loading blocks evenly and the stress amplitude of the tensile steel reinforcement is thought to be invariable in each loading block. Considering the degradation of material performance, including concrete creep, the stress amplitude of the tensile steel reinforcement is obtained by using the traditional sectional analysis method. Therefore, the fatigue life of the strengthened beam is carried out by using the well-known Palmgren-Miner rule. The reliability of the proposed analytical model is validated through comparisons with previous test results reported by the relative research groups. The compared results show that the proposed models can predict the fatigue life of the strengthened beam with an acceptable degree of accuracy.

KEYWORDS

FRP sheets, strengthening, RC beam, steel rupture, fatigue life.

INTRODUCTION

Due to the repetitive cyclic loading, many reinforced concrete structures, such as bridges, are needed to be rehabilitated so as to satisfy its serviceability. Up to now, some strengthening methods, like externally bonding steel plate, external prestressing strand and enlarging member section, have been developed for strengthening those deficient/damaged reinforced concrete structures. However, one potential solution is via the bonding of FRP sheets due to the merits of FRP materials, such as high strength-to-weight ratio, non-corrosive property and easy of handling (Teng *et al*. 2002; Rougier *et al*. 2007; EIsayed *et al*. 2007).

The research works, including theoretical analysis and experimental program, of FRP strengthened RC beams subjected to the fatigue load have been well established (Barnes *et al*. 1999; Papakonstantinou *et al*. 2001; Heffernan *et al*. 2004; Quattlebaum *et al*. 2005; Toutanji *et al*. 2006; Yu *et al*. 2011; Xie *et al*. 2012). However, limited models have been proposed for predicting the fatigue life of FRP strengthened RC beams. In 2001, El-Tawil *et al*. presented an analytical model to compute the static and fatigue responses of FRP strengthened RC beams. This model was constructed with the fiber section method and taken into the consideration of fatigue damage of the concrete. In 2011, Ferrier *et al*. used the sectional analytical approach to analysis the increased deflection of FRP strengthened RC beams under fatigue loading. When refers to the finite-element analysis, some researchers (Zhang *et al*. 2008; Loo *et al*. 2012) used the finite-element software to model the debonding behavior between concrete and steel/FRP sheets for strengthened beams under fatigue loading.

Generally, the fatigue failure process of the FRP sheet strengthened RC beams could be divided into three distinct stages (as seen in Figure 1): 1) Crack propagation stage. During this stage, flexural and shear cracks appeared in the pure moment and moment-shear regions of the beams and some of these rapidly developed into the main cracks. It was demonstrated that this first stage takes up no more than 10% of the total fatigue load cycles; 2) Damage accumulation stage. After the first stage, the changes in observable fatigue damage become minimal for a long period of time. The increments in the number of cracks and developments of the maximum crack length and width were all stable basically. This second stage takes up more than 90% of the total fatigue life, and little degeneration of the flexural stiffness is observed; 3) Failure stage. After substantial fatigue damage accumulation, the tensile steel reinforcement ruptured at a certain main cracked section (i.e. maximum bending moment section). Then, the tensile force carried by the steel reinforcement was transferred to the FRP sheets, which led to the debonding or rupture of the FRP material. The strengthened RC beams lost their fatigue capacities with vanish of the tensile materials (as seen in Figure 2). This final stage lasted a relatively short time.

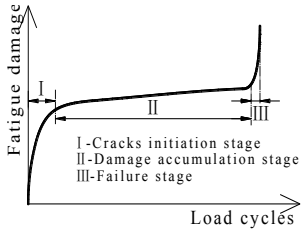

Figure 1 Fatigue failure process

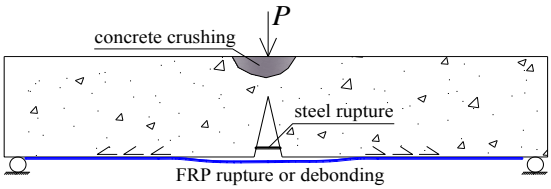

Figure 2 Typical fatigue failure mode

As above mentioned, the rupture of tensile steel reinforcement at the main cracked section was the controlling failure mode for the FRP sheets strengthened RC beams under fatigue loading. Therefore, the fatigue life of such strengthened members can be determined according to the fatigue life of tensile steel reinforcement. In this paper, an analytical model for predicting the fatigue life of FRP sheets strengthened RC beams was proposed based on the Palmgren-Miner rule (Miner 1945) and the sectional analysis method. The FRP debonding induced slippage between FRP and concrete was ignored in this analytical model, since the relative slippage can be restricted by the mechanical interlocking and friction at the debonding area (Iwashita *et al*. 2007).

PREDICTED MODEL OF FATIGUE LIFE

Failure Criterion

According to the Palmgren-Miner rule, applying n_0 cycles with a stress amplitude σ_{s0} and corresponding fatigue life endurance N_0, is equivalent to consuming n_0/N_0 of the fatigue resistance (Schijve 2009). This assumption can be applied to any subsequent block of load cycles until happening of the tensile steel reinforcement rupture. When the tensile steel reinforcement experiences more than one block of load cycles, the total consumed fatigue resistance can be written as:

$$D = \sum \frac{n_i}{N_i} \tag{1}$$

where D is the consumed fatigue resistance ($D \leq 1$); n_i is the specified number of repetitions for the specified stress amplitude σ_{si}; N_i is the corresponding number of repetitions to failure for the stress amplitude σ_{si}. The relationship between N_i and σ_{si} for ribbed and smooth steel reinforcement is given as (BS5400 1978):

$$N_i \sigma_{si}^m = K_0 \Delta^d \tag{2}$$

where m is the inverse slope of the mean-line $\log\sigma_{si}$-$\log N_i$; K_0 is the constant term relating to the mean-line of the statistical analysis results; Δ is the reciprocal of the anti-log of the standard deviation of $\log N_i$; d is the number of standard deviations below the mean-line. The values of these terms with the mean-line relationship are shown in Table 1.

Table 1 Parameters for Eq. (2)

Parameter	m	K_0	$\triangle$	d
Ribbed steel reinforcement	4	2.34×10^{15}	0.657	0
Smooth steel reinforcement	3.5	1.08×10^{14}	0.625	0

Using the determined fatigue failure criterion of tensile steel reinforcement, the fatigue life of FRP strengthened RC beams can be predicted by the summation of the corresponding fatigue load cycles of each stress amplitude until the rupture failure of tensile steel reinforcement occurs (i.e. D=1):

$$N_p = \sum n_i \tag{3}$$

where N_p is the predicted fatigue life.

Determining Stress Amplitudes of Tensile Steel Reinforcement

In order to use the aforementioned Palmgren-Miner rule to predict the fatigue life of a FRP strengthened RC beams, the variable stress amplitudes of tensile steel and the corresponding number of load cycles for the specified stress amplitude should be determined at first. As such, the discretized method was adopted to divide

the whole fatigue loading process into many constant loading blocks and the sectional analysis method was used to calculate the stress amplitude corresponding to each loading block.

Discretizing of the variable stress amplitudes

The stress amplitude of the tensile steel reinforcement changed continuously with increasing load cycles due to the generation and propagation of flexural and shear cracks and the deterioration of the material performance (ACI Committee 215 1997), as shown by the dotted line in Figure 3. It is obvious that a strong nonlinear relationship exists between the stress amplitude in the tensile steel reinforcement and the number of load cycles. For simplicity, the discretized method was adopted here to divide the fatigue loading process into many constant loading blocks (i.e. each block with the same number of load cycles), and the stress amplitude was assumed to be unchanged within each specific loading block. It is noting form Figure3 that there is a large gap between the supposed stress amplitude and actual one in the first few loading blocks (i.e. crack propagation stage) when ignoring the gradual development of flexural cracks and this gap will diminish quickly with increasing load cycles. Therefore, this large gap can be neglected because the crack propagation stage experiences a short period of time relative to the total fatigue life.

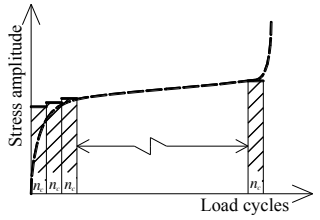

Figure 3 Discretization of steel stress amplitude

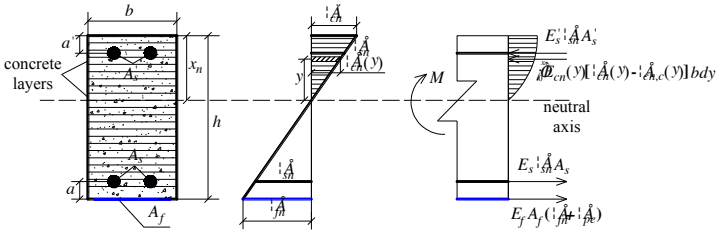

Figure 4 Strain-stress distributions

Calculating the stress amplitude of each loading block

Before determine the stress amplitude of each loading block using the sectional analysis method, the following assumptions should be noted: 1) Plane sections are considered to remain plane during the fatigue loading. This assumption is reasonable because an approximately linear strain distribution along the beam height was experimentally observed during the fatigue loading (Shahawy *et al*. 1999); 2) No bond-slip is assumed between concrete and other component materials (i.e. steel reinforcement and FRP); and 3) Due to the low tensile strength of concrete, the tension role of concrete is ignored in the calculation.

A cracked section of a strengthened beam is shown in Figure 4. The concrete portion in the top of the beam section can be conceptually divided into many thin layers along the depth direction. Then, based on the sectional equilibriums of external and internal forces and moments, the following equations can be expressed:

$$P = E_s\varepsilon_{sn}A_s + E_f(\varepsilon_{fn}+\varepsilon_{pi})A_f - \int_0^{x_n} E_{cn}(y)[\varepsilon_{cn}(y)-\varepsilon_{cn,c}(y)]bdy - E_s'\varepsilon_{sn}'A_s' \quad (4)$$

$$M = E_s\varepsilon_{sn}A_s(h-x_n-a) + E_f(\varepsilon_{fn}+\varepsilon_{pi})A_f(h-x_n) + \int_0^{x_n} E_{cn}(y)[\varepsilon_{cn}(y)-\varepsilon_{cn,c}(y)]bydy + E_s'\varepsilon_{sn}'A_s'(x_n-a') \quad (5)$$

where P is the axial force (for a simply supported beam: P=0); M is bending moment induced by external actions; x_n is the depth of the compression zone for concrete at the n^{th} cycle; E_s', E_s and E_f are the elastic modulus of compressive steel reinforcement, tensile steel reinforcement and FRP, respectively; $E_{cn}(y)$ is the effective elastic modulus of the specified concrete layer at the n^{th} cycle; ε_{sn}' and ε_{sn} are the longitudinal strains at the centroid of the compressive steel reinforcement and tensile steel reinforcement, respectively; ε_{fn} is the FRP strain caused by the fatigue load; ε_{pe} is the pre-strain of the FRP sheets if there is a prestress; $\varepsilon_{cn}(y)$ and $\varepsilon_{cn,c}(y)$ are the total strain and the creep strain of the specified concrete layer at the n^{th} cycle; A_s', A_s and A_f are the cross sectional areas of the compressive steel reinforcement, tensile steel reinforcement and FRP, respectively; b is the beam width; a' is the distance from the center of the compressive steel reinforcement to the top surface; a is the distance from the center of the tensile steel reinforcement to the subsurface; y is the distance between the centroid of the specified concrete layer and the neutral axis.

Using an iterative approach and combining Eq. 4 and Eq. 5, the stress of the tensile steel reinforcement σ_{sn} can be obtained after determining the concrete layer stress $\sigma_{cn}(y)$, the compressive steel reinforcement stress σ_{sn}' and the FRP stress σ_{fn}. When the upper limit of the fatigue load acts on the strengthened beam, the maximum stress

of the tensile steel reinforcement $\sigma_{sn,\max}$ can be calculated by substituting the corresponding maximum moment $M_{\max}$ into Eq. 5. Similarly, the minimum stress of the tensile steel reinforcement $\sigma_{sn,\min}$ is corresponding to the minimum moment $M_{\min}$ induced by the lower limit of the fatigue load. Therefore, the stress amplitude of the tensile steel reinforcement can be determined according to the following equation:

$$\sigma_{si} = \sigma_{sn,\max} - \sigma_{sn,\min} \tag{6}$$

where $\sigma_{sn,\max}$ and $\sigma_{sn,\min}$ are the maximum and minimum stresses generated in the tensile steel reinforcement, respectively.

Time-dependent Constitutive Relationships of Component Materials

To obtain the maximum and minimum stresses of the tensile steel reinforcement accurately, the time- dependent constitutive relationships of all of the component materials should be considered within the analytical model.

Fatigue performance of concrete

Some experimental results showed that the compressive stress-strain relationship of concrete changed continuously with the repetitions of a fatigue load due to the internal damage accumulation of the concrete (Holmen 1982). The typical concrete compressive stress-strain curve begins with an approximately linear shape, and then gradually enters into a characteristic convex shape as the peak strain is reached. Since the external load induced concrete strain is relatively low under service conditions and the shape of this curve is generally unsusceptible with the increase of load cycles, it is reasonable to assume an approximately linear stress-strain relationship for concrete in fatigue calculations, as shown in Figure 5.

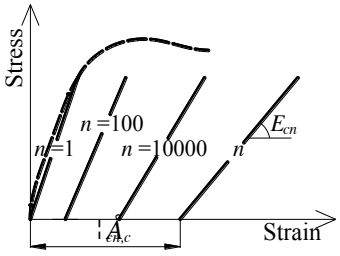

Figure 5 Stress-stain relationship for concrete

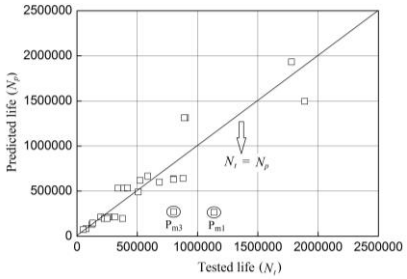

Figure 6 Predicted life versus tested life

The effective elastic modulus of concrete under a certain number of load cycles n can be written as (Sherif 2001):

$$E_{cn} = (1 - 0.33\frac{n}{N_f})E_c \tag{7}$$

where E_{cn} is the effective elastic modulus of concrete; n is the number of fatigue load cycles; E_c is the initial elastic modulus of concrete; N_f is the number of load cycles to failure for concrete, which can be calculated using the following equation (Holmen 1982):

$$\log N_f = 1.978 S_{\max}^{-3.033} (-\log K)^{0.0596} \tag{8}$$

where $S_{\max}$ is the maximum stress level and $S_{\max}=\sigma_{c,\max}/f_c$; f_c is compressive strength of concrete prism; K is defined by $K=1-p$; p is the probability of failure.

On the other hand, the total concrete strain (ε_{cn}) during the fatigue load is consist of two parts: e.g. elastic strain ($\varepsilon_{cn,e}$) and inelastic strain ($\varepsilon_{cn,c}$):

$$\varepsilon_{cn} = \varepsilon_{cn,e} + \varepsilon_{cn,c} \tag{9}$$

where $\varepsilon_{cn,e}$ is the elastic strain of concrete; $\varepsilon_{cn,c}$ is the inelastic strain and considered to be equal to the creep strain of concrete. Holmen (1982) proposed the following expressions to calculate the total concrete strain during fatigue loading:

$$\varepsilon_{cn}=\begin{cases}\dfrac{1\times10^{-3}}{tg\alpha}\left|S_{\max}+3.180(1.183-S_{\max})\left(\dfrac{n}{N_f}\right)^{0.5}\right|+0.413\times10^{-3}S_c^{1.184}\ln(t+1) & for\ 0<\dfrac{n}{N_f}\le 0.1\\ \dfrac{1.11\times10^{-3}}{tg\alpha}\left|1+0.677\left(\dfrac{n}{N_f}\right)\right|+0.413\times10^{-3}S_c^{1.184}\ln(t+1) & for\ 0.1<\dfrac{n}{N_f}\le 0.8\end{cases} \quad (10)$$

where $tg\alpha$ is secant modulus of the concrete ($tg\alpha=S_{\max}/\varepsilon_0$); ε_0 is the concrete strain caused by the upper limit of the fatigue load at the first cycle; S_c is the characteristic stress level and given as $S_c=S_m+RMS$; t is the duration of the fatigue load (unit in hours); S_m is the mean stress level, $S_m=(S_{\max}+S_{\min})/2$; $S_{\min}$ is the minimum stress level, $S_{\min}=\sigma_{c,\min}/f_c$; RMS is the root mean square value and for sinusoidal loading and $RMS=(S_{\max}+S_{\min})/2\sqrt{2}$.

Fatigue performance of steel and FRP

Although the repeated loading on steel reinforcement causes the accumulation of fatigue damage, Barsom (1987) and Joachim Rösler (2007) both demonstrated that the elastic modulus of steel reinforcement remains unchanged until just before failure, and no significant plastic deformation was observed by the action of high cycle fatigue loading. Besides, test results in Hull's (1981) research suggested that the mechanical behavior of FRP was virtually unaffected by fatigue loading. Hence, the constitutive relationships of steel and FRP materials are considered to be similar to the initial relationship in each load cycle.

Procedure to Estimate Fatigue Life

The detailed procedure for predicting the fatigue life is as follows: 1) Use Eqs. 4 and 5 to calculate the maximum and minimum stresses of the concrete layers with the applied maximum and minimum fatigue loads at the beginning. At the beginning, the elastic modulus of concrete is E_c and the creep strain of each concrete layer is zero; 2) Substitute these stresses into Eq. 7 to Eq. 10 to build the constitutive model for each layer of concrete. These constitutive models are assumed to represent the fatigue behavior during the whole process of the fatigue loading; 3) With the constitutive models for each concrete layer, the sectional analysis at the cracked section is conducted to calculate the maximum and minimum stresses and the stress amplitude of the tensile steel reinforcement in the each loading block using Eq. 4 to Eq. 6; 4) Substitute the value of the stress amplitude of the tensile steel reinforcement into Eqs. 1 and 2 to calculate the fatigue damage of the tensile steel reinforcement for each loading block and further obtain the total accumulated fatigue damage; 5) Adjust the constitutive model for each layer of concrete at the end of last loading block, then the corresponding stress amplitude and fatigue damage of steel reinforcement in the next loading block using the same method (i.e.sectional analysis); 6) Repeat from step 3 to step 5 until the total fatigue resistance is consumed and then the fatigue life can be obtained after summing the numbers of each loading block using Eq. 3. The above described procedure was implemented in a computer program based on MATLAB langue.

MODEL VERIFICATION

To validate the proposed model, an experimental database consisting of 28 prestressed/non-prestressed FRP sheets strengthened RC beams (Barnes *et al*. 1999; Papakonstantinou *et al*. 2001; Heffernan *et al*. 2004; Quattlebaum *et al*. 2005; Toutanji *et al*. 2006; Yu *et al*. 2011; Xie *et al*. 2012) was established. All beams were reported to have failed with the rupture of tensile steel reinforcement. Those specimens that failed with other modes or without essential parameters were not included in this database. Table 2 summarizes the geometric and material data for all 28 beams. In the table, the notations $F_{\max}$ and $F_{\min}$ denote the corresponding maximum and minimum fatigue load, respectively. All selected test beams had a rectangular section and were simply supported on the two rollers. The four-point or three-point fatigue loading was applied on the top face of the strengthened beams.

A comparison between measured fatigue lives (N_t) and those (N_p) predicted by the proposed model is presented in Table 2 and Figure 6. It is clearly shown that the predicted values for all FRP strengthened RC beams are distributed around the line of $N_t/N_p=1.0$, except for the test beams P_{m1} and P_{m3}. The main reasons for this big difference are believed to be the discreteness of material behavior, measuring error and model simplification. Therefore, the analytical model can be used to predict the fatigue life of FRP strengthened RC beams effectively.

CONCLUSIONS

An analytical model has been developed for predicting the fatigue life of FRP strengthened RC beam proposed in this paper. The model takes into account the degradation of the component material performance as well as the creep of concrete. After determining the failure criterion of steel reinforcement fracture, the load cycles are divided into several same loading blocks. The stress amplitude of the steel reinforcement is considered as a constant value in each loading block. To obtain the stress amplitude of the steel reinforcement, the traditional sectional analysis method and the Palmgren-Miner rule are applied. Comparisons between the model predictions and experimental ones reported by the relative researchers show a good correlation, which demonstrate the

effectiveness of proposed model.

ABSTRACT

As the fibre reinforced polymer (FRP) sheets/textiles strengthening the inorganic cementitious materials technique was presented by some researchers, a few of potential shortcomings, such as penetrating difficultly of cementitious materials to and much brittle of FRP sheets, have been found in recent years. Therefore, a new strengthening system, which was FRP grid strengthening ECC system, in combination with the Engineered Cementitious Composites (ECC) and FRP grid was proposed by the present authors. By applying this system to reinforce the reinforced concrete (RC) beams, the dual strengthening effects can be provided and the intermediate crack-induced debonding failure can also be suppressed by externally bonded the FRP gird reinforced ECC composite layer to the tensile surface of the original RC beams. To investigate the tensile mechanical behaviour of FRP gird reinforced ECC composite layer, six non-strengthened ECC specimens and eighteen basalt fibre reinforced polymer grid (BFRP) strengthening ECC composite specimens (FRP-ECC specimens) subjected to the unidirectional axial tensile loading were conducted in this paper. Three kinds of different thickness BFRP grid were applied to investigate their reinforcement effects. The test results showed that there was no slip at the interface of BFRP grid and ECC substrate significantly. The failure modes were the internal PVA fibers ruptured or pulled out from ECC substrate for the non-strengthened ECC specimens and the rupture of BFRP reinforcements of grid for the strengthened FRP-ECC specimens. The axial stiffness of FRP-ECC specimens and the ultimate tensile stress and strain were obviously increased after the ECC substrate cracked, which indicated the contribution of the internal BFRP grid reinforcements. Moreover, an analytical model was also presented to predict the stress-strain relationship and the tensile strength of the FRP-ECC specimens and validated through comparison with the rest results.

INTRODUCTION

With the deepening of research works and wide applications of fiber reinforced polymer (FRP) composites in strengthening reinforced concrete (RC) elements, a few of potential drawbacks, such as interfacial debonding and poor resistance ability of epoxy resin for fire and ultraviolet (UV), have been realized by some scholars when using the epoxy resin as the bond and impregnated agents in recent years (Wang *et al*. 2012; Wang *et al*. 2013a; Wang *et al*. 2013b; Wang *et al*. 2014; Zhang *et al*. 2014). Therefore, the inorganic cementitious materials were applied to replace the epoxy resin so as to develop the relatively new strengthening techniques, e.g., the FRIP (fiber-reinforced inorganic polymer) (Dai *et al*. 2014; Ding *et al*. 2014), TRM (textile reinforced mortars) (Al-Salloum *et al*. 2012; D Ambrisi *et al*. 2012; Chalioris *et al*. 2014; Larrinaga *et al*. 2014; D'Ambrisi *et al*. 2015; Escrig *et al*. 2015) and cement based dry fiber sheets (Hashemi. S *et al* 2009; Zhang *et al*. 2014). Even so, the inorganic cementitious materials are much brittle and may be difficult to penetrate when fiber sheets/textiles are used as the reinforcing materials. For this purpose, an innovated strengthening system, FRP grid strengthening engineered cementitous composites (FRP-ECC strengthening system), in combination with the FRP grid and engineered cementitious composite (ECC) has been presented by the authors (Zheng *et al* 2015). In this system, FRP grid acts as the internal reinforcement and the ECC is applied as a bonding agent between the FRP grid and the concrete substrate. The authors hope the dual strengthening effects can be provided and the intermediate crack-induced debonding failure can also be suppressed by externally bonded the FRP gird reinforced ECC composite to the tensile surface of the original concrete RC beams.

Before implementing the FRP-ECC strengthening system, some basic research works should be conducted. One is most important to determine the stress-strain relationship (i.e. constitutive relation) of FRP gird strengthening ECC composite layer. Furthermore, the numerical simulations using the finite element analysis software and the analytical works for predicting the flexural and shear capacities of strengthened RC beams can be resolved after achieving the key constitutive relation of that composite material. Therefore, an experimental program was done to try to obtain the stress-strain relationship under the uniaxial loading, and an analytical model for predicting tensile capacity of FRP gird reinforced ECC composite was also presented based on the test results in this paper.

EXPERIMENTAL PROGRAMS

A total of twenty-four specimens subjected to the unidirectional loading were manufactured in this test program. Among them, six non-strengthened ECC specimens and eighteen FRP grid strengthening ECC (FRP-ECC) composite specimens were made to study their tensile mechanical performance. All test specimens were divided into four groups (i.e. Group E0, Group FE1, Group FE3 and Group FE5) and each group had six same specimens, as listed in Table 1. The ECC and FRP-ECC composite specimens were both the sheet shape and had the same geometrical dimension with 400 mm in length, 100 mm in width and 30 mm in thickness, as shown in Figure 1. The non-metallic reinforcement material embedded in the ECC substrate was basalt fiber reinforced polymer (BFRP) grid. The dimension of BFRP grid were 100 mm in width and 400 mm in length and the orthogonal BFRP reinforcements were arranged at a space of 50 mm center to center along the longitudinal and transverse directions, as indicated in Figure 2. To investigate the effect of internal reinforcement, three kinds of different thickness (i.e. 1 mm, 3 mm and 5 mm) BFRP grids were used in this test program. Moreover, two 100 mm ×100 mm thin square aluminium plates were attached to the cement-base surface at the two ends of specimens to ensure those specimens can be clamped tightly with the stretching machine, as shown in Figure 1. The details of all test specimens are summarised in Table 1.

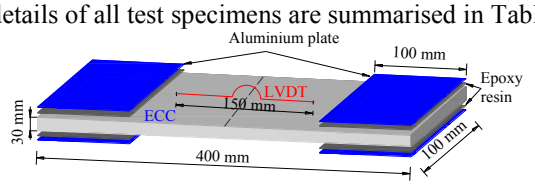

Figure 1 FRP-ECC specimen

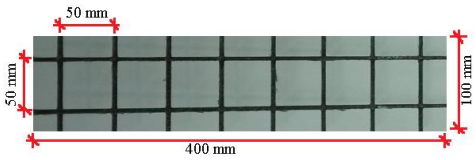

Figure 2 BFRP grid coupon

Before the unidirectional tensile test, nine BFRP grid coupons (i.e. three coupons for 1 mm, 3 mm and 5 mm, respectively) were prepared to determine their mechanical behavior. The geometrical dimension of BFRP grid coupons were the same with that of the BFRP grids used for strengthening FRP-ECC composite specimen. The average tensile strengths of 1 mm, 3 mm and 5 mm thick BFRP grids were 357 MPa, 386 MPa and 416 MPa, respectively, while the average elastic module were 51 GPa, 53 GPa and 57 GPa, respectively. As a result, the average elongation was 27%, 26% and 22%, respectively. ECC was made from the ordinary Portland cement, fly ash, fine sand, polyvinyl alcohol (PVA) fiber and some admixtures. The Polyvinyl Alcohol (PVA) fibre used for making ECC was produced by a Japanese company. All material properties of PVA fibres were listed in Table 1 and the mixed proportion of ECC were designed in the Table 2.

Table 1 Material properties of PVA fibres

Diameter (μm)	Length (mm)	Density (g/cm^3)	Elastic module (GPa)	Tensile strength (MPa)	Elongation (%)
39	12	1.3	40	1530	7

Table 2 Mixed proportion of ECC

Water (kg)	Cement (kg)	Fly ash (kg)	Silica sand (kg)	Fiber volume content (%)	Silica fume (kg)	Water reducer (kg)	Water/cement materials (%)
0.33	0.40	1.00	0.32	2	0.040	0.005	46

After all specimens were cured 28-day in a curing chamber with a temperature of 20 centigrade degree and a relative humidity of 95%, the unidirectional tensile test was conducted. The specimens were placed into and then clamped by two steel collets of the computer-controlled universal testing machine, as shown in Figure 3. One 'Ω' shape linear variable displacement transducers (LVDT) was bonded to one side surface of the tested specimen to measure the longitudinal deformation and the initial measuring distance (i.e. the gauge length) was 150 mm, as seen in Figure 3. The loading was run by the displacement and the implementary rate was 0.5 mm/min uniformly in the whole test process. The applied loading and the longitudinal deformation were both acquired by an automatic acquisition system.

RESULTS AND DISCUSSIONS

Failure modes

Two failure modes were observed in those specimens. For the non-strengthened ECC specimens (i.e. Group E0), the internal PVA fibers were fractured or pulled out from the cement base at a certain section, as shown in Figure 4(a). For the BFRP grid strengthening ECC (FRP-ECC) specimens, the rupture of one longitudinal reinforcements of the BFRP grid was observed at the location of maximum crack width, as shown in Figure 4(b).

Specimens in Group E0 were used as the reference specimens without the reinforcement material of BFRP grid. The first fine crack was formed at the middle section of the specimen shortly after the external loading applied. Then more fine cracks were appeared uniformly along the longitudinal direction of specimen and propagated toward two side edges of specimen as the applied loading increased. When the ultimate load applied, the specimen were eventually separated two parts along a main crack, which indicated the final failure occurred. For the specimens were internally strengthened with 1 mm thickness of BFRP grid (i.e. Group FE1), a few of fine cracks were observed on the surface of specimen when the load approached to 8.20 kN (average measured value of six specimens) or approximately 68% of ultimate load. With the load further increased, some new fine cracks were constantly formed and old fine cracks extended to the both sides of specimen. When the load was applied to the 12.03 kN (average measured value of six specimens), slightly "cracking" sound from the BFRP grid was heard and one longitudinal reinforcement of BFRP grid was finally ruptured at the position of main crack. For all the rest of strengthened specimens (Groups FE-3 and FE-5), the similar tensile behavior were observed during the whole testing process.

Stress-strain responses

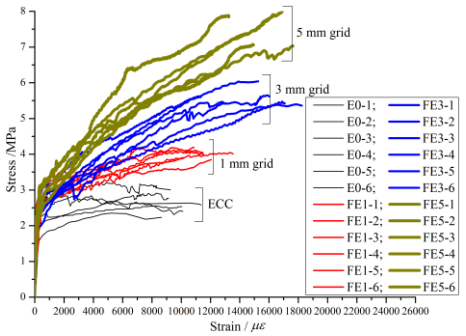

Figure 5 Stress-strain curves of all tested specimens

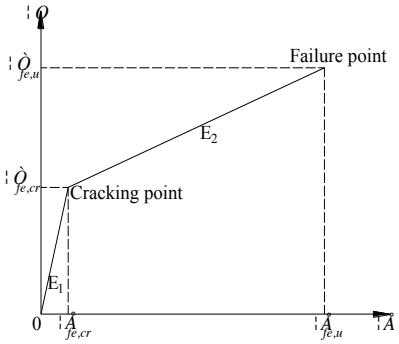

Figure 6 Proposed stress-strain relationship model

Figure 5 presents the stress-strain response of all tested specimens under the uniaxial tensile loading. It should be noted that the tensile stress shown in Figure 5 can be obtained as:

$$\sigma_{fe} = P_t / A_{fe} \quad (1)$$

Where σ_{fe} is the tensile stress of the test specimen; P_t is the applied loading and A_{fe} is the cross-sectional area of the test specimen neglecting the cross-sectional area of BFRP grid. The corresponding strain can be deduced as:

$$\varepsilon_{fe} = \Delta L / L \quad (2)$$

Where ε_{fe} is the tensile strain of the test specimen; ΔL is the increment of gauge length and L is the gauge length (i.e. 150 mm).

It is apparently observed from Figure 5 that the stress-strain curves for the non-strengthened ECC and FRP-ECC specimens can be divided into two stages. In the first stage, the strain is a linear growth with the stress increasing before ECC cracked. Therefore, this stage can be considered to be the linear-elastic stage. After ECC cracked, the growth rate of strain is greater than that of stress and the slope of stress-strain curves is changed due to the axial stiffness decreased continuously. For the ECC specimens, lager strain is observed while the stress almost is kept a constant value in the second stage (see the stress-strain curves of ECC in Figure 5). This phenomenon is well known as the strain-hardening performance of ECC. For the specimens strengthened with different thickness BFRP grid, the axial stiffness remains increasement due to the contribution of the internal BFRP reinforcements. Moreover, the combined action of ECC and BFRP grid results in a larger ultimate tensile strain compared with ECC specimen. Here we define the stress corresponding to the crack loading of specimen as the cracking stress. Therefore, the corresponding axial tensile strain is defined as the cracking strain. The key

values of stress and strain for each specimen at the different stages (i.e. crack and ultimate stages) are listed in Table 1.

It is found from Table 1 that the average cracking stress increases from 2.28 MPa for the ECC specimen to 2.73 MPa, 2.50 MPa and 2.76 MPa for the strengthened FRP-ECC specimens in Group FE1, Group FE3 and Group FE5 respectively, which indicates the effective tensile contribution of BFRP grid for the ECC cementitious base. Furthermore, there is a remarkable improvement in the ultimate stress when the internal BFRP grid was added. The increase of ultimate stress ranges from 49% to 174% for the strengthened FRP-ECC specimens compared to the non-strengthened reference specimens.

PREDICTED MODEL

As seen from the above tensile test results, the stress-strain response of FRP-ECC specimens can be divided into two stages. Therefore, a bi-linear theoretical model based on the test results is presented in this section to define the stress-strain relationship of the FEP-ECC composite under the uniaxial loading, which is:

$$\sigma_{fe} = \begin{cases} E_1 \varepsilon_{fe} & (0 \le \varepsilon_{fe} \le \varepsilon_{fe,cr}) \\ E_2(\varepsilon_{fe} - \varepsilon_{fe,cr}) + \sigma_{fe,cr} & (\varepsilon_{fe,cr} \le \varepsilon_{fe} \le \varepsilon_{fe,u}) \end{cases} \tag{3}$$

Where E_1, E_2 is the tangent slopes of stress-strain curve for the FRP-ECC composite at the first and second stages, respectively; $\varepsilon_{fe,cr}$ and $\varepsilon_{fe,u}$ is the cracking strain and ultimate strain of FRP-ECC composites, respectively. $\sigma_{fe,cr}$ is the cracking stress of FRP-ECC composite corresponding to the cracking strain $\varepsilon_{fe,cr}$.

To determine the stress-strain relationship of the FRP-ECC composite, the values of E_1, E_2, $\varepsilon_{fe,cr}$ and $\varepsilon_{fe,cu}$ should be obtained firstly. As shown in Figure 6, a non-cracked FRP-ECC composite specimen is consisted of the ECC cementitious base and internal BFRP grid. Based on the equilibrium conditions of the axial forces acted on the each material element, the following equation can be deduced:

$$E_{fe}\varepsilon_{fe}A_{fe} = E_e\varepsilon_e A_e + E_f\varepsilon_f A_f \tag{4}$$

Where E_{fe} ,E_e and E_f is the elastic modulus of FRP-ECC composite, ECC layer and BFRP grid, respectively ; ε_e and ε_f is the tensile strain of ECC and BFRP grid, respectively; A_{fe}, A_e and A_f is the cross section area of FRP-ECC composite, ECC layer and BFRP grid, respectively .

If considering $\varepsilon_{fe} = \varepsilon_e = \varepsilon_f$, Equation (4) can be rewritten as:

$$E_{fe} = E_e + E_f \frac{A_f}{A_{fe}} \tag{5}$$

In fact, the elastic modulus of FRP-ECC composite could be decreased due to the stress softening and the development and formation of the internal micro-crack of ECC cementitious base (Contamine *et al*. 2011; Contamine *et al*. 2014). Therefore, a reduction coefficient α is induced to reflect the influences of those factors and Equation (5) can be given as:

$$E_1 = \alpha E_{fe} = \alpha\left(E_e + E_f \frac{A_f}{A_{fe}}\right) \tag{6}$$

Where E_1 is the modified elastic modulus of FRP-ECC composite and can be thought of as the tangent slope of the stress-strain curve at the first stage. Substituting the measured values of the tangent slope of the stress-strain curve at the first stage and the relative values of the elastic modulus and the cross-section area of the ECC and BFRP grid into Equation (6), the reduction coefficient α can be obtained as list in Table 1.Taking the average value of the reduction coefficient α for all FRP-ECC composite specimens, we can obtain:

$$\alpha = 0.57 \tag{7}$$

The tangent slope E_2 of stress-strain curve at second stage is mainly affected by the elastic modulus of FRP grid after ECC cracked. Therefore, the second stage tangent slope E_2 can be obtained through regressing the measured values of E_2 and the elastic modulus of FRP grid E_f (Figure 8):

$$E_2 = 0.03E_f - 1468 \tag{8}$$

As discussed above, the cracking load of FRP-ECC was primarily determined by the tensile strength of the ECC cementitious base. Thus, it is assumed the cracking strain of FRP-ECC composite is equal to that of ECC, and taken as $\varepsilon_{fe,cr} = \varepsilon_{e,cr}$ (where $\varepsilon_{e,cr}$ is the cracking strain of ECC cementitious base). Whereas, the ultimate strain of FRP-ECC composite mainly depended on the ultimate strain of BFRP grid. After analyzing the measured ultimate strain of FRP-ECC composite carefully, it can be found that there is no regular relation between ultimate strain of FRP-ECC composite and the ultimate strain of BFRP grid. Hence, an empirical coefficient γ is introduced and the following equation is given:

$$\varepsilon_{fe,u} = \gamma\varepsilon_{fu} \tag{9}$$

In which, $\varepsilon_{fe,u}$ and ε_{fu} is the ultimate strain of FRP-ECC composite and BFRP grid, respectively. By averaging the ratios of the measured ultimate strain of FRP-ECC composite specimens and that of BFRP grid (i.e. $\gamma = \varepsilon_{fe,u} / \varepsilon_{fu}$), the value of empirical coefficient γ is equal to:

$$\gamma = 1.97 \tag{10}$$

After determining stress-strain relationship of FRP-ECC composite, the predicted cracking load $P_{cr,p}$ and ultimate load $P_{u,p}$ can be respectively given as:

$$\begin{cases} P_{cr,p} = \sigma_{fe,cr} A_{fe} \\ P_{u,p} = \sigma_{fe,u} A_{fe} \end{cases} \tag{11}$$

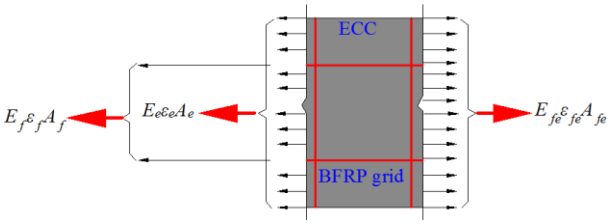

Figure 7 Analytical model

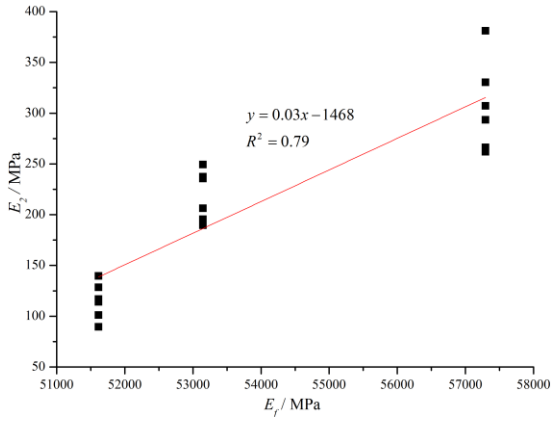

Figure 8 Regression of tangent slope E_2

Two FRP-ECC composite specimens FE3-3 and FE5-4 were selected to validate the accuracy of the analytical model. The experimental and predicated stress-strain curves were shown in Figure 9. Moreover, the predicated values of the cracking and ultimate loads for all strengthened specimens were list in Table1. It should be noted that the predicted curves follows very closely to the experimental one with the slightly discrepancies. Furthermore, the average ratio of experimental values to the predicated ones is 1.09 for both the cracking load and the ultimate load and the coefficient of variation (COV) is 0.10 for the cracking load, 0.06 for the ultimate load, respectively. Therefore, the reliability of proposed model for predicting the stress-strain relationship and the tensile strength of the FRP-ECC composite under the unidirectional loading is validated.

(b) Specimen FE5-4

Figure 9 Comparisons between the experimental stress-strain curves and predicated one of specimens FE3-3 and FE5-4

CONCLUSIONS

(1) The final failure modes of the internal PVA fibers ruptured and then pulled out from ECC for the control non-strengthened specimen and the rupture of BFRP reinforcements for the FRP-ECC composite specimen were observed in the test program.

(2) After strengthened with BFRP grid, the axial stiffness, the ultimate tensile stain and the tensile strength of the FRP-ECC specimens were greatly improved compared with the non-strengthened specimens, which showed the effective contribution of the internal FRP grid for improving the tensile performance of the strengthen FRP-ECC composite.
(3) An analysis method has been proposed for predicting the material constitutive relation and the tensile capacity of FRP-ECC composite and its validity is demonstrated through comparisons with test results.

ABSTRACT

In this paper, the thermal-moisture analogy schemes were applied to simulate moisture diffusion in an epoxy resin and CFRP strengthened concrete system numerically. The two thermal-moisture analogy schemes were adopted for homogeneous material (e.g., epoxy adhesive) or multi-component material systems. The direct analogy (DA) is only valid for the homogeneous material system and can simulate the moisture diffusion in an epoxy adhesive accurately. The normalized analogy (NA) was proved be an effective tool for the CFRP-concrete system. In addition, based on NA, the interfacial stress and swelling stress induced by water can be simulated accurately.

Keywords

Direct analogy, normalized analogy, CFRP/adhesive interface, adhesive/concrete interface.

INTRODUCTION

Externally bonded fibre reinforced polymer (FRP) composites for civil rehabilitation has become a popular technology in recent years (Shrestha, Ueda et al. 2014). Strengthening depends highly on the integrity of the bond between FRP and concrete substrate (Lau and Büyüköztürk 2010). Some research have been conducted to investigate the long-term performance of bond property experimentally. Until now, however, the effects of the harsh environments on the bond is not yet completely understood, e.g., water immersion, high humidity exposure or freeze-thaw cycles. The durability of FRP-to-concrete system under water immersion is largely controlled by the rate at which water and deleterious ions that use water as a carrier over through the system (Ouyang and Wan 2008). The bond interface at adhesive/concrete and constitute materials are susceptible to water uptake. It is necessary to study the moisture diffusion in the FRP-to-concrete system.

As reported, for the bond between CFRP and concrete substrate, immersion into water at 23 °C and 50 °C for 8 weeks decreases the fracture toughness by 13.8% and 51%, respectively (Au and Büyüköztürk 2006). Exposure to 100% humidity for 10000hrs reduces the bonding strength by 37% for CFRP plate - concrete beam and 10% for CFRP wet layup to concrete (Grace and Grace 2005). Water molecules were found at the interface between the adhesive and concrete after 338 hrs of immersion in water at 24 ^{o}C (Nguyen, Byrd et al. 1998). The interface between adhesive and concrete substrate and the adhesive layer are susceptible to degradation significantly owing to the ingress of water. To quantify the moisture transport in the bonding zone between FRP-to-concrete system is needed to understand the effect of moisture ingress on the long term bond performance.

Absorbed moisture in a substance may bring in hygrothermal stress. Therefore, the moisture diffusion on the hygrothermal stress) was analyzed subsequently. The mass diffusion modelling results are difficult to translate into the subsequent analysis for ABAQUS (e.g., static analysis) (Systèmes 2010). In practice, thermal diffusion (heat transfer) function can be adopted to simulate the moisture diffusion by the thermal-moisture analogy scheme. Many researchers have modelled the moisture diffusion in a FRP sheet/plate, an epoxy or the bond area between FRP-concrete (Ouyang and Wan 2008). However, investigations on the moisture diffusion in a multi-component material system are very scarce. As expected, the thermal-moisture analogy can be developed for the simulation of the water diffusion in the constitute materials and interface between the components, e.g., the interface between the resin matrix and fibre.

The present study is to simulate the moisture transportation in a FRP-to-concrete system. The direct analogy and normalized analogy schemes were adopted to investigate the moisture diffusion in the resin matrix and the FRP-concrete system.

THEORETICAL BACKGROUND

THE DIRECT ANALOGY

The moisture diffusion phenomenon can be described by Fick's first law as (Ouyang and Wan 2008, Systèmes 2010).

$$\frac{\partial C}{\partial t} = \nabla(D \times \nabla C) \tag{1}$$

where D is the moisture diffusivity, C is the moisture concentration (the water content in unit volume of substrate), and t is time. Assuming that the moisture diffusivity is uniform ($\nabla D = 0$), and Eq.1 is changed to

$$\frac{\partial C}{\partial t} = D\nabla^2 C \tag{2}$$

However, it cannot apply for movement in the multi-component material system (e.g., FRP) because the moisture content is continuous at the interface.

The result of moisture diffusion is difficult for static analysis. In order to resolve this problem, a thermal analysis is introduced. Conduction heat transfer can be described by Fourier's law (Yoon, Han et al. 2007, Systèmes 2010).

$$\frac{\partial T}{\partial t} = \frac{1}{\rho C_p}\nabla(k \times \nabla T) \tag{3}$$

where T and q are the temperature (K) and the heat flux($W\,m^{-2}$), respectively; ∇ is the gradient operator; k is the thermal conductivity ($W\,m^{-1}\,K^{-1}$) for isotropic thermal diffusion. Assuming that the thermal conductivity is uniform ($\nabla k = 0$), the Eq.3 yields the heat conduction equation as

$$\frac{\partial T}{\partial t} = \alpha\nabla^2 T \tag{4}$$

where α is the thermal diffusivity($m^2 s^{-1}$) , defined as $\alpha = k / \rho C_p$.

In comparison of Eq. 2 and Eq. 4, the temperature (T) and the diffusion coefficient (α) can be equal to the concentration(C) and the moisture diffusion (D), respectively. The direct analogy can be expressed as

Temperature (T) = Concentration (C) (5)

Diffusion coefficient (α) = Moisture diffusion (D) (6)

THE NORMALIZED ANALOGY

Eqs 5 and 6 are valid for the uniform within a homogenous material. In order to be applied for the multi-component materials, the normalized concentration was introduced by Samson Yoon et al. (Yoon, Han et al. 2007). The new variable field can be defined as

$$\phi = \frac{\mathrm{C}}{\mathrm{S}} \tag{7}$$

ϕ is referred to as the "activity" of the material (Systèmes 2010). In this case, the variable is continuous at the interface. The Eq.7 is submitted into Eq.2, it can be expressed as

$$\frac{\partial C}{\partial t} = DS\nabla\phi + D\phi\nabla S \tag{8}$$

It can be assumed that the S is a constant under the given temperature. The Eq.8 can be simplified as

$$\frac{\partial C}{\partial t} = DS\nabla\phi \tag{9}$$

Eq.9 is independent on the S and is only valid when $\frac{\partial S}{\partial t} = 0$. The normalized concentration analogy can be expressed as

Temperature (T) = Normalized concentration (ϕ) (10)

$$k = DS \tag{11}$$

$$\rho C_p = S \tag{12}$$

FINITE ELEMENT MODEL

In the present study, a finite element analysis using ABAQUS software was employed to simulate the moisture diffusion in a substance. The DC2D8 was used for the implementation of the thermal-moisture analogies. It was assumed that the moisture diffusion was driven by the concentration gradient and a two-dimensional model was adopted. The nodes at the interface for the multi-component material are shared. FEM was used to model the changes of the water content based on Eqs 5 and 6 and Eqs 10 - 12, respectively.

The water ingress in a short period is dependent on the capillary action. However, the long-term moisture movement in concrete is generally controlled by the moisture transportation through the gel pores, which is driven by concentration gradient (Ouyang and Wan 2008). Therefore, the water transportation through the concrete, adhesive and CFRP plates are assumed to follow the Fickian law (Yoon, Han et al. 2007, Ouyang and Wan 2008).

DIFFUSION MODELING IN AN EPOXY ADHESIVE

At room temperature, the specimens (25 x 25 x 2 mm) were used for water absorption test. The moisture uptake was determined by periodically weighing the samples taken from the water bath. Due to the symmetric geometry, only half of the epoxy was considered in the finite element analysis. It was assumed that the moisture flux only translate into the epoxy adhesive along the thickness direction of the specimens. Fig.1 shows the specimens geometry and typical results for finite element analysis.

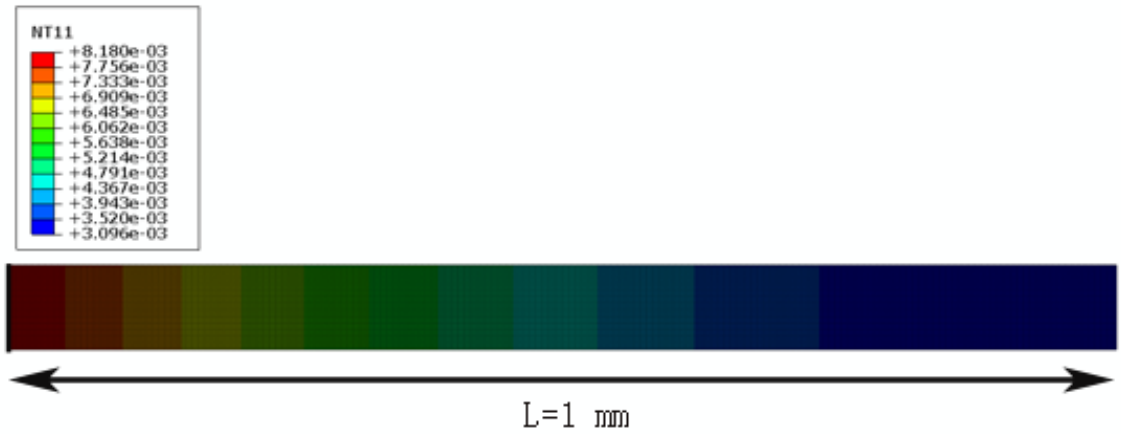

Figure 1 The geometry and typical results of an epoxy adhesive plate sample at 39.32 hrs.

The left boundary condition (black line) was exposed to 100% RH at room temperature. To ensure a high level of numerical accuracy, the element size is set as 0.002 mm. Table 1 shows the properties of the epoxy samples in the simulation.

Table 1 The properties of epoxy adhesive.

		Direct analogy(DA)	Normalized analogy(NA)
	Field variable	Moisture concentration (C)	Normalized concentration (ϕ)
Epoxy Adhesive	Density	1	1
	Conductivity	2.17×10^{-6}	1.8×10^{-7}
	Specific heat	1	0.818

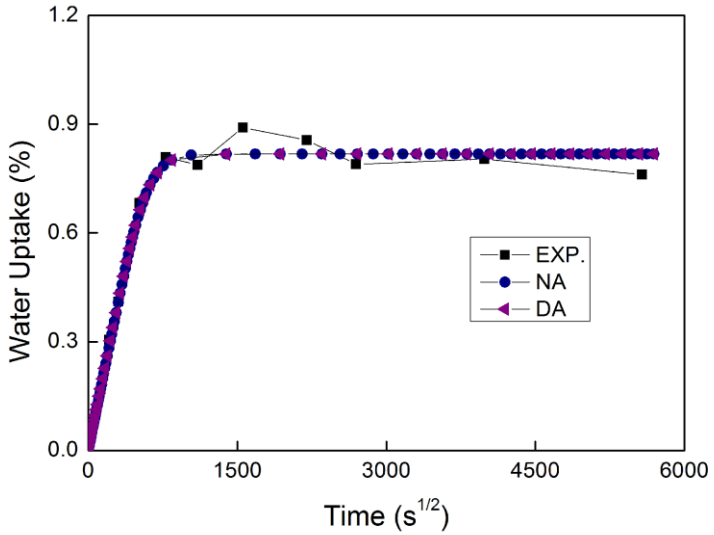

Figure 2 Comparison of the water uptake – square root of exposure time curves from experimental test and simulation based on NA and DA.

The moisture uptake of the epoxy adhesive as square root of the exposure time is shown in Fig.2. The weight gains of the adhesive samples increase proportionally to the square root of immersion time before reaching the saturation level, after one year and it follows the Fickian law of moisture uptake (Karbhari and Xian 2009).

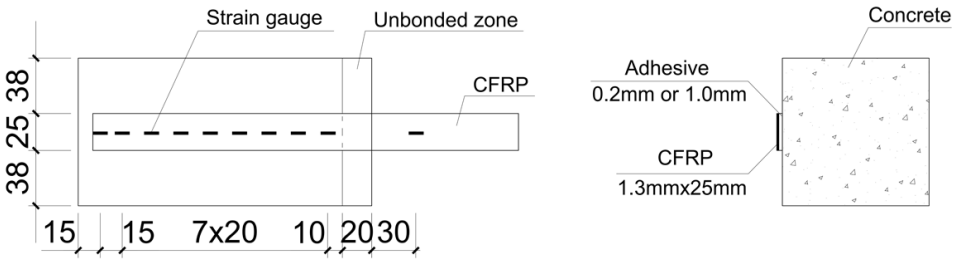
$$M_t = M_\infty \left\{1 - \exp\left[-7.3\left(\frac{Dt}{h^2}\right)^{0.75}\right]\right\} \quad (13)$$

where M_t is the moisture uptake at time t, M_∞ is the quasi-equilibrium moisture uptake, D is the diffusion coefficient, h is the thickness of the sample (2 mm for the samples in the experiment). D and M_∞ were determined using curve fitting with Eq.13, and 0.217 x 10^{-6}, 0.818% were determined for D and M_∞, respectively.

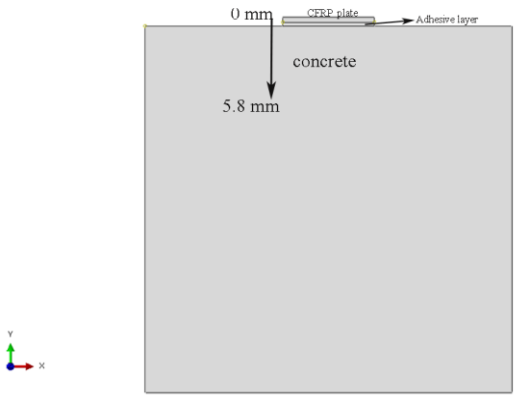
The results obtained from analogy schemes of the NA and DA are shown in Fig.2. It is obviously observed that both NA and DA produce the same moisture diffusion process. Fig.2 shows that the test of water uptake-time curve are accurately predicted by FEM model. It indicates that the NA and DA can handle the single-material system. The discrepancy after 167 days between FEM results and experimental results obtained owing to the swelling, plasticization, and irreversible damage (Karbhari and Xian 2009). It results in the damage of epoxy. The damage of epoxy was not considered in present FEM model.

DIFFUSION MODELING IN CFRP-TO-CONCRETE SYSTEM

In practice, the adhesive is located at the interface between CFRP plate and the concrete substrate and it is not feasible to directly measure the water ingress. It was assumed that there is no moisture flux along the longitudinal direction of the specimens. Figure 3a schematically represents the single-lap shear testing specimen and a two-dimensional model was shown in Figure 3b. Table 2 shows the constitute materials property in the simulation.



(a)



(b)

Figure 3 Schematic sketch of the single-lap shear testing setup (a), and 2 D model in ABAQUS (all units in millimeters) (b).

Table 2 Material properties of CFRP-concrete system.

		Direct analogy(DA)	Normalized analogy(NA)
	Field variable	Moisture concentration (C)	Normalized concentration (ϕ)
CFRP plate	Density	1	1
	Conductivity	4.36×10^{-7}	3×10^{-8}
	Specific heat	1	0.007
Adhesive	Density	1	1
	Conductivity	4.4×10^{-5}	1.2×10^{-6}
	Specific heat	1	0.027
Concrete	Density	1	1
	Conductivity	3×10^{-3}	2.1×10^{-4}
	Specific heat	1	0.071

Figure 4 shows the simulation results based on the two analogy schemes. The average moisture content in the CFRP-to-concrete system at different location (from 0 mm to 5.8 mm) in terms of the nodal heat corresponding to various immersion times was determined. As shown in Figure 4a, the moisture content in the concrete is more than that of the adhesive and CFRP plate. The water mainly comes from the adjoining laminate, e.g., the moisture molecular migrating from the concrete to the adhesive. The phenomenon is observed from the simulation results based on both NA and DA from 2 weeks to 8 weeks in Figure 4. It can be understood that more moisture molecular comes from the materials with higher equilibrium moisture content of materials to the materials with lower equilibrium moisture content. The continuous moisture distribution for the direct analogy is observed at CFRP/adhesive (1.4 mm) and adhesive/concrete (2.4 mm) interfaces. The moisture content at CFRP/adhesive interface (1.4 mm) subjected to 2 weeks immersion is more than the equilibrium moisture content of the adhesive (as shown in Figure 4b,c&d), whereas it violates the constrains of the analogy schemes. The same case is found at 2.4 mm.

The normalized analogy produces the discontinuity of moisture distribution both at CFRP/adhesive and adhesive/concrete interface (see in Figure 4). This discrepancy at the interface is mainly attributed to the different constitute equilibrium moisture content. The swelling stress is determined by Eq.14 (Systèmes 2010).

$$\sigma = \alpha \Delta c \tag{14}$$

where α is coefficient of moisture expansion, Δc is moisture content.

In comparison of the normalized analogy, it indicates that the DA causes the substantial errors in calculating. The interfacial stress and constitute materials of swelling stress can be induced by water.

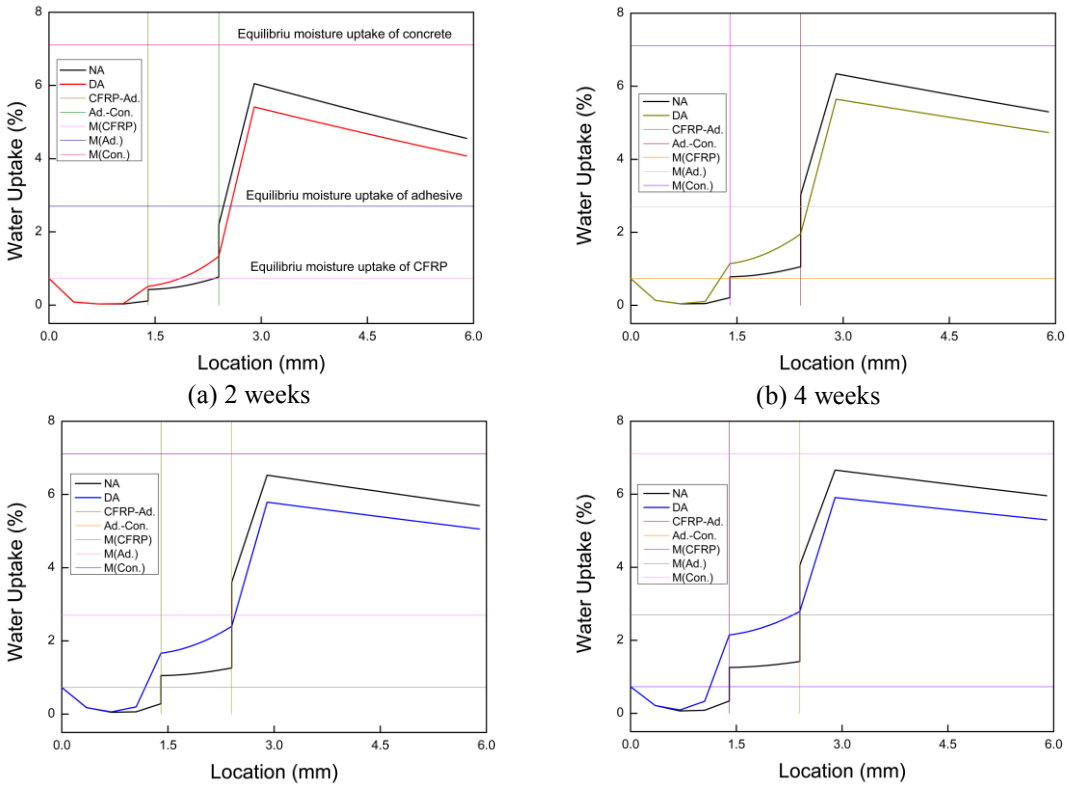


Figure 4 Moisture diffusion in the CFRP-to-concrete system.

CONCLUSION

The paper reviewed the thermal-moisture diffusion analogy schemes and investigated the diffusion and distribution of moisture in a homogeneous material system (i.e., epoxy adhesive) and CFRP-to-concrete system by FEM. Based on the simulated results, the following conclusions can be drawn.

1) The direct analogy is only valid for the homogeneous material. It cannot simulate the moisture distribution at the interface for the multi-component material system.

2) The normalized analogy can obtain the correct moisture distribution at the interface for the multi-component material system. It is an effective method to investigate the swelling stress induced by the water ingress for CFRP-to-concrete system.

ABSTRACT

Basalt fiber-reinforced polymer (BFRP) bars can replace steel bars in sea sand concrete structures to prevent the corrosion of steel by chloride ions; thus, sea sand can be directly added to concrete material in construction. Shear tests on 16 sea sand concrete beams with BFRP bars (including ten beams with stirrups and six beams without stirrups) are performed, and their failure modes, shear capacities and influencing factors are analyzed. The results reveal two main failure modes for sea sand concrete beams with BFRP bars: bending failure and shear-compression failure. The shear capacity increases with the concrete strength and stirrup ratio but decreases with an increased shear-span ratio, and the longitudinal reinforcement ratio has an insignificant effect on shear capacity.

INTRODUCTION

As the primary construction material of concrete, the river sand resource is being depleted, and the trend of exploitation of the abundant sea sand resource is inevitable. However, sea sand contains a high concentration of chloride ions, which can corrode bars in concrete structure and substantially affect the durability of concrete. Research on sea sand concrete in China primarily focuses on the chloride ion corrosion mechanism in sea sand concrete and the sea sand processing technology. The substitution of fiber-reinforced plastic (FRP) bars, which has superior durability, in place of bars in sea sand concrete has vast application prospects. FRP bars substituting steel bars in buildings leave much to be desired. Study on the shear capacity of sea sand concrete structures with FRP bars is one of the most important issues.

The analysis of the shear capacity of a concrete beam with FRP bars is primarily based on the rebar concrete shear model, including the variable truss model (Razaqpur *et al*. 2011) and the modified compression field theory model (Thanasis and Costas 2000). However, the shear model of a rebar concrete structure is based on plasticity theory, which considers plastic stress redistribution. A FRP bar is a linear elastic material without a distinct yield phenomenon; thus, a shear model based on elasticity theory is suitable for a FRP bar-reinforced concrete structure. Among existing FRP concrete design specifications (ACI 2006, CAN/CSA 2010, JSCE 1997), the bearing capacity calculation formulas for FRP bar-reinforced concrete beams primarily focus on influence factors, such as the concrete strength, the longitudinal reinforcement ratio, and the section size. Few specifications consider the stirrup ratio's effect, and the shear-span ratio's effect is completely disregarded. The shear capability of concrete is the main source of the shear capability of a FRP bar-reinforced stirrup-free concrete beam. Thus, the shear capability of a FRP bar-reinforced stirrup-free concrete beam increases with concrete strength (El-Sayed *et al*. 2006). Because FRP bar has a smaller elastic modulus than bar and different types of FRP bars have an extensive range of elastic moduli, some studies show that (Alakhrdaji *et al*. 2001, Sayed *et al*. 2005) an increase in the area of a FRP longitudinal reinforcement section can significantly improve the shear capacity of a structure. However, other tests reveal that the area of a FRP longitudinal reinforcement section does not have a significant effect on a structure's bearing capacity. In addition, the load position can affect the shear capability of a FRP bar-reinforced stirrup-free concrete beam. A higher shear-span ratio will result in a lower shear capability of a FRP bar-reinforced stirrup-free concrete beam. For a shear-span ratio that exceeds 2.5, the shear capacity of a FRP bar-reinforced stirrup-free concrete beam is approximately proportional to the cubic root of the product of three factors: the concrete strength, the longitudinal reinforcement rigidity and the shear-span ratio. Shear capability provided by a FRP bend-up bar or stirrup is determined by the orientation of a FRP bar and the development pattern of a diagonal crack; the stress on a FRP bar in the crack's direction is critical.

The bond performance between a FRP bar and concrete has a significant impact on the shear capacity of concrete; thus, research on the bond between a FRP bar and concrete is also an important research area. Although FRP bars exhibit excellent quality in terms of durability and anti-corrosion (Wu *et al*. 2014), water and temperature also exert a significant impact on the performance of the bond between FRP and concrete (Refai *et al*. 2014 a). A design of FRP bar in concrete should consider many factors, including service life (Banibayat and Patnaik 2013) and stress condition; therefore, comprehensive knowledge of the material properties and influencing factors of FRP bar-reinforced concrete in normal conditions is important to the application of FRP bar sea sand concrete material.

This paper is based on an experimental analysis of shear capacity for 16 BFRP bar-reinforced sea sand concrete beams (including ten beams without stirrups and six beams with stirrups). The failure mode, load-deflection curve, strains on the longitudinal reinforcements and stirrups, and the ultimate bearing capacity are analyzed. The effects of the shear-span ratio, longitudinal reinforcement section, concrete strength and stirrup ratio on the shear capacity of a BFRP-reinforced sea sand concrete beam are compared.

TEST DESIGN

Test Beam Design

Based on Chinese specifications, 16 specimens are designed for the test, including BFRP-reinforced sea sand concrete beams without stirrups and beams with stirrups. The beam length is 1200 mm, the span is 1000 m, the section size of the beam without stirrups is 150×150 mm, and is 150×250 mm for beam with stirrups. The test variable parameters primarily include the concrete strength, the BFRP bar longitudinal reinforcement section, the shear-span ratio and the stirrup ratio. To facilitate the study of how the shear failure mode of a BFRP bar sea sand concrete beam and its changes in various parameters affect the shear strength, the specimen parameters and reinforcement listed in Table 1 and Table 2 are utilized. Fig. 1 displays the reinforcement diagram for the beam with stirrups.

Test Load and Measurement

In the test, the SOS500 electro-hydraulic servo dynamic and static tester is employed to add load, and a distribution beam and sensor are employed to perform two-point loading; the loading schematic is shown in Fig. 2. Displacement control is applied during loading, and the loading rate is 0.2 mm/s. During the test, the items observed and recorded include beam midspan deflection, concrete strain, FRP bar strain and crack.

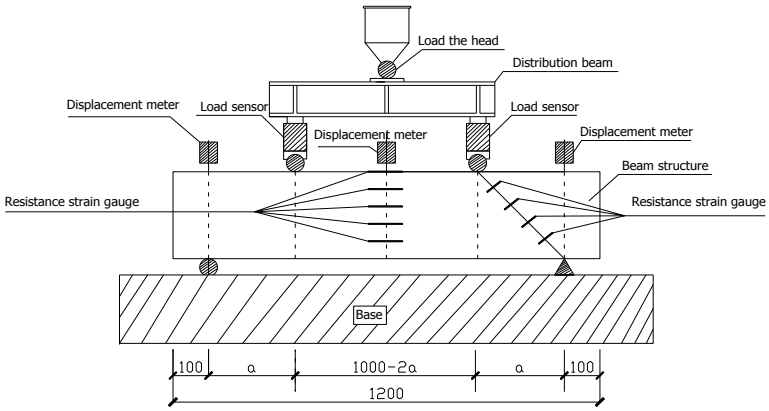

Figure 2 Loading diagram

TEST RESULTS AND ANALYSIS

Test Phenomenon and Results

The shear test for the BFRP bar-reinforced sea sand concrete beam demonstrates that the crack in BFRP bar-reinforced sea sand concrete beam rapidly expand, which is a distinct indication of brittleness. A vertical crack in the pure bending section extends at a faster rate; however, after it reaches the concrete compression area, its growth decelerates. A short horizontal crack is formed at the edge of the concrete compression area, and the crack width continues to grow with the load. In the area near the beam base that is under the load point, a vertical bending crack is observed. This bending crack grows and extends toward the load point; in the middle or at a position near the load point, it gradually inclines and evolves into a bend-shear crack toward the support base. When the load increases and approaches the ultimate shear capacity of the beam, diagonal crack penetration rapidly occurs, and local concrete crush is observed under the load point. With the exception of individual beams that experience beam normal section failure before the load reaches the shear capacity limit, which is due to concrete crush in the compression area, the majority of beams are damaged by stress on the concrete diagonal section. For all BFRP bar-reinforced sea sand concrete beams, deformation is recovered after offloading, which shows that BFRF bars have excellent linear elasticity. BFRP bar-reinforced sea sand concrete beams with or without stirrups exhibit similar crack development patterns with two common failure modes: shear-compression failure and bending failure as shown in Fig. 3 (a) and (b) and are provided in Table 6 and 7.

Relationship Between Load and Deflection

In the case of beams without stirrups, the effects of the longitudinal reinforcement ratio and the shear-span ratio on deflection are shown in Fig. 4 and Fig. 5, respectively. The load-deflection curve shows that the load-deflection curve of the BFRP bar-reinforced stirrup-free sea sand concrete beam does not have a distinct yield platform and declining trend and is similar to a bilinear graph; its turning point occurs when the test beam crack occurs, the change in the slopes before and after crack initiation is not significant, and the change in slope is smaller after crack initiation.

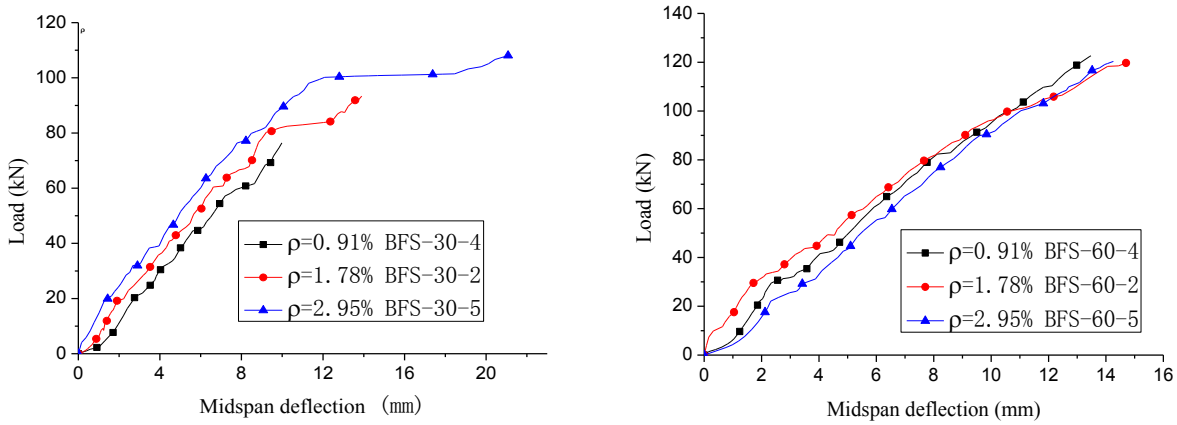

Figure 4 Effect of longitudinal reinforcement ratio on the deflection of the beams without stirrups

The load-deflection curve of the BFRP bar-reinforced stirrup-free beam assumes the form of a straight line before crack initiation because BFRP bar is a linear elastic material that differs from bar and does not have a distinct yield phenomenon. The elastic modulus of BFRP bar is approximately 25% that of bar, which does not significantly contribute to the section rigidity. The BFRP-reinforced stirrup-free beam abruptly cracks; the cracks rapidly extend to a relatively high position of the beam section. Concrete in the tensile zone ceases to bear any load, which causes an instant decline in beam section rigidity. After the beam cracks, the cracks rapidly increase, reach the edge of the concrete compression area, and stop growing. After the concrete cracks, the rigidity of the test beam section exhibits only slight changes; thus, the load-deflection curve continues to assume the form of an approximate straight line after the test beam cracks.

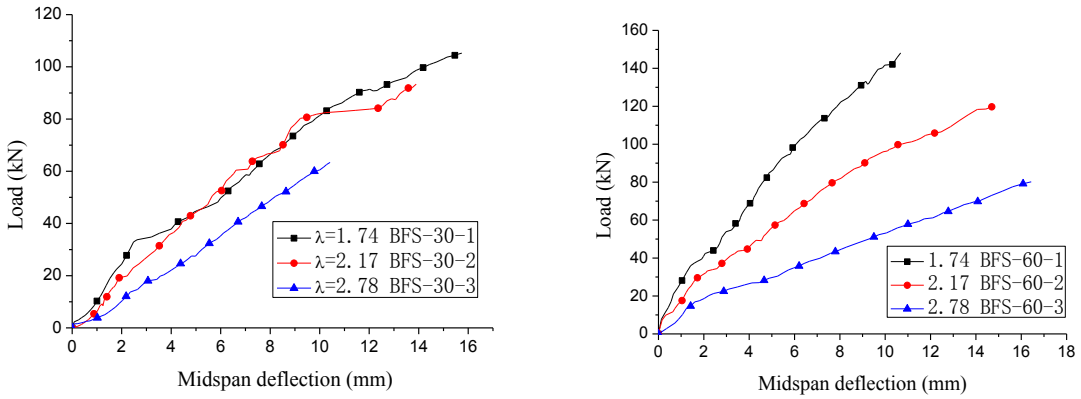

Figure 5 Effect of shear-span ratio on the deflection of the beams without stirrups

Although the elastic modulus of BFRP bar is smaller than the elastic modulus of bar, it is larger than the elastic modulus of concrete. An increase in the longitudinal reinforcement ratio indicates an increase in the bending rigidity of the test beam and a decrease in the beam deflection. As shown in Fig. 4 for the case of the C30 beam, the beam with a higher reinforcement ratio has a smaller deflection for the same level of load, and the change in deflection with an increase in load is significantly smaller than the case of the beam with a lower reinforcement ratio. In the case of the C60 beam, an increase in the reinforcement ratio has an insignificant effect on deflection because C60 concrete has a higher elastic modulus than C30 concrete, and the effect of an increase in the longitudinal reinforcement ratio on the bending resistance rigidity of the section is not as prominent as in the case of the C30 beam. As shown in Fig. 5, the deflection of the beam without stirrups increases with an increase in the shear-span ratio. In the four-point load test, the pure bending section of the beam decreases with an increase in the shear-span ratio. Consequently, the total rigidity of the concrete that counters the bending

moment also decreases; thus, deflection increases. Fig. 6 is the effect of the stirrup ratio on the deflection of the beams with stirrups

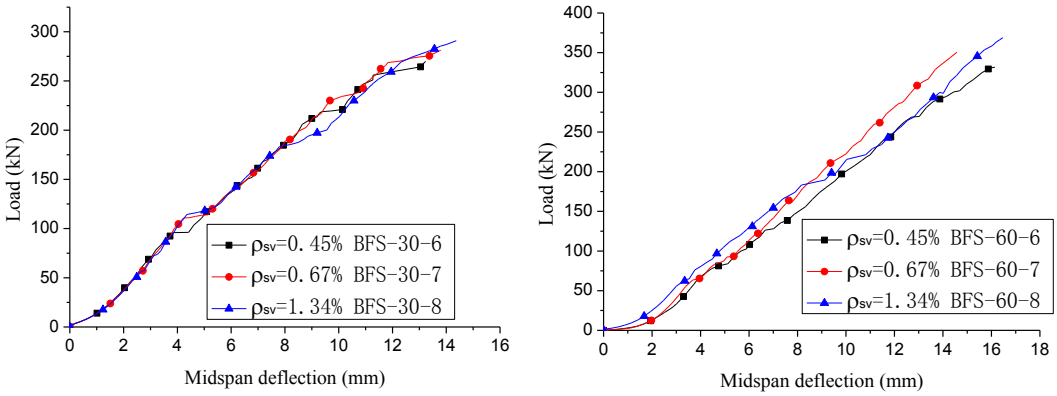

Figure 6 Effect of the stirrup ratio on the deflection of the beams with stirrups

Strains on Longitudinal Reinforcement and Stirrups

The effect of the shear-span ratio and longitudinal reinforcement ratio of a stirrup-free beam on the longitudinal reinforcement strain is shown in Fig. 7 and 8, respectively. Before concrete cracks, the strain on the longitudinal reinforcement of a BFRP-reinforced stirrup-free beam is very small—usually less than 100 $\mu\varepsilon$ —because the total strain is relatively small and the tensile stress in the tensile zone is primarily created by concrete before a beam cracks. After it cracks, concrete does not carry additional stress, and tensile stress is carried by the FRP longitudinal reinforcement. After concrete cracks, the strain on the FRP longitudinal reinforcement rapidly increases in a linear pattern. However, the cracking point is likely to be the point of abrupt change for the strain on the longitudinal reinforcement of a stirrup-free beam. The main reason for this finding is that a concrete crack instantly transfers the stress that is originally carried by concrete to the FRP longitudinal reinforcement, and the vertical crack that subsequently occurs near the midspan beam will also cause an abrupt change in strain on the longitudinal reinforcement. After beam failure, the load suddenly declines, and the strain on the longitudinal reinforcement also abruptly decreases.

As shown in Fig. 7, the effect of the shear-span ratio on the longitudinal reinforcement shear-strain slope is insignificant in the case of the C30 beam. In the case of the C60 beam, the larger is the shear-span ratio, the smaller is the slope of the longitudinal reinforcement shear-strain curve, i.e., the acceleration of the increase in the strain on the longitudinal reinforcement, because the test beam's pure bending section shrinks and the midspan deflection accelerates when the shear-span ratio increases.

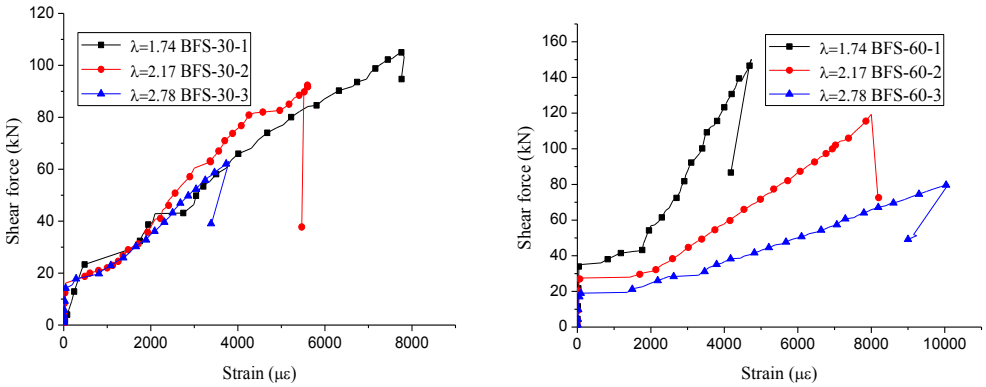

Figure 7 Effect of shear-span ratio on the longitudinal reinforcement strain of the beams without stirrups

Fig. 8 shows that the slope of the longitudinal reinforcement shear-strain curve for the C30 beam is less affected by an increase in the longitudinal reinforcement ratio of the BFRP bar, whereas the slope of the shear-strain curve for the longitudinal reinforcement of the C60 beam slightly increases with the longitudinal reinforcement ratio of the BFRP bar. The effect of the longitudinal reinforcement ratio on the longitudinal reinforcement strain is insignificant, which can be explained by the minimal contribution to the total rigidity of the beam by the BFRP bar with the smaller elastic modulus.

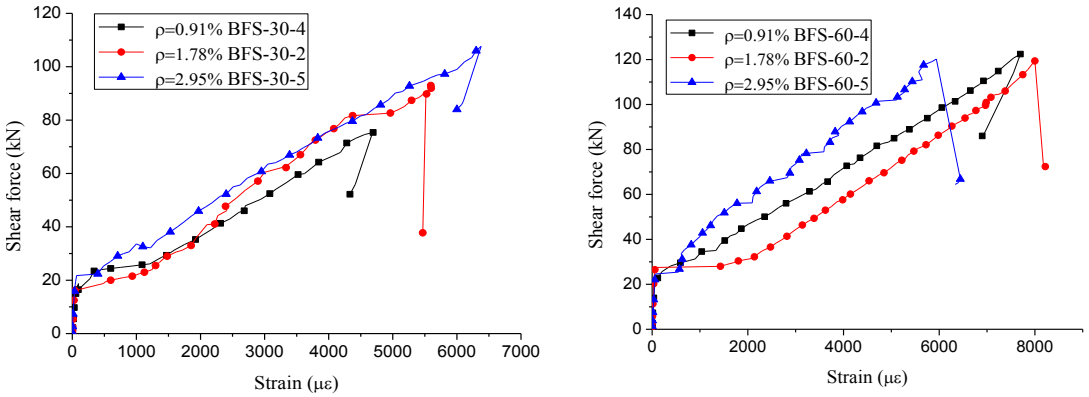

Figure 8 Effect of longitudinal reinforcement ratio on longitudinal reinforcement strain for beams without stirrups

The strains on the longitudinal reinforcement and stirrup for the beam with stirrups are shown in Figure 9. The strain on the longitudinal reinforcement for the beam with stirrups has a development pattern that is similar to the case of the longitudinal reinforcement of the stirrup-free beam: before concrete cracks, the strain on the longitudinal reinforcement is very small; after concrete cracks, the strain rapidly increases in a linear pattern. The strain on the longitudinal reinforcement for the beam with stirrups differs from the case of the beam without stirrups in the following three aspects: first, improvement in the total rigidity of the beam with stirrups increases the cracking load, the point of abrupt change for the longitudinal reinforcement strain is in a higher position than in the case of the beam without stirrups; second, the addition of stirrups effectively constrains beam crack development, and with the exception of the situation in which the beam cracks and the point of abrupt change is observed, the strain on the longitudinal reinforcement for the beam with stirrups seldom causes an additional abrupt change; and third, the maximum longitudinal reinforcement strain for the beam with stirrups is larger than the maximum longitudinal reinforcement for the beam without stirrups, the maximum strain on the C30 beam's longitudinal reinforcement is 7000 $\mu\varepsilon$, the maximum strain on the C60 beam's longitudinal reinforcement exceeds 10000 $\mu\varepsilon$, and both are approximately 2000 $\mu\varepsilon$ higher than the corresponding cases of the maximum longitudinal reinforcement strains of the stirrup-free beam.

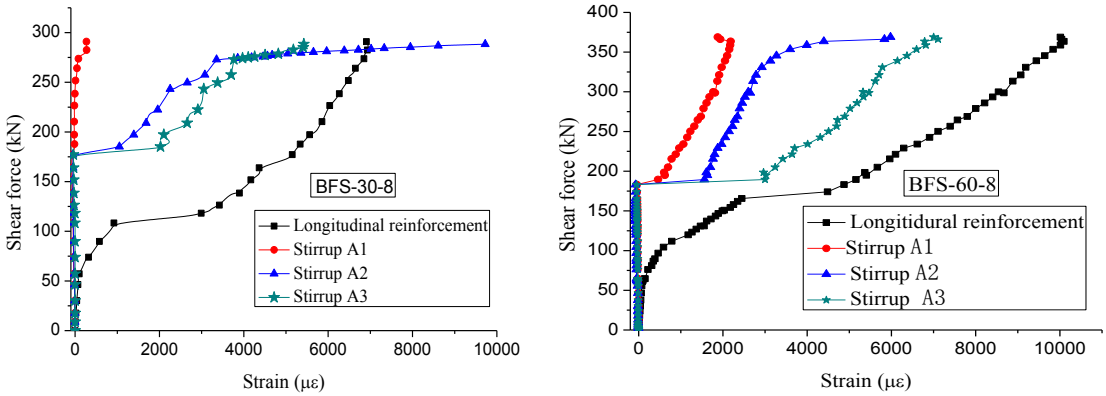

Figure 9 Strains on the longitudinal reinforcement and stirrup for the beams with stirrups

The stirrup strain for the beam with stirrups slowly increases in the initial stage, which usually occurs at approximately 100 $\mu\varepsilon$, and compressive strain will occur. After the initial crack occurs and penetrates the stirrup, the stirrup strain suddenly and rapidly increases. When the shear force approaches the beam's shear capacity, diagonal crack penetration rapidly occurs, and the stirrup strain also experiences abrupt change and exceeds 5000 $\mu\varepsilon$. As shown in Fig. 9, the BFS-30-8 stirrup A1 has not been directly penetrated by a diagonal crack, and its strain is not conspicuous in the diagram. However, for the remaining two stirrups of BFS-30-8—A2 and A3—and the stirrup of BFS-60-8, after being penetrated during the diagonal crack's extension process, the strains on the stirrups follow a linear development pattern. When a beam is about to be damaged, an abrupt change in the stirrup strain occurs, which may reach or exceed the strain on the longitudinal reinforcement. An increase in the stirrup ratio can enhance stirrup strain because a reduction in the stirrup spacing enhances the

stirrup's shear capability. The stirrup ratio increase has an insignificant effect on the improvement in longitudinal reinforcement strain, which is consistent with the relationship between the stirrup ratio and the midspan deflection. The stirrups barely enhance the section bending resistance rigidity.

Influencing Factors for BFRP Bar Shear Capacity

Effect of concrete strength

Fig. 10 (a) shows the comparison between the test groups of the BFRP bar-reinforced stirrup-free beams with identical section size and shear-span ratio for the concrete strengths of C30 and C60. The ultimate shear load of the C60 beam is significantly higher than that of the C30 beam. The differences in strength for the three groups (1, 2 and 3) of beams with varying shear-span ratios (shear-span ratios of 1.74, 2.17 and 2.78, respectively) are 42%, 28% and 27%, respectively. The differences in strength for the three groups (4, 2 and 5) of beams with varying longitudinal reinforcement ratios (0.91%, 1.78% and 2.95%, respectively) are 60%, 28% and 11%, respectively. The effect of the shear-span ratio on the relationship between concrete strength and shear capacity is insignificant. The C60 beam with the modified longitudinal reinforcement ratio demonstrates a significant improvement in shear capacity compared with the C30 beam.

Fig. 10(b) shows the comparison among test groups 6, 7 and 8 for the C30 and C60 beams with stirrups with identical section size, reinforcement and shear-span ratio. The stirrup ratios for test groups 6, 7 and 8 with stirrups are 0.45%, 0.67% and 1.34%, respectively. The ultimate shear loads of the C60 beams of groups 6, 7 and 8 increased by 23%, 25% and 27%, respectively.

The ultimate loads of the first three groups of beams with identical section size and reinforcement and the ultimate loads of the last three groups of beams with identical shear-span ratio are listed in Table 8. The shear capacity of the BFRP bar concrete is approximately proportional to the square root of the concrete strength.

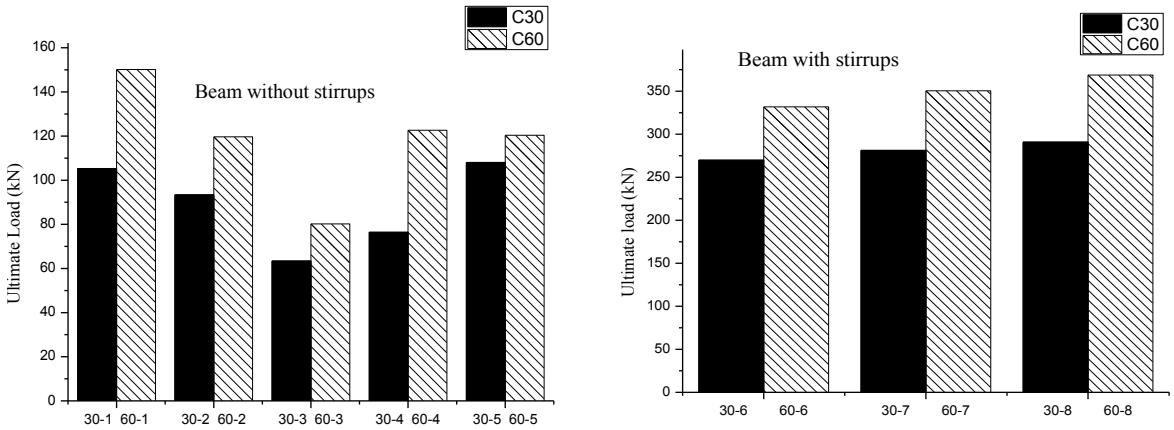

Figure 10 Effect of concrete strength on ultimate load

Effect of longitudinal reinforcement ratio

Fig. 11 shows the three groups of BFRP bar-reinforced beams with identical section size and shear-span ratio and different reinforcement ratios. The shear capacity of the C30 beam increases with reinforcement ratio, whereas the shear capacity of the C60 beam insignificantly increases with reinforcement ratio. The intrinsic shear elastic modulus of BFRP bar is relatively small, and its contribution to shear capacity primarily occurs through dowel action and its effect on the variation in the concrete compression area height. The C30 concrete beam has a lower crack position and a smaller initial crack because BFRP bar can function in tandem with concrete and its dowel action is more significant when the reinforcement ratio increases. Thus, it can enhance the shear capacity more significantly than the C60 beam. The C60 beam has a higher crack position, which is usually above the longitudinal reinforcement located position, and the crack is relatively wider because the BFRP bar's dowel action is relatively weak and the elastic modulus of C60 concrete experiences minimal change when the longitudinal reinforcement ratio increases. Thus, the reinforcement ratio has no significant contribution to the shear capacity of the C60 concrete beam.

The relation between the cracking load and the reinforcement ratio corresponds with the effect of the reinforcement ratio on the ultimate load. A beam's cracking load is determined by the concrete tensile strength

and beam section rigidity. The change in the BFRP bar's reinforcement ratio has a greater impact on the section rigidity of the C30 concrete beam than that of the C60 beam. The C30 concrete beam's cracking load increases with changes of reinforcement ratio, whereas the cracking load of C60 beam experiences minimal change with the variation of reinforcement ratio.

Table 8 Effect of concrete strength on the shear capacity of sea sand concrete beams with BFRP bars

Specimen group	Beams with identical section size and reinforcement			Beams with identical shear-span ratio		
	1	2	3	6	7	8
C30	105.32	93.36	63.38	269.95	281.26	290.92
C60	150.18	119.54	80.20	331.06	350.46	368.84
Strength ratio C60/C30	1.42	1.28	1.27	1.23	1.25	1.27

Effect of shear-span ratio

Fig. 12 shows that the ultimate load and cracking load of the stirrup-free beam decrease with an increase in the shear-span ratio. For instance, when the shear-span ration for the C60 concrete beam increases from 1.74 to 2.17, the ultimate load reduces by 20%. When it increases from 2.17 to 2.78, the ultimate load reduces by 32%. When the shear-span ratio of the C30 concrete beam increases from 1.74 to 2.17 and from 2.17 to 2.78, its cracking loads decrease by 22% and 6%, respectively. The variation in the slope of the curve in the diagram shows that the shear capacity of the BFRP bar-reinforced concrete beam decreases with an increase in the shear-span ratio. The reduction is more distinct for higher shear-span ratios; the cracking load decreases with an increase in shear-span ratio, which is more prominent for smaller values of shear-span.

Effect of stirrup ratio

Fig. 13 shows the effect of the stirrup ratio on the shear capacity of a stirrup reinforced beam. The graph shows that the beam's ultimate load increases with stirrup ratio. In the case of the C30 beam, when the stirrup ratio increases from 0.45% to 0.67%, the ultimate load increases by 4.2%; when the reinforcement ratio increases from 0.67% to 1.34%, the ultimate load increases by 3.4%. For the C60 beam, when stirrup ratio increases from 0.45 to 0.67% and from 0.67% to 1.34%, the ultimate loads increase 5.6% and 5.2%, respectively. With an increase in the stirrup ratio, the C60 beam exhibits a more significant increase in ultimate load than the C30 beam, which indicates that high-strength concrete can leverage the stirrup's shear capability. When the stirrup ratio increases from 0.67% to 1.34%, the increase in beam ultimate load is smaller than the case in which the stirrup ratio increases from 0.45% to 0.67%, which shows that the stirrup's shear capability can be exploited more thoroughly in a beam with a lower stirrup ratio.

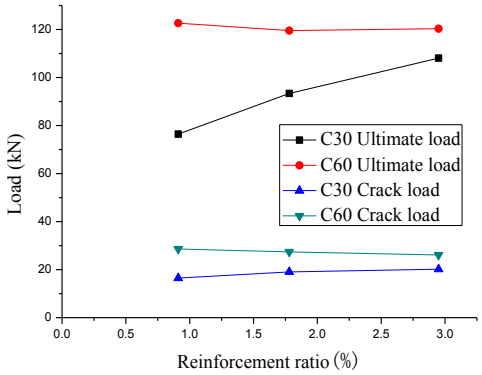

Figure 11 Effect of reinforcement ratio on shear capacity

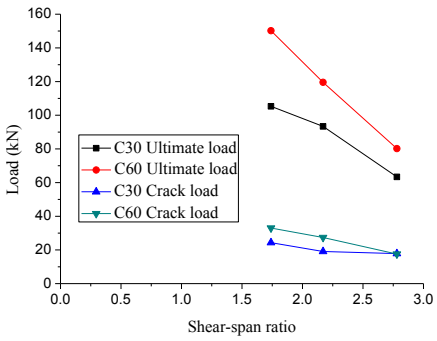

Figure 12 Effect of shear span ratio on shear capacity

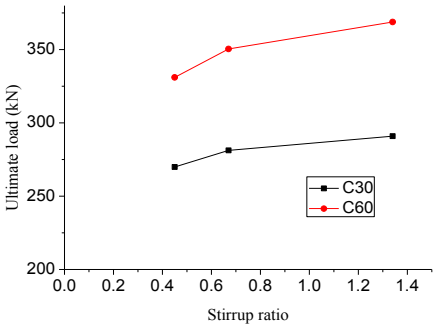

Figure13 Effect of stirrup ratio on shear capacity

With the reduction in stirrup spacing, the number of stirrups that are penetrated by diagonal cracks in the shear-span zone, the resultant forces of shear force and tensile stress carried by the stirrups, and the contribution by the stirrups to the beam's shear capacity all increase. The increase in stirrup ratio has a certain enhancing effect on the ductility of the beam section; the stirrup can effectively restrain a diagonal crack from growing too fast and excessively wide, which will indirectly help concrete in the crack zone to continue to carry shear force. Thus, when a load suddenly becomes oversized, the beam is protected from shear brittleness failure, and its shear ductility can be guaranteed.

CONCLUSIONS

An analysis of a beam's shear capacity is conducted using shear tests of 16 BFRP bar reinforced sea sand concrete beams. The following conclusions are obtained: (1) Beam failures primarily include two failure modes: bending failure and shear-compression failure. The C60 beam attains a higher crack position than the C30 beam does. (2) The load-deflection curve usually assumes the form of a bilinear graph. Deflection decreases with an increase in the shear-span ratio. The longitudinal reinforcement ratio and stirrup ratio have an insignificant effect on deflection. (3) The strain on the longitudinal reinforcement for a beam without stirrups is likely to abruptly change when cracks occur around the midspan of the test beam, whereas the shear-strain curve of the longitudinal reinforcement for the beam with stirrups is relatively smooth. The strain on the longitudinal reinforcement increases with the grade of the concrete strength and the shear-span ratio. The strain of stirrup increases with the stirrup ratio. (4) The beam's shear capacity increases with the stirrup ratio and decreases with the increase of shear-span ratio.

ABSTRACT

The resource utilization and direct application of sea sand in construction engineering is a hot topic of interest. In order to avoid the problem of steel corrosion in the sea sand concrete, basalt fiber reinforced plastic (BFRP) mesh instead of steel mesh to reinforce sea sand mortar thin plate was considered. This novel thin plate resulted in a structural performance clearly superior to that of a steel mesh thin plate. In this paper, the durability performance was investigated for both natural indoor environments and wet-dry environments. The experimental results showed that the tensile strength of the BFRP mesh thin plate varied slightly, the bending strength decreased significantly, and the ductility improved after 1 year indoor environmental exposure, which is marginally better than that of the steel mesh thin plate. Subjected to wet-dry environments in a salt solution for 1 year, however, the tensile strength, flexural strength and ductility of the BFRP mesh thin plate were all significantly decreased. The performance of the steel mesh thin plate in this condition was clearly better.

BFRP mesh, steel mesh, sea sand mortar thin plate, indoor environments, wet-dry environments.

INTRODUCTION

Because of the reduction in available river sand and development of ocean engineering, the exploration and utilization of sea sand resources has been gaining increased attention. Currently, there are two main approaches to maximizing the utilization of sea sand: after washing and using directly. Because of the high cost and low efficiency of the latter approach, direct usage will be the predominant approach in the future. However, chloride in sea sand causes steel corrosion, which is a direct challenge to the use of sea sand in concrete. To avoid this problem, many studies have considered using fiber reinforced plastic (FRP) materials to replace steel (Hempel 1998; Reinhardt *et al*. 2003; Butler *et al*. 2010). Much research has been conducted on carbon fiber reinforced plastic (CFRP) as an alternative material (Täljsten 2003; Meftah *et al*. 2007; Bigaud and Ali 2014), but it costs high.

Basalt fiber reinforced plastic (BFRP) is a new type of composite material with high performance and relatively low cost. It has good durability and chemical stability as well as excellent electrical insulation, fire resistance, and thermal resistance (Zych and Krasodomski 2012; Rybin *et al*. 2013; Jiang *et al*. 2014). In previous efforts, the present authors used a BFRP mesh to replace the steel mesh in a sea sand mortar thin plate. The initial flexural toughness and flexural bearing capacity were better than those of the steel mesh thin plate. The initial tensile strength was slightly lower, but the ductility was higher (Xie *et al*.2014). This paper presents a further study on the durability of the BFRP mesh. Natural indoor environments and wet-dry environments were considered.

MATERIALS AND METHODS

Materials

(1) The mix proportions of sea sand mortar were as follows: cement:sea sand:super-plasticizer:water = 1:2.23:0.012:0.45 (mass ratio). Sea sand was filtered to use particles in the range of 0.063–0.355 mm. Portland cement was P·O 42.5. The super-plasticizer had a water reduction rate of ≥38%. Sea sand mortar has the advantages of high density, low water absorption, and high compressive and flexural strengths.

(2) For comparison, two types of mesh were used: BFRP mesh and steel mesh, which grid sizes were 10 mm × 10 mm both. Chinese standard GB/T3362-2005 was used to test the fiber and steel properties.

The linear density of fiber bundle of BFRP mesh was 800g/km and the density was 2.65g/cm^3， so the section area of the fiber bundle was 0.3 mm^2; The ultimate tensile capacity of fiber was 291.5 N, and the elongation at

break was 1.8%. The steel wire diameter was 0.7 mm, and the wire cross-sectional area was 0.38 mm^2. Table 1 lists the mechanical properties of the meshes.

Table 1 Mechanical property of bundles

Materials	Yield strength (MPa)	Elastic modulus (GPa)
BFRP bundle	970	100
Steel wire	300	200

Methods

(1) Sample preparation: A wooden mold was made from a thin plate with dimensions of 800 mm × 150 mm × 8 mm. Two layers of BFRP or steel mesh were placed in the mold and fixed. Then, the mold was filled with mixing mortar and vibrated. Finally, the surface was smoothed. The specimens were cured at 20 °C and RH > 95%. After 7 days, the mold was removed. Curing continued up to 28 days. Some of the specimens were selected for testing directly: B(I) and S(I), where B represents the BFRP mesh and S represents the steel mesh. Some of the specimens were cured under natural indoor environments for 1 year(condition (II)): B(II) and S(II). The rest were cured in a salt solution with wet-dry environments for 1 year (condition (III)): B(III) and S(III). For the wet-dry environments in a salt solution, the salt solution contained 3.5% NaCl, which is similar to the concentration of salt in seawater. The temperature was 40 °C, and the circulation time was 24 h (14 h dry and 10 h in water) over 360 cycles.

(2) Test method: The sample preparation and testing of tensile were reference to literature of Lee (Lee *et al*. 2014). Thin plant specimens were cut into dimensions of 150 mm × 50 mm, and each specimen contained four complete grids in the transverse direction. Before testing, the two ends of the specimens were treated with epoxy resin and then clamped. Figure 1 shows the tensile test of thin plate.

In addition, single fiber bundles and steel wires were tensile tested according to GB/T3362-2005. Some of them were put into saturated NaCl solution for 30d, 60d and 90d and the the mass loss rate and tensile capacity were detective. The specimens were washed with distilled water and put in vacuum dryer after removing from the salt solution. Figure 2 shows the samples and tensile test of single bundle.

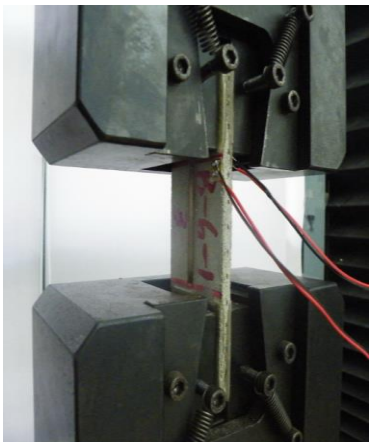

Figure 1 Tensile test of thin plate

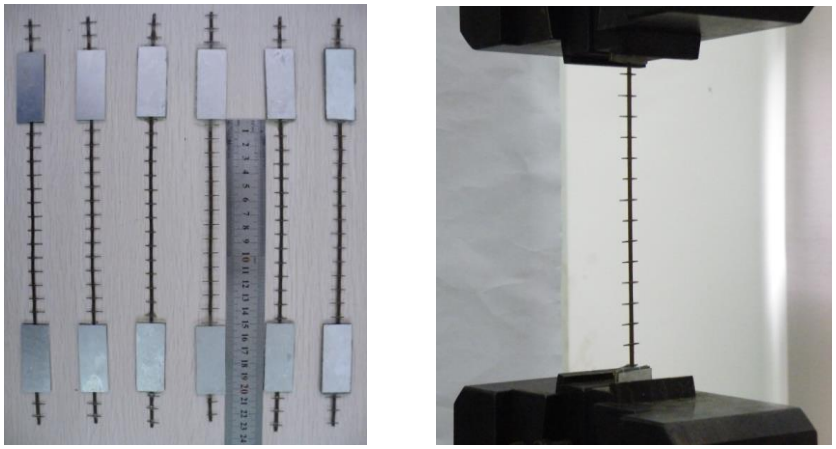

Figure 2 Samples and tensile test of BFRP multifilament

For the bending test, specimens were cut into dimensions of 700 mm × 150 mm, and the GB/T19631-2005 standard was referred to. A DDL100 electronic universal testing machine was used for the tensile and bending tests. To obtain the tensile load–deformation curves, the treated specimens were clipped in a folder on both ends of the instrument wedge chuck and loaded by displacement control at a loading rate of 0.2 mm/min. To approximate the clamped condition, the ends of each specimen were fixed to a G-type clamping device to obtain the maximum deformation. Thus, a three-point bending test with the ends clamped was simulated. The effective span was 500 mm. On the basis of the results, the bending load–span deflection curve was derived. Figure 3 shows the bending test of the thin plate.

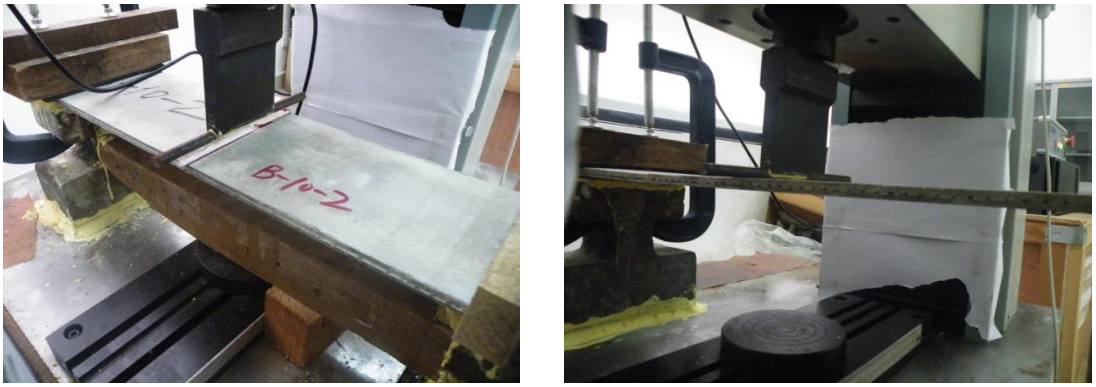

Figure 3 Bending test of thin plate

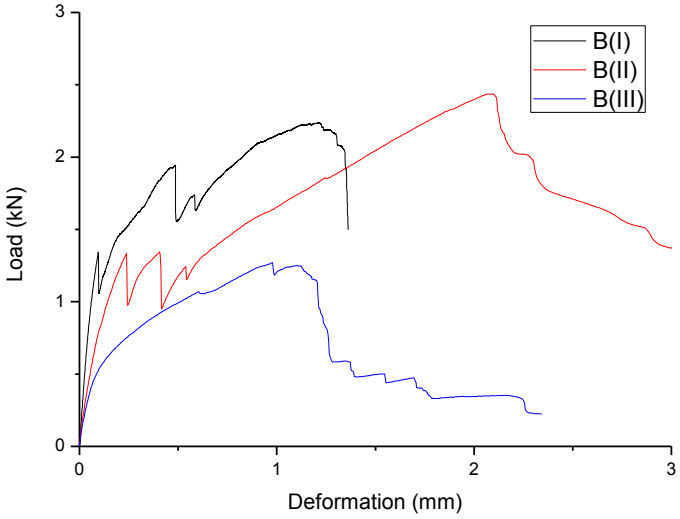
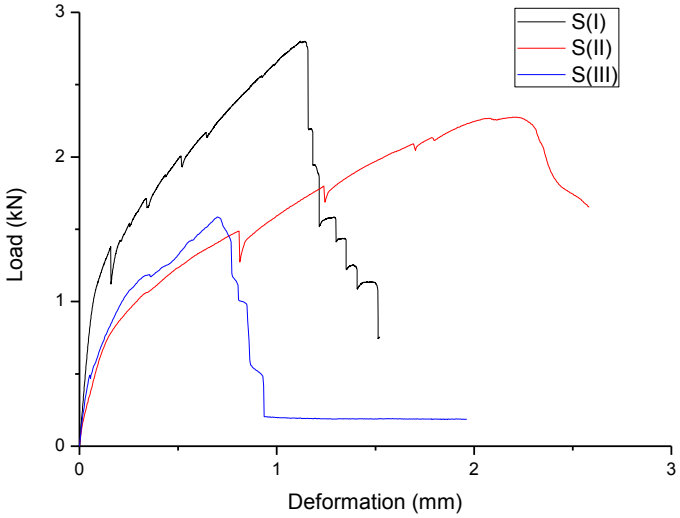
RESULTS

Tensile Test

Figure 4 shows the tensile load–deformation curves.



(a) BFRP mesh thin plate



(b) Steel mesh thin plate

Figure 4 Tensile load–deformation curves

Curves in Fig.4 were coincided with the typical tensile load–deformation curve. In terms of the testing process, the curves can be divided into two stages. The first is the linear ascent stage: where the thin plate does not show cracking and the main load is on the mortar. The second stage is the crack development stage where the mesh starts working to bear the load. Because of the coupling effect of the mesh and restraint of the mortar, the development and expansion of micro-cracks are subject to certain restrictions. As the load continues to increase, more micro-cracks develop in the thin plate. When the mortar reaches the limit tensile strain, macroscopic cracks appear, and a significant turning point emerges on the load–deformation curve. Then, the mortar fails, and the mesh bears the entire load. As the load increases, the mesh is pulled apart and the specimen sustains damage.

As shown in Figures 4(a) and (b), the ductility of the B and S specimens followed the order of (II) > (I) > (III) for tensile failure. That is, in condition (II), the ductility of the thin plates improved. In condition (III), the ductility of the thin plates declined. For the same conditions, B showed a better ductility than S.

Table 2 presents the characteristic parameters of the thin plates on the basis of the experimental results.

Table 2 Characteristic parameters of tensile test

Specimen	First cracking load F_r (kN)	Failure load F_u (kN)

B (I)	1.34	2.24
B (II)	1.34	2.43
B (III)	0.47	1.26
S (I)	1.38	2.80
S(II)	1.47	2.27
S (III)	0.50	1.58

The first cracking load of B(I) and B(II) were the same and the failure load were slightly different. The BFRP mesh of B(II) showed tensile failure: fibers were exposed outside the fracture section, and the fiber bundles became loose. The first cracking load and failure load of B(III) showed significant declines of 53% and 43.8%, respectively. In condition (III), only a few short fibers were exposed outside the fracture section, and a few tiny pores appeared at the interface between the mortar and mesh. Compared with S(I), S(II) showed a slightly increased of cracking load, but the failure load decreased by 23.3%. There was no significant corrosion phenomenon on the fracture surface of the steel mesh. The first cracking load and failure load of S(III) showed larger declines of 63.8% and 58%, respectively. The steel mesh showed striking corrosion, and significant separation occurred at the interface between the steel wire and mortar in condition (III).
To investigate the effect of chlorine, the single bundles of BFRP and steel mesh were placed in NaCl solution. The mass loss rate and tensile capacity of single bundles were measured, and the results are given in Table 3.

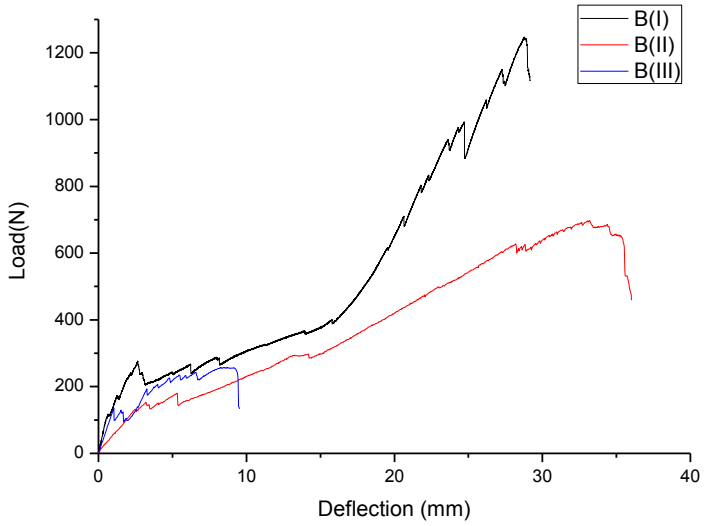
Table 3 Mass loss rate and tensile capacity of bundles after placed in NaCl solution

Time (Day)	Mass loss rate (%)		Tensile capacity (kN)	
	BFRP bundle	Steel wire	BFRP bundle	Steel wire
0	0	0	0.29	/
30	2	0.08	0.29	0.26
60	3	9	0.24	0.15
90	11	40	0.1	0.07

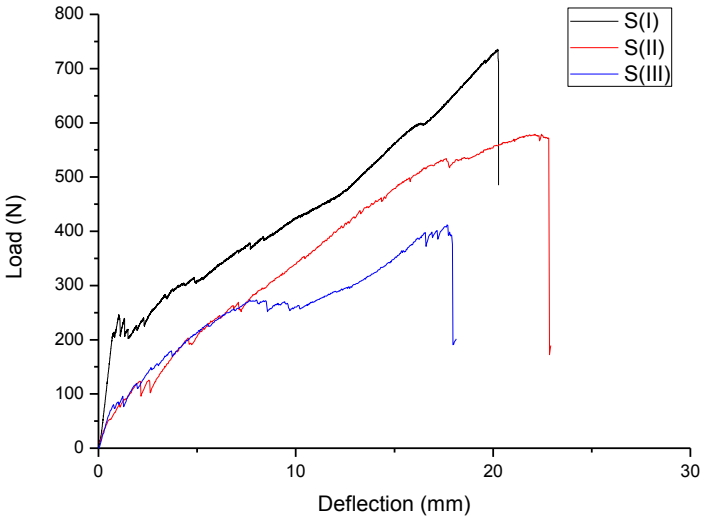
As the duration of the bundles in the NaCl solution increased, the mass loss rate of both the steel mesh and BFRP mesh increased, whereas the tensile strength decreased. The 30 day mass loss rate of the BFRP mesh was higher but those of 60 days and 90 days were much lower than those of the steel mesh. This result suggests that although the BFRP mesh was affected by the NaCl solution, the dissolution of the substance was much less than that of the steel mesh. The rate of decrease in the tensile capacity of the steel mesh was higher than that of the BFRP mesh, especially before 60 days. However, the rate of decrease in the tensile capacity of the BFRP mesh at 90 days was as high as 65.5%. This result suggests that the deterioration of the tensile strength of the steel mesh was worse than that of the BFRP mesh before 60 days, but only slightly worse subsequently. The corrosion mechanism of BFRP will be studied in a following work.

Bending Test

Figure 5 shows the bending load–deflection curves.



(a) BFRP mesh thin plate



(b) Steel mesh thin plate
Figure 5 Bending load–deflection curves

As shown in Figure 5(a), the load–deflection curves of B(I) and B(II) fit the typical bending load–span deflection curve. In terms of the testing process, the curves can be divided into three stages. The first stage is from the initial load to the occurrence of the first crack. The second stage is called the crack development stage where a number of cracks develop occur on the bottom and ends of the thin plate. During these two stages, mortar and BFRP mesh bear the load together. During the third stage, the number of cracks becomes saturated; then, the main crack begins to expand, and the mortar gradually stops bearing the load. The load is borne by the BFRP mesh until the plate fails. Because the BFRP bundles do not approach the ultimate load simultaneously, there are a series of mutation points on the curves in the third stage that correspond to the intermittent fracture of the fibers. Although the load–deflection curve of B(III) is similar to those of B(I) and B(II), its mortar stopped bearing the load quickly after the cracks appeared, and the BFRP fibers rapidly fractured at a small load and slight deflection before the plate failed.

As shown in Figures 5(a) and (b), the load–displacement curves of the steel mesh thin plates are different from those of the BFRP thin plate because steel is elastoplastic; its stress–strain constitutive relation is different from that of fiber, which has a linear constitutive relation. The steel mesh thin plates were damaged in a relatively short period, and the damage deflection was less than that of the BFRP thin plates. During the process of steel mesh thin plate failure, only one crack developed in the mid-span where the plate fractured, and the steel wire

made a popping sound at the same time. The steel mesh thin plates tended to fail in brittle fracture mode. On the basis of the test results, Table 4 lists the flexural failure characteristic parameters.

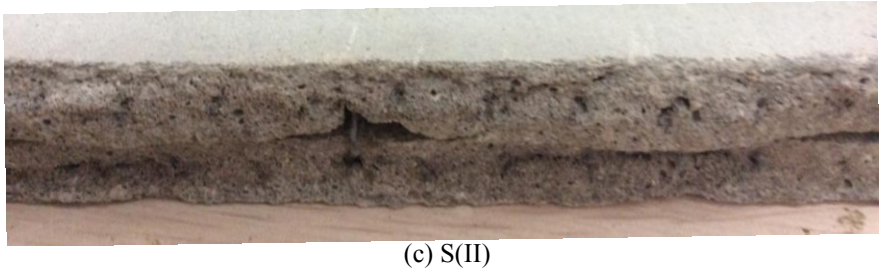
Table 4 Characteristic parameters of bending test

Specimen	First cracking load P_r (N)	Failure load P_u (N)	Mid-span deflection D (mm)
B (I)	272	1249	28.7
B (II)	180	697	33.1
B (III)	137	257	9.0
S (I)	212	734	20.3
S(II)	123	576	22.8
S (III)	93	409	17.7

As the conditions deteriorated, both the cracking and failure loads of the thin plates decreased. Compared with B(I), the cracking and failure loads of B(II) declined by 33.8% and 44%, whereas those of B(III) decreased by 49.6% and 79%, respectively. Compared with S(I), the cracking and failure loads of S(II) decreased by 42% and 21.5%, whereas those of S(III) decreased by 56.1% and 44.2%, respectively. The conditions clearly had a more significant impact on the failure load of the BFRP thin plates than on the failure load of the steel mesh thin plates. The mid-span deflection was also affected by the conditions. The mid-span deflections of both the BFRP and steel mesh thin plates increased in condition (II), but all of them decreased in condition (III). In particular, the mid-span deflection of B(III) was only 9 mm. The bending failure section of the B specimens was similar to the tensile test results; the basalt fibers of B(I) and B(II) were pulled apart with fibers exposed in the fracture section. The fiber bundle of B(II) was looser than that of B(I), but the pulled fibers were longer. For B(III), the fibers were only pulled to a short length. Small pores were observed at the interface between the mortar and fiber. For the steel mesh thin plates, there was no significant corrosion in S(I) and S(II), but S(III) showed significant corrosion. Figure 6 shows the fracture surface of the thin plates during the bending test.

(a) B(II)

(b) B(III)



(c) S(II)

(d) S(III)

Figure 6 Fracture surface of thin plates in bending test

DISCUSSION

The initial tensile strength properties of B(I) were similar to those of S(I), especially the bending strength and ductility were superior. In condition (II), the performance of mortar was relatively stable. Because the load was mainly borne by the mortar in the first stage of the tensile test, the first cracking loads of B(II) and B(I) were almost the same. However, the BFRP was corroded by the high alkalinity of cement, which deteriorated the interface and affected the integrity of the fiber bundles. Because of this, relative slip occurred between the fibers during the tensile and bending tests, which improved the ductility and the failure load of B(II). But it inevitably led to a decrease in the shear strength of the mesh. Thus, the first cracking load and failure load of B(II) of bending were greatly reduced. This analysis was consistent with the phenomena of the bending test. In condition (I), the bare fiber bundles in the fracture section were more holistic, and the length varied which indicated tensile damage. Otherwise, in condition (II), the bare fiber bundles in the fracture section were loose and the fiber bundles fractured abreast, which indicated shear damage.

In condition (III), the performances of the BFRP mesh and mortar changed greatly. Not only did the interface of the fiber bundle deteriorate but the fibers also suffered severe corrosion. Furthermore, the interface between the fiber bundle and mortar separated too. Therefore, the tensile and bending strength of B(III) significantly decreased and the ductility was greatly reduced. In particular, the mid-span deflection was only 9 mm, which is approximate to the brittle fracture of cementitious materials. In both the tensile and bending test, the bare fibers in the fracture section were few and short. This indicates that the fibers were seriously corroded and broke easily when subjected to a minute load. Clearly, the BFRP mesh has poor durability in wet-dry environments.

The tensile and bending properties of the steel mesh thin plate varied similarly to those of the BFRP mesh thin plate in conditions (II) and (III), but the principles were not the same. In condition (II), the direct bonding force between the mortar and steel mesh was reduced because of mortar dehydration and shrinkage. Afterwards, peeling and slip occurred between the mortar and steel mesh in the tensile and bending tests, which resulted in a slight increase in ductility. However, the bonding interface deterioration reduced the strength, so the tensile and flexural strengths declined. In condition (III), the steel mesh was severely corroded because of the chloride ions in the salt solution, which greatly reduced the effective cross-sectional area of the steel wire. Meanwhile, the corroded steel wire exhibited severe peeling off from the mortar. All of these factors significantly degraded the tensile and bending properties of the thin plate, but the rate of decrease was less than that of the BFRP mesh thin plate.

CONCLUSIONS

The durability of BFRP mesh-reinforced sea sand mortar thin plates in natural indoor environments and wet-dry environments was studied and compared with that of steel mesh thin plates. When exposed to natural indoor environments for 1 year, the tensile strength of the BFRP mesh thin plate varied slightly and the bending strength decreased significantly, whereas the ductility improved, which was marginally better than that of the steel mesh thin plate. When exposed to wet-dry environments for 1 year, the tensile strength, flexural strength, and ductility of the BFRP mesh thin plate all significantly decreased, and the performance of the steel mesh thin plate was clearly better.

In future research, the rate and mechanism of corrosion of BFRP will be considered and a modified BFRP will be tested.

ABSTRACT

The seismic strengthening of the concrete columns improperly designed or constructed is in an urgent need. There has been an enormous interest in the research and application of conventional fiber reinforced polymers (FRPs) in RC column seismic retrofitting. However, due to low fracturing strain capacity of conventional FRPs, the fiber materials tend to fail sooner due to fiber breakage. New fiber materials such as polyacetal fiber (PAF), polyethylene naphthalate (PEN) and polyethylene terephthalate (PET) have properties of large fracturing strain and low stiffness in comparison to aramid, carbon, and glass fibers. In this paper, an experimental study is presented on the influence of PET warping on shear capacity, ductility and energy absorptivity of RC columns with stirrup corrosion before strengthening. The experimental program involved an electrochemical process to accelerate the migration of chlorides from an external electrolyte into the tested columns, a wetting–drying cycle process with a controlled current to speed up the corrosion of the stirrup in the tested columns, the strengthening of corroded columns with PET warping, and a Pseudo static test to determine the shear capacity of the tested beams. The shear performance of PET wrapped RC columns with different corrosion levels in stirrups, including the yield strength, the peak strength, the ductility ratio and the energy dissipation ability was examined and the related mechanism was discussed.

INTRODUCTION

Even though many latest design specifications in the world specifies confinement regions at the ends of columns and beams to ensure their seismic resistance, field observations indicated that this requirement was not followed in many buildings, especially in old structures in some developing countries. Many structures were reported to fail due to inadequate confinement in concrete columns as large hoop spacing and lack of seismic hoops, as reported after 2008 Sichuan (Wang 2008), 2010 Maule earthquake in Chile (Yen et al. 2011), 2011 Vann earthquake in Turkey (Baran et al. 2012), and 2014 Yunnan earthquake in China (Cheng et al. 2015), etc. Following the spalling of cover concrete at the plastic hinge locations in concrete columns under the effect of earthquake-induced reversed moments, the hooks at the ends of hoops open up because of insufficient anchorage. Once the ends of the hoops open up, the confinement effect on the core concrete diminishes, which in turn causes crushing of concrete in the entire cross section. Large hoop spacing and lack of stirrup anchorage at the plastic hinge locations of columns also lead to buckling of column longitudinal bars. The seismic strengthening of the concrete columns improperly designed or constructed is in an urgent need.

Extensive investigations on the seismic retrofitting of reinforced concrete (RC) columns have been undertaken in recent years. There has been an enormous interest in the research and application of fiber reinforced polymers (FRPs) in RC column seismic retrofitting since the 1980s. The basic concepts and relatively recent survey in the use of FRPs for strengthening of concrete structures are covered in a review article by Triantafillou (2001). Many researchers have proven the effectiveness of applications of conventional FRP materials such as aramid, carbon, and glass in shear and ductility enhancement (Bakis et al. 2002; Benzaid et al. 2008; Teng ed al. 2003; Wu et al. 2006). However, due to low fracturing strain capacity of conventional FRPs (around 1.5% for carbon FRP (CFRP), 2% for glass FRP (GFRP) and 3% for aramid FRP (AFRP)), the fiber materials tend to fail sooner due to fiber breakage which causes a loss of confinement and hence the load-carrying capacity as well as the ductility potential. New fiber materials such as polyacetal fiber (PAF), polyethylene naphthalate (PEN) and

polyethylene terephthalate (PET) have properties of large fracturing strain and low stiffness in comparison to aramid, carbon, and glass fibers (Jirawattanasomkul et al. 2013). Previous studies (Anggawidjaja et al. 2006; Dai et al. 2011; Dai et al. 2012) proved that concrete or RC members wrapped by PET and PEN fiber sheets with large fracturing strain could efficiently enhance the ductility of concrete or RC members regardless of their low stiffness. The large fracturing strain allowed the fiber to contribute sufficient shear force at the ultimate state while avoiding fiber rupture.

Corrosion of the reinforcement is one of the major causes of deterioration in reinforced concrete structures. Corrosion damage is usually observed as rust stains and minute cracking over the concrete surface running parallel to the underlying steel bars, as a result of volume increase associated with the formation of corrosion products. Past experiences have shown that reinforcement corrosion reduces the column capacity due to steel area losses. Despite a large body of literature on the influence of reinforcing steel corrosion on the flexural capacity of RC columns with or without FRP strengthening (Li et al. 2014; Pantazopoulou et al. 2001; Ma et al. 2012) , there are few works that have dealt with the reduction in shear capacity of RC columns due to the corrosion of stirrups (Xia et al. 2011). Actually, stirrups would be first attacked by chlorides in a chloride environment since they are nearer to the concrete surface than the longitudinal steel bars.

In this paper, an experimental study is presented on the influence of PET warping on shear strength, ductility and energy absorptivity of RC columns with stirrup corrosion before strengthening. The experimental program involved an electrochemical process to accelerate the migration of chlorides from an external electrolyte into the tested columns, a wetting – drying cycle process with a controlled current to speed up the corrosion of the stirrup in the tested columns, the strengthening of corroded columns with PET warping, and a Pseudo static test to determine the shear capacity of the tested beams. The shear performance of PET wrapped RC columns with different corrosion levels in stirrups was examined.

EXPERIMENTAL PROGRAM

Details of test setup

A total of 11 RC rectangular columns with footings were constructed, which consisted of four un-strengthened control specimens with different level of stirrup corrosion (designed to be 0, 10%, 15% and 25%) and seven strengthened specimens with different layers of PET fiber warping (1or 2 layers), as indicated in Table 1. The acronym designation adopted for the specimens was as follows: “C” represents corrosion pre-damage, and the number following “C” stands for degree of corrosion of stirrups before strengthening; “L” means PET warping and the last number corresponds to the number of warping layers. For example, specimen “C-10-L-2” is the RC column with expected degree of corrosion of stirrups of 10%, which was warped by 2 layers of PET fiber.

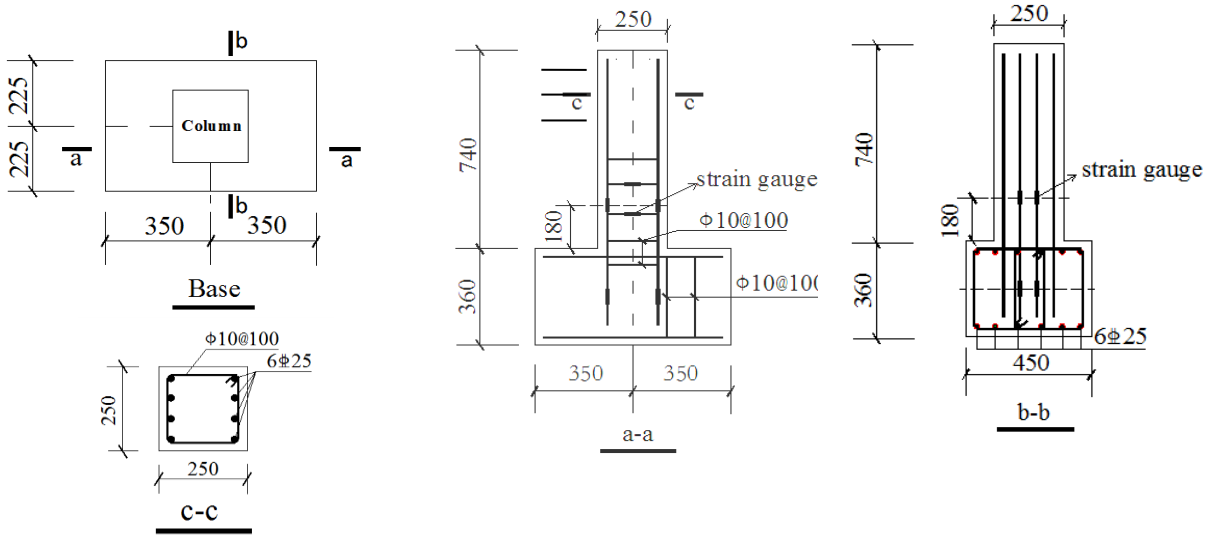

Figure 1 Geometry and reinforcement information of specimens (unit: mm)

The column had a cross section of 250 x 250 mm and a total height of 740 mm. The corners of columns to be strengthened were rounded with a rounding radius of 20mm. The footings had a size of 700 x 450 x 360 mm (length x width x height). Each specimen used eight 25mm deformed bars for longitudinal reinforcement and 10mm plain bars for stirrups spaced at 100mm. The hooks of stirrups had 135-degree bend plus 5db

(db=diameter of stirrup) extension, which is weaker than the minimum requirement of existing seismic design specifications (10 db at 135-degree in JSCE design code (2012), 6 db at 135-degree in ACI 318-11 code (2011), and 5 db at 150-degree in CEB-FIP model code 2010 (2010)), to represent the improper design or construction of stirrups. With the above extension length, the hooks were expected to open up under cyclic loading. The longitudinal reinforcements in the columns were extended into the footing with a sufficient anchorage length. Details of the reinforcement arrangement are shown in Figure 1.

Table 1 Parameters of test specimens

Material properties

Same batch of ready mixed concrete were used to cast the specimens. The 28 days cubic (150 x 150 x 150 mm) compressive strength of concrete was 26.6 MPa. Table 2 and 3 show the properties of the reinforcement and PET fiber sheet used in this experiment. The epoxy resin used for PET warping had a tensile strength of 41.0 MPa, elastic modulus of 2.6 GPa and an elongation at break of 1.6%, as provided by the manufacturer.

Table 2 Mechanical properties of steel bars

Bars	Diameter (mm)	Yield stress （MPa）	Ultimate stress （MPa）	Extension ratio （%）	Tensile modulus （MPa）
Longitudinal bar	25	476	580	38.2	2.12×10^5
stirrup	10	342	499	36.2	2.03×10^5

Name	Tensile strength f_{tu} (MPa)	Tensile modulus E_f (GPa)	Ultimate strain (%)	Area density ρ (g / m^2)	Thickness (mm)
PET	719	9.35	≥7%	1161	0.841

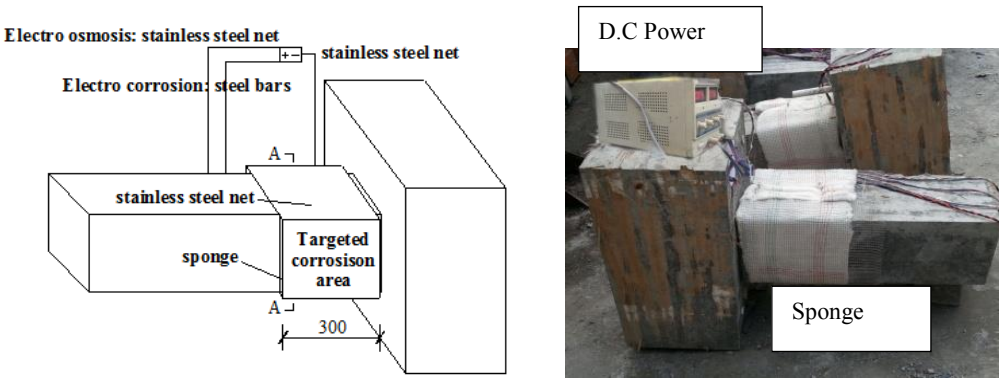

Figure 2 Accelerated corrosion techniques (unit:mm)

Accelerated corrosion procedure

In order to reduce the experimental time to match the corrosion process and behavior happened in real RC members. An accelerated corrosion procedure suggested by Xia et al. (2011) was applied. As indicated in Figure

2, the accelerate corrosion procedure can be divided into two phases, namely the electro-migration phase and the wetting–drying cycle phase. The specimens were corroded within 300 mm portion of the plastic hinge zone. In the electro-migration phase, chloride ions were electro-migrated into the concrete cover using an electrochemical method. A stainless steel sheet was placed along the longitudinal centroid line of the column. A constant voltage of 30 V was then applied between the outside stainless steel nets and the embedded stainless steel sheets using a DC power source. A wetting–drying cycle process was used immediately after the electro-migration process. Each cycle of the wetting–drying process involved 3 days of drying followed by 4 days of wetting as suggested by Xia et al. (2011) to reach a similar corrosion of steel reinforcement as in a real environment. A current density of 0.20 mA/cm^2 was applied through the stirrup (acting as the anode) and the stainless steel nets (acting as the cathode). Insulation tapes were bonded to longitudinal reinforcement at its intersection with stirrup. The estimated time for corrosion was calculated based on Faraday's law. The wetting-drying cycles lasted for 7, 10 and 16 weeks for the expected degree of corrosion of 10%, 15% and 25%, respectively.

Instrumentation and testing procedure

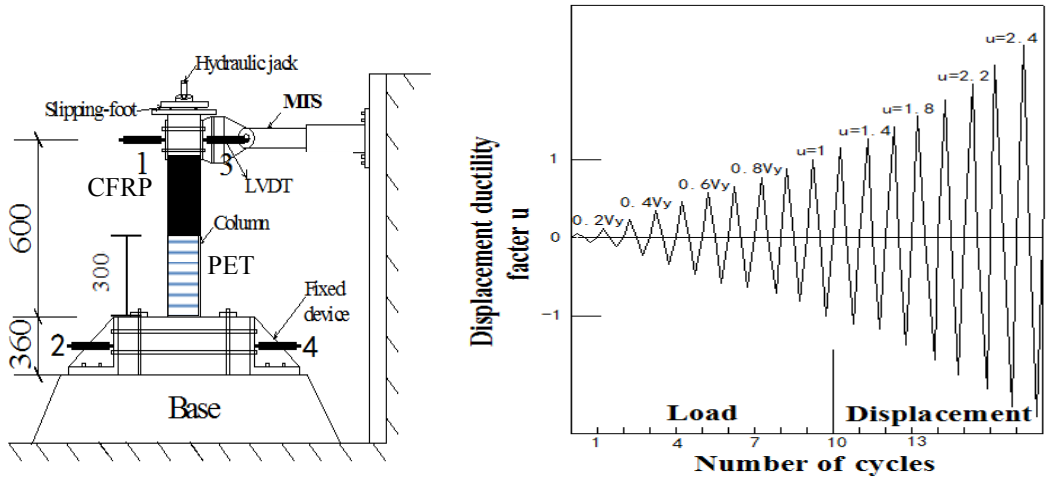

Figure 3 Loading device and loading steps

As shown in Figure 3, the specimens were subjected to a combination of cyclic horizontal load and constant axial load. The compressive vertical load represents the service and dead load of superstructures and equals to 180 kN, which is about 30 % of the expected axial loading capacity of un-corroded control column. A MTS actuator was used to apply the horizontal cyclic load. The cyclic tests were first conducted under load control for load cycles until the yielding of the longitudinal reinforcement, which was approximately evaluated based on the strain gages readings. The horizontal load was adopted to control the loading procedure. In the second phase, the specimens were loaded cyclically under displacement control until the failure of the specimens. The horizontal displacement of the actuator was adopted to control the loading procedure. Load and displacement can be controlled and recorded during the tests by a computer connected to the hydraulic actuator. Load increments and displacement increments between adjacent load cycles are illustrated in Figure 3. Each controlling step lasts for one cycle.

Two transducers (LVDT) were mounted on the rigid frames to measure lateral displacement of columns. Two LVDTs were mounted at the footing to measure horizontal slip and rotation of the footing, as indicated in Figure 3. Strain gages were used to measure the strain development in the flexural reinforcements, shear reinforcements and PET fibers. The location of strain gages is indicated in Figure 1.

RESULTS AND DISCUSSIONS

Gravimetric Mass Loss Measurements

After loading the test specimens to failure, the stirrups were extracted and cleaned for the purpose of calculating mass loss following the ASTM G1-03 Standard (2011). Four coupons with a length of 100 mm within the targeted 300 mm long corrosion area per stirrup per column were used. The weight of the stirrup without corrosion was determined by weighing the 100 mm long stirrup in the uncorroded zone of the same column such that the weight of the extracted coupons after corrosion could be compared to the original weight and the mass loss due to corrosion could be estimated. The average measured mass loss (degree of corrosion) in the stirrup of

the corroded columns is listed in Table 4. It can be concluded that the expected mass losses were achieved in the laboratory.

Failure mode

(a) Unstrengthened column (b) Strengthened column (c) Open-up of stirrup hook

Figure 4 Typical failure modes of test specimens

All un-strengthened specimens showed brittle shear failure with extensive X shape diagonal concrete shear cracks together with the spalling or crushing of cover concrete (Figure 4(a)). After removing the cover concrete, the hooks of stirrups were observed open-up due to insufficient length of hook extension. For all PET strengthened specimens, the PET fiber sheet showed no breakage till the end of the test (Figure 4(b)), while hook open-up of stirrups were also observed after removing the PET sheet and cover concrete (Figure 4(c)). For all the specimens, no bucking of longitudinal reinforcements was observed.

(c) C-10-L-0 (d) C-10-L-1

Figure 5 Sample hysteretic responses of the tested specimens

Hysteretic response and Energy dissipation ratio

Due to space limitation, the sample hysteretic responses of several tested specimens are shown in Figure 5. The skeleton curve of all the specimens are presented in Figure 6.The lateral load at the first yield of longitudinal reinforcement (P_y) and the maximum load (P_{max}) at the positive and negative bending cycles are summarized in

Table 4. Energy dissipation ratio has been used to evaluate the energy dissipation ability of structures under cyclic loading. The energy dissipation ratio at each load cycle of each specimen can be calculated and the accumulated energy dissipation (E_{sum}) is calculated using Eq.1.

$$E_{sum} = \sum_{i=1}^{n} (E_i) \tag{1}$$

where E_i is the energy dissipation of i th load cycle, E_{sum} is the accumulated energy dissipation, n is the number of loading cycles. The accumulated energy dissipations of test specimens are presented in Table 4.

Effect of stirrup corrosion

As shown in Figure 6(e-f) and Table 4, for both unstrengthened and strengthened columns, the yield load, the peak load and accumulated energy dissipation decreased with the increase of degree of stirrup corrosion. The corrosion of the stirrups caused deterioration of the bond between the concrete and the stirrups, and cover concrete cracking, which reduced the effective concrete area for load bearing and energy assumption.

(e) L-0 series (f) L-1 series (g) L-2 series

Figure 6 Skelton curves of test specimens

Effect of PET wrapping

The unstrengthened specimens showed brittle behavior after the peak load, while the specimens with PET wrapping showed sudden drop of load carrying capacity after the peak load to a certain level and then exhibited a ductile response. The peak load was reached after the open-up of hooks of stirrups, which caused the loss of stirrup contributions and spalling of cover concrete. As shown in Figure 6(a-d) and Table 4, the yield load, the peak load and the accumulated energy dissipation after PET wrapping comparing to the unstrengthened columns with similar degree of stirrup corrosion was enhanced. The enhancement was more obvious with the increase of number of PET layers. The effect of stirrup corrosion on the peak load was reduced after the PET wrapping. Although the specimens were designed with insufficient shear capacity, the PET confinement could provide additional shear capacity and confinement to the concrete, which delayed the open-up of stirrups and could still carry the shear force after that.

Table 4 Summary of test results

Specimens	Average corrosion degree	Negative moment		Positive moment		Total energy dissipations
	η_{ave}	Yield load P_y+	Peak load P_{max}+	Yield load P_y-	Peak load P_{max}-	E_{sum}

CONCLUSIONS

This paper presented the experimental study on the influence of PET wrapping on shear strength, ductility and energy absorptivity of RC columns with stirrup corrosion before strengthening. The following conclusions can be drawn:

For unstrengthened columns, the yield load, peak load, ductility ratio and energy dissipation ratio decreased with the increase of degree of stirrup corrosion.

The yielding load, peak load and accumulated energy dissipation after PET wrapping comparing to the unstrengthened columns with similar degree of stirrup corrosion was enhanced. The enhancement was more with the increase of number of PET layers.

For uncorroded columns, the ductility ratio was reduced after the PET wrapping, mainly attributing to the sudden drop of load carrying capacity after the open-up of stirrup hooks. For corroded columns, the ductility ratio was slightly increased after the PET wrapping, which indicated that the PET wrapping can compensate the loss of column ductility due to stirrup corrosion.

ABSTRACT

This paper focuses on behavior of full scale prestressed concrete (PC) box girder with difference degrees of damage derived from service stage. According to typical structural damage, strengthening measures are proposed, including gluing steel plate, gluing prestressed CFRP plate and so on. In order to testify the effectiveness of reinforced method, bending behavior test are conducted for full scale PC box girder both before and after strengthening. After the test, the bending behaviors of test girder are comparatively analyzed, and the failure mechanism of test girder reinforced by prestressed CFRP plate is studied. What's more, the strengthening method of gluing prestressed CFRP plate is applied in in-situ prestressed concrete box girder bridge with obvious damage. The static and dynamic testing of this reinforced bridge shows the feasibility and effectiveness of gluing prestressed CFRP plate strengthening method. Studies in this paper provide reliable guidance for engineering application.

INTRODUCTION

With increasing service life, coupled with other factors like fire, earthquake, overload, design and construction defection, traffic accident and so on, many highway bridges cannot meet the service demand all over the world. Therefore, it is necessary to strengthen these bridges to recover structural performance and ensure service safety. In recent years, researchers have conducted a series of experiment studies and a lot of achievements were acquired (Wang *et al*. 2011, Nie *et al*. 2007, Zhuang 2005). The hot research topic includes structural behaviour study after strengthening, strengthening effectiveness, and constructional simplicity. The popular strengthening methods include bridge deck pavement strengthening method, enlarge cross section method, external tension prestress strengthening method, gluing steel plate strengthening method, change structural system method, adding longitudinal or transversal girder method and so on (Wang *et al*. 2010, Nie *et al*. 2011).

Bonding the carbon fiber strengthening plastic (CFRP) plate method is a strengthening method developed in recent years. CFRP is an excellent material for strengthening concrete structures, because its superior characters of high strength, low density, corrosion resistance, fatigue resistance and so on. CFRP is more and more used in strengthening project of civil engineering (Li *et al*. 2014). Normally, CFRP is glued to concrete surface by resin material to achieve composite effect to ensure the overall behaviour. Prestressed CFRP plate strengthening method combines the advantages of general CFRP plate and prestressing technique, which effectively improve the anti-cracking capacity, structural rigidity and deformation performance. This strengthening method makes full use of the high strength of CFRP plate, which helps save the strengthening material and cost.

In the bridge strengthening project, CFRP laminate or plate can be directly glued to the strengthening parts by epoxy adhesive material, which is easy to guarantee construction quality, avoid bolted work in gluing steel plate strengthening method. Compared with gluing plate strengthening method, CFRP plate strengthening technology has no damage for the original structure. Meanwhile, since the CFRP plate is a high tensile strength and low shear strength materials, it can be cut at the constructional site and the whole strengthening process is simple and convenient since no other constructional machine is needed. Although CFRP is an expensive material compared with traditional constructional material, its superior characters like corrosion resistance enable its application in serious environmental region and post maintenance work can be avoid after strengthening (Garden *et al*. 1998). Thus, CFRP strengthening method is a beneficial chose for bridge engineering.

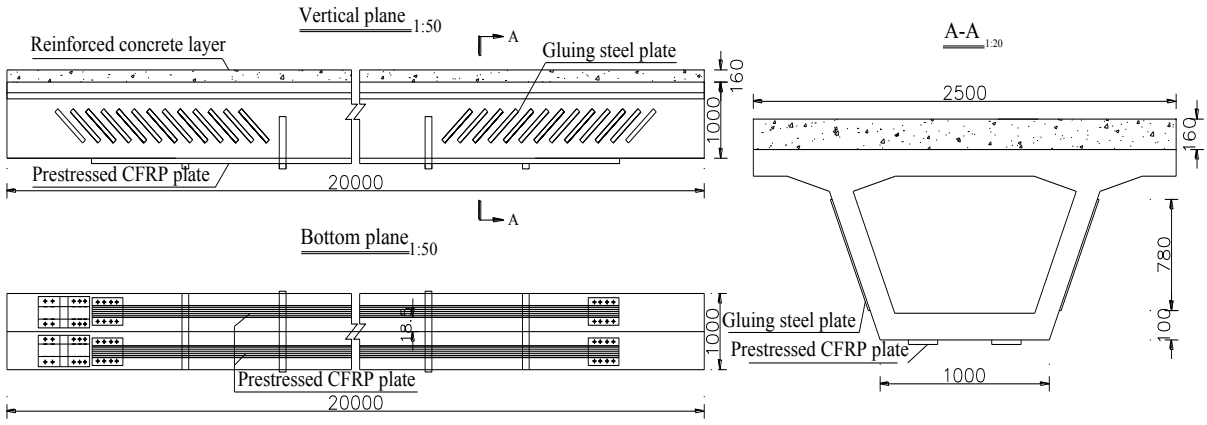
According to typical structure damages, strengthening measure of gluing steel plate and gluing prestressed CFRP plate are adopted. This paper is focus on bending behavior of full scale PC box girder before and after prestressed CFRP plate strengthening method. After the test, the bending behaviors of test girders are comparatively analyzed, and the failure mechanisms of test girders are studied. Based on test result, the strengthening method of gluing prestressed CFRP plate is applied in in-situ PC box girder bridge with obvious damage. The static and dynamic testing of this reinforced bridge shows the feasibility and effectiveness of gluing prestressed CFRP plate strengthening method.

TEST PROGRAM

Full-scale Test Girder

Test girders in this paper are 20m simple supported PC box girder removed from a real bridge. The in-situ inspection results show difference degrees of damage were existed in components of full-scale test girder. For example, lateral and longitudinal cracks were existed at bottom flanges near mid-span regions; many vertical, inclined and longitudinal cracks appeared in the webs; cracks were normally found in the concrete diaphragms; connecting steel plate are fractured; most of longitudinal concrete wet jointing were cracked, damaged and leaking. Strengthening measures were adopted by gluing steel plate and gluing prestressed CFRP plate for the test girder. Bending tests were conducted for simple supported full-scale test girders before and after strengthening, respectively.

For strengthening process, two prestressed CFRP plates were glued at bottom flange with distance of 400mm. The selected prestressed CFRP was 1.4mm thick and 100mm wide, with standard tensile capacity no less than 2400MPa, elastic modulus no less than 1.6×10^5 MPa and elongation rate no less than 1.7%. One end of CFRP plates were anchored by Q345 steel plates, which were attached at bottom flange by both adhesive glue and M20 bolts. Hydraulic jack were located at another end of CFRP plates, which is moveable, and CFRP plates were anchored by the same size Q345 steel plates after prestressed by hydraulic jack. The prestressed force for CFRP plates were 1560MPa, which was equal to 0.65 times the ultimate tensile standard strength. Effective initial prestressed force was 1326MPa and effective initial strain was 8288με, considering 15% prestressed force loss. Then, four Q235 steel plates were compressively attached at bottom of prestressed CFRP plate by both adhesive glue and M12 bolts (with 12mm diameter) along span length to enhance overall behaviour, shown in Figure 1. The compressive steel plates were 100mm in width and 6mm in thickness. In Figure 1, two compressive steel plates were 1955mm from mid-span section and the steel plates anchored both bottom flange and webs. Another two compressive steel plate were 4635mm far away from mid-span section, which anchored at the bottom flange by M12 bolts. Besides prestressed CFRP plate, the steel plate was glued at web within the field of 1.5 to 1.6m away from supporting section with distance of 300mm, and the steel plate was 45° from horizontal direction. The top flange is reinforced by 160mm concrete composite layer. There are two layers rebar arranged in this concrete composite layer and steel rebar are embedded at original to flange to enhance composite effect (GB 50367-2006). The test girder after strengthening is shown in Figure 1.

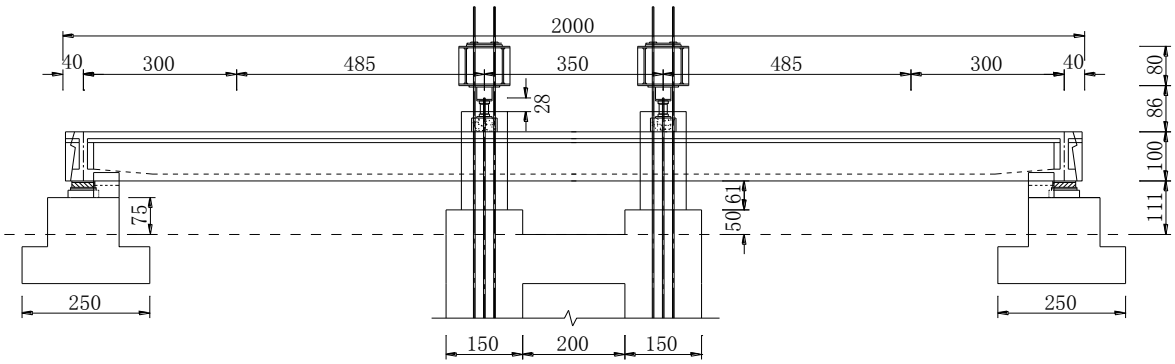


(a) Overall distribution (b) A-A cross section

Figure 1 Test girder strengthening by concrete composite layer, gluing steel plate and prestressed CFRP

Test Setup

Four-point loading were adopted during the bending test. The test setup were mainly composed with four ant-pull piles, screw-thread steel rebar, steel diaphragms and hydraulic jack, shown in Figure 2. The test girders were all located in east-west direction, while the west side was fixing supporting section and the east side was movable supporting section. During the bending test, strain and deformation were recorded by TDS-602 machine. The strain measure points were mainly arranged at mid-span region in concrete, longitudinal rebar and CFRP plate. These measure points were arranged for testing plastic region length and the neutral axle location.



(a) Bending test

(b) In-situ bending test

Figure 2 Test setup

BENDING TEST WITH AND WITHOUT STRENGTHENING

Failure Mode

Before the test, the preloading was conducted for several times, in order to inspect the overall system workability and to eliminate the strain gauge mechanical hysteresis properties. During the bending test, initial loading increment can be appropriately greater, while this loading increase should be smaller and stable as steel rebar yielding to ascending to ultimate capacity. The bending test results are shown in Table 1 for test girder with and without strengthening, respectively. To clearly describe girder behavior with prestressed CFRP strengthening method, two failure modes were took into consideration, including preliminary failure mode and ultimate failure mode. The preliminary failure mode marks the failure of prestressed CFRP plate and test girder can carry capacity continuously after failure of CFRP plate. At this moment, test girder has small deflection and concrete strain of top flange is less than ultimate strain. Ultimate failure mode marks the full plastic ultimate state of test girder and unloading follows automatically. At this state, obvious deflection can be observed and concrete strain at compressive top flange attaining ultimate strain.

Table 1 Bending test result

Test girder	Cracking capacity (kN)	Yielding capacity (kN)	Ultimate capacity (kN)	Maximum deflection (mm)	Preliminary failure mode	Ultimate failure mode
Without strengthening	340	880	1047.4	295.1	Excessive deflection	
After strengthening	200	1022.8	1337.7	614.2	CFRP plate fracture	Excessive deflection

During bending test for full scale test girder without strengthening, no new crack was found in concrete when loading was less than 340kN. The test girder showed very well overall performance and the strain of main strengthening was much less than yield strain. When the load increased beyond 340kN, there was continuous sound and new vertical cracks were appeared. A big sound was heard as loading to 362.6kN, the concrete slag dropped out and crack width turned winder at bottom flange near middle span at 392kN. When the load reached 588kN, vertical crack extended to 1/2 height of the girder. The inclined cracks appeared in the web at 1/4 span section when loading to 784kN. As loading to 980kN, severe cracks with maximum crack width of 3mm were appeared at bottom flange and web. These cracks extended quickly and part of them extended to the top flange. When loading to 1048.6kN, the concrete strain at top flange did not reach ultimate strain, but there was 30cm deflection at middle span. This excessive deflection marked termination of bending test. At this moment, the bending test girder attained plastic ultimate limit state. There were lots of vertical cracks at middle span region and inclined cracks in web outside of pure bending region. The maximum width of these cracks reached to 3~4mm. The failure mode of test girder without strengthening is shown in the Figure 3.

(a) Vertical cracks near mid-span region (b) Inclined cracks outside of pure bending region

Figure 3 Failure mode of full scale test girder without strengthening

Figure 4 shows the cracks distribution for test girder without strengthening. Learn from Figure 4, the crack distributions have two characters. Firstly, vertical bending crack in pure bending region were uniform and the spacing distance was about 30 to 40cm. Most vertical cracks extended to haunch and some cracks extended even to the top flange. Secondly, inclined cracks were mainly located in shear span region and some vertical cracks were appeared near loading point region. Most cracks extended to haunch with angle about 45°.

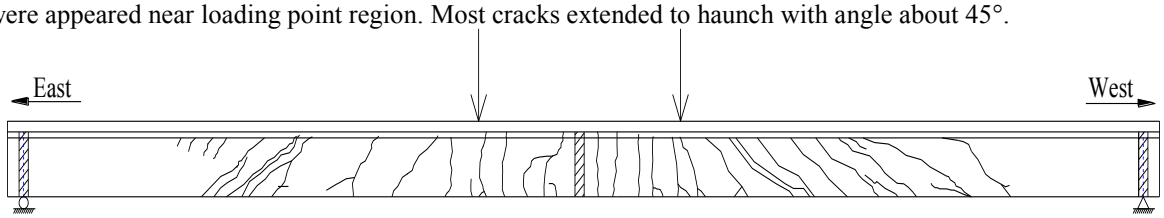


Figure 4 Cracks distribution for test girder without strengthening

In the bending process for test girder reinforced by gluing steel plate in web and prestressed CFRP plate in bottom flange, there was no new concrete crack developed when loading was less than 200kN and the test girder shew very well overall performance. New vertical crack appeared when loading beyond 200kN and continuous sound were heard as loading to 350kN. When loading to 416.5kN, vertical epoxy resin adhesive lay at north web near middle span region was cracked, and the original crack in test girder extended and turned wider. Prestressed CFRP plates at bottom flange were split when loading from 1078kN to 1205.4kN and the maximum width of concrete crack was 1.5mm. When loading from 1127kN to 1274kN, there was stripping between steel plate and concrete at web. The pre-stressed CFRP plate was fractured as loading to 1289.7kN and the test girder was unloading automatically when loading to 1317.4kN. As unloading to 1272.9KN, one CFRP plate burst apart with a loud sound and the test girder unloaded to 1225kN. The test girder was loaded again, another CFRP plate fractured at 1239.7kN and test girder unloaded to 1173.8kN automatically. Deflection of the test girder and width of the crack increased rapidly as the test girder was loaded once again. In this stage, both the bottom flange and webs had severe cracks. The widest crack was 2mm and vertical crack extended quickly to the top flange. The load did not increased and test girder unloaded automatically when loading to 1338.1kN. In this moment, the test girder approached ultimate bending plastic state in which the widest crack was 5mm and the deflection was 60cm. But the top flange was still not crushed. Figure 5 shows the failure characteristic of test girder.

(a) CFRP plate fracture (b) Inclined crack in webs

Figure 5 Failure characteristic of test girder strengthened by prestressed CFRP and gluing steel plate

Figure 6 shows crack distributions on the north web. Learn from Figure 6, the cracks after test was much more intensive than test girder without strengthening. The cracks in Figure 6 were mainly concentrated in middle span region. There were mainly vertical intensive crack in pure bending section, most of which were extended to the top flange or even to the composite strengthening layer. There were mainly inclined crack with the angle of 45° in shear span region.

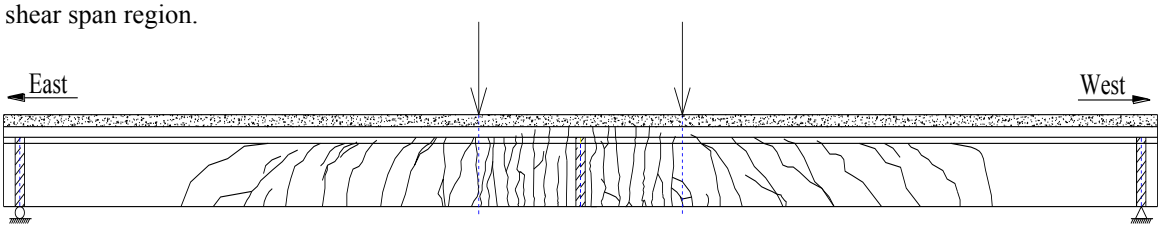

Figure 6 Crack distribution for test girder with strengthening

Test Result Analysis

(1) Test result analysis for PC box girder without strengthening

For the test girder without strengthening, the load and deformation curves at both mid-span and loading points are shown in Figure 7. Learn from Figure 7, the load-deformation curve in the mid span and loading point is basically identical with each other. The deformation increases continuously with the increase of loading, leading to concrete cracking, stiffness decreasing gradually and deformation growth rate increasing gradually. Learn from Figure 7, the bending process of the test girder can be divided into three stages. The first stage is elastic stage. In this stage, the deformation of each section increases linearly with loading, and the load is less than 340kN, which indicated no crack appearing and the girder deflection was less than 15mm. The second stage is elastic-plastic stage, corresponding to load between 340kN and 880kN. In the second stage, the load and deformation curves turned nonlinear and the stiffness of test girder declined, which indicated new cracks appeared in the test girder and both old and new cracks expanded continuously. The third stage is plastic stage, corresponding to load exceeded 880kN. In this stage, the growth of deflection increased, and the load-deformation curves tended to be horizontal. When the load reached 1047.4kN, the test girder was close to the limit state of plastic bending, and the maximum deflection is 300mm. Then the bending test was terminated due to the excessive deflection of test girder.

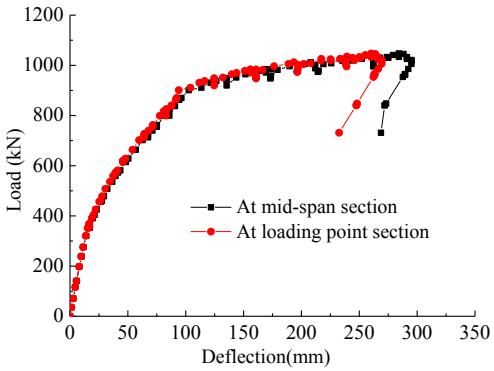

Figure 7 Load and deformation curves for test girder without strengthening

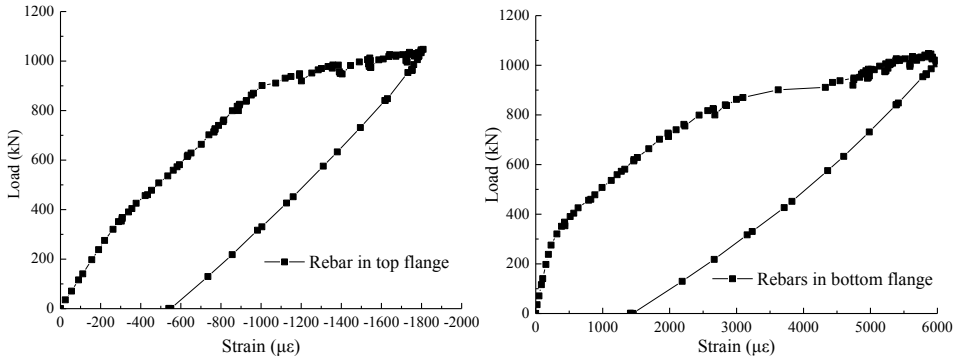
Figure 8 shows the load-strain curves of rebars in the top flange and bottom flange respectively. Learn from Figure 8, the strain has three symbols in the whole loading process, including new crack appeared in concrete, yield of rebar at bottom flange and failure of test girder. After the test, the cracking load, the yielding load and the ultimate load of the test girder were 340kN, 880kN and 1047.4kN respectively. There was no new crack in the test girder at the initial loading stage, and the strain of rebar was growing linearly. When the load reached about 300kN to 380kN, the concrete appeared new cracks, and the strain growth of rebar began to speed up. With the propagation of concrete cracks, the strain of rebar grew obviously. When the load reached 800~900kN, the rebar at bottom flange was gradually yielding, corresponding to the second typical point. As the continued increase of load, the strain growth rate of rebar still increased, corresponding to leap-growth of the strain in Figure 8. In this stage, the rebar at bottom flange showed obvious plastic characteristic. When loading to 1047.4kN, the test girder was close to the plastic bending limit state, and then the bending test was terminated.



(a) Rebar in top flange (b) Rebar in bottom flange

Figure 8 Load and strain curves at mid-span section

Figure 9 shows load and concrete strain curve at top flange at mid-span section. Learn from Figure 9, the concrete strain increased linearly with the increase of load under 340kN, and the test girder was in the elastic stage. With the loading continued, the concrete strain growth rate accelerated and the load-strain curve turned nonlinear. New cracks appeared continuously and the original cracks continued propagation. Then the load and concrete strain curve appeared mutation again, and the rebar at bottom flange was yielded. The concrete strain growth rate of the test girder turned greater, and the load - strain curve in Figure 9 reached horizontal stage. When loading to 1047.4kN, bending test was terminated. The residual strain was about 600με which can be seen from the Figure 9.

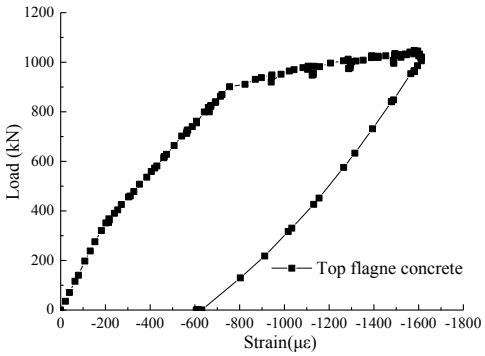


Figure 9 Load and concrete strain curve at top flange of mid-span section

(2) Test result analysis for PC box girder after strengthening

Figure 10 shows the load-displacement curves for reinforced test girder. Learn from Figure 10, the deflection curves at mid-span and at loading point were basically coincident. When loading less than 200kN, the load and displacement had linear relationship, which illustrated no new concrete crack appeared and the test girder was in elastic stage. The deflection in this stage was small, which was less than 8mm. When loading between 200kN and 1000kN, the test girder appeared new cracks, the stiffness decreased and the deflection increased. The relation between the load and displacement turned nonlinear, corresponding to elastic-plastic stage. During the loading process, both the old and new concrete cracks were propagated and the crack widths increased. When

the load exceeded 1000kN, the prestressed CFRP plate was splited, and the displacement increased. When the load reached 1317.4kN, the curves in Figure 10 appeared sudden drop due to the successively fracture of the prestressed CFRP plate and the test girder was unloaded to about 1200kN automatically, which demonstrated the brittle failure of prestressed CFRP plate. Then, the displacement increased rapidly and the curves tended to be flat, although the load was still increasing. Learn from test result, the prestressed CFRP plate strengthening technique would not increase the bending capacity of the test girder, but it could enhance bending rigidity to a great extent. The load did not increased anymore when reaching 1338.1kN, which indicated attaining fully plastic state, and the maximum deflection reached 61.4cm.

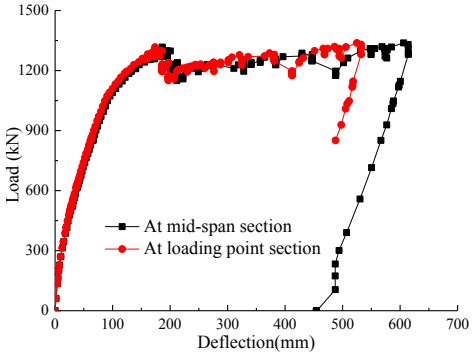

Figure 10 Load and deformation curves for test girder after strengthening

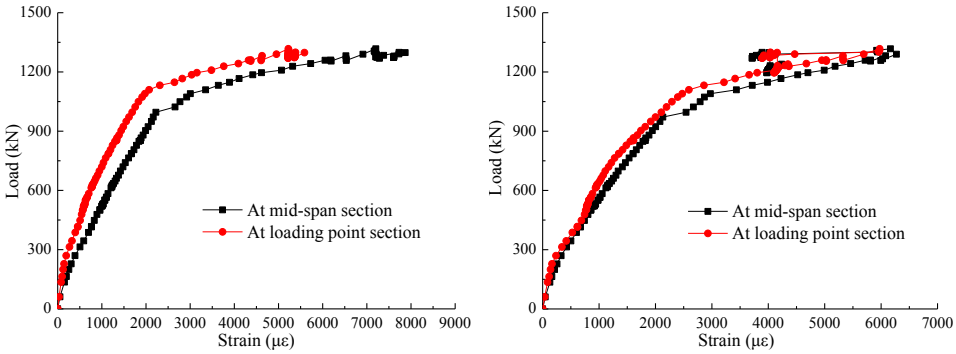
When the prestressed CFRP plate was close to collapse, the relative displacement between the prestressed CFRP plates and concrete was less than 0.1mm, which could be neglected. Figure 11 (a) and (b) show the curves between load and strain of the prestressed CFRP plate at the mid-span section and the loading point section, respectively. Learn from Figure 11, the strain increasing rate of prestressed CFRP plate was increased gradually with the continuous decrease of test girder stiffness. There are two obvious mutation points in Figure 11 at about 200kN and 1000kN respectively, corresponded to new concrete cracking development and the rebar yielding at bottom flange. After that, the strain increase of prestressed CFRP plate was not stable, because the prestressed carbon fiber plate splitting continuously after 1000kN. When the load reached about 1300kN, the prestressed CFRP plate in the south broke partly, leading to the sudden drop of strain curve in Figure 11 (b). When load fell to about 1200kN and then loading again to 1239.6kN, prestressed CFRP plate in the south side broke off. Learn from test result, prestressed CFRP plate occurred brittle failure. The strain of prestressed CFRP plate at south side was relatively uniform, and the strain differences at the mid span and the loading point were not obvious. However, for prestressed CFRP plate at north side, the strain in the mid span was significantly higher than that in the loading point.



(a) Prestressed CFRP plate at north side (b) Prestressed CFRP plate at south side

Figure11 Load and prestressed CFRP plate strain curves

(3) Comparative analysis

Learn from the bending test results, critical cracking capacity of test girder with strengthening was smaller than that of test girder without strengthening. Cracks existed in original girder, so concrete tensile stress was relatively small for unreinforced test girder, resulting in lagging development of new concrete cracks. For strengthened test girder, test girder was repaired by the crack grouting treatment, but concrete cracks would appear again in relatively early time of bending process. The yielding capacity of the reinforced test girder was greater than that of test girder without strengthening. This testified pasting CFRP plate strengthening method

improved the bending rigidity of test girder. What's more, the strengthening method also improved the ultimate capacity of the test girder by 28%, which was mainly contributed from the 16cm composite strengthening layer for top flange.

Table 2 gives mid-span deflections of the test girders under different load levels. In Table 2, 200kN is the cracking capacity of the prestressed CFRP plate, 880kN is the yield capacity of the un-reinforced test girder and 1047.4kN is the ultimate capacity of the un-reinforced test girder. Experimental results showed that under different load levels, the pasting prestressed CFRP plate strengthening method can result improvement of ω_0/ω_1 ratio, which indicate the improvement of bending rigidity.

Table 2 Stiffness analysis for the test girders

Load (kN)	Deflection at mid-span (mm)		ω_0/ω_1
	Without strengthening (ω_0)	With strengthening (ω_1)	
200	8.14	6.37	1.28
880	98.32	68.94	1.43
1047.4	284.18	90.93	3.13

Table 3 gives deflections of the test girders at yielding and ultimate states. Learn from Table 3, test girder without strengthening has relatively reasonable steel rebar ratio and good ductility. For the test beam after strengthening, the ductility decreased obviously because of strengthened by prestressed CFRP plate. Prestressed CFRP plate would achieve ultimate strain and fracture in earlier bending process, and test girder shew fine ductility thereafter. According to the test result, the value of $\omega_p/\ \omega_y$ for strengthened test girder reached 2.2, which satisfying the requirement of structural ductility.

Table 3 Ductility analysis of the test girders

Test girder	Yield deflection ω_y (mm)	Ultimate state deflection ω_{pu} (mm)	$\omega_p/\ \omega_y$
Without strengthening	98.32	295.05	3.00
With strengthening	87.74	194.42	2.22

IN-SITU APPLICATION AND TESTING

Engineering Background

Baolan Railway Interchange Bridge, which is a prestressed concrete box girder, on the southern section of freeway around Ningxia city was taken as an engineering example to testify the effectiveness of prestressed CFRP reinforcement method. To determine the specific reinforcement measures, in-situ inspection was conducted. Table 4 shows typical damage in the bridge.

Table 4 Typical damages of 20m PC box girder

Position	Damage
Bottom plate	Transverse and longitudinal cracking, which are sandwiched with mud partially.
Web	Diagonal cracking, vertical cracking, longitudinal cracking
Wet joint	Cracking and seepage in multiple wet joints
Transverse connection	Water erosion and concrete cracking in the middle cross beam, fracture of steel plate connection
Girder inside	Water accumulation
Strand	Hole damage and bellows exposure appeared in web and bottom flange
Stirrup	Stirrups are erosion in the bottom plate at mid-span of multiple box girders

According to the inspection result, the specific strengthening measures were determined. Firstly, prestressed CFRP plate was tensioned at the bottom plate to decrease the rebar stress at bottom plate. Three prestressed CFRP plates were tensioned in the exterior girder while two prestressed CFRP plates were tensioned in interior girder. Secondly, strengthening rebars were added in negative moment at pier top to ensure continuous system and increase safety factor. Thirdly, steel plate was pasted on webs within the range of 1.5m to 6.5m away from supporting section, in order to decrease rebar stress at the supporting section and to prevent development of inclined concrete cracking in web. Fourthly, the existing bridge deck pavement was milled and then 16cm thick C45 waterproof concrete layer was paved as well as 8cm thick asphalt concrete surfacing course, to improve flexural rigidity and capacity of the bridge. Double-layer reinforcing mesh was arranged in the bridge deck,

improving transverse integrality of the bridge deck and structural transverse stress condition. The bridge after strengthening is shown in Figure 12.

(a) Right half of bridge (b) Strengthening at bottom plate and web

Figure 12 In-situ bridge after strengthening

Load Testing

In order to testify structural safety under service stage, both static and dynamic load tests were conducted for this reinforced bridge from November 22nd to November 23rd in 2014. Analysis and evaluation were conducted on the strengthening effect. The four axles truck was adopted in static load test, and the axle spacing was 1.95m+2.90m +1.3m. The front two axles were single axle with two tires and the center distance of two tires was 2.03m while the outside distance was 2.25m. The rear two axles were single axles with four tires and the outside distance was 2.46m. The empty car was 14t weigh while the loaded car after weighted was 58.9t in total. From the front axles to the rear axle, the four axle loads were 5t, 9t, 25.4t, 21.5t respectively. In order to ensure the effectiveness of the loading, the static load test were carry out under the most unfavorable load condition, including 0.4L section and the mid-span section.

Through dynamic load test, it were acquired the dynamic effects of bridge (such as dynamic strain and dynamic deflection) and dynamic response with known load weight under the certain driving speed and traffic lane. Two exterior lanes were selected as dynamic loading lanes, respectively. Each drive pattern should consider different driving speeds, and record the dynamic response of the measuring point under the corresponding conditions. Different driving speeds were considered, including 5km/h, 20km/h, 40km/h, 60km/h and 80km/h.

Each static and dynamic load condition was repeated for twice. Checking coefficient can be calculated by the ratio of testing value to calculated value, which is a significant parameter to evaluate structural safety. The average deflection and strain were taken for analysis. The checking coefficients for all the static deflection measure points were around 1.1, while the checking coefficients for all the dynamic deflection measure points were between 0.36 and 0.77. Learn from the deflection measurement results, the static loading test resulted in greater effect under static loading, and the average checking coefficients for every measuring point were about 1.1, which belong to acceptable limits. However, the effect under the dynamic load was smaller, and the average checking coefficients were about 0.6. Thus it can be seen that the structural stiffness meets the requirements.

For strain analysis, it were measured the strain from the static load test, strain from dynamic load test and the theoretical calculated strain. There were totally 21 measuring points in static load test. After static load test, checking coefficients of five measure points were varied from 0.24 to 0.37, and check coefficients of sixteen strain measuring points were between 0.43 and 0.77. So the average check coefficient for all the measuring points was 0.59 and the standard deviation was 0.196. In dynamic load test, there were totally 21 measuring points. After dynamic test, checking coefficients of nineteen measuring points were between 0.4 and 0.91. So the average value for all the dynamic measuring points was 0.64 and the standard deviation was 0.3. To sum up, structural stress condition satisfies the requirements.

According to the comparison of static and dynamic load test, the difference between the static test data and dynamic test data was small, and speed had little influence on the dynamic strain under each dynamic loading condition. In this test, comparative analysis was conducted for concrete strain checking coefficient at bottom flange and strain checking coefficient at prestressed CFRP plate under both static and dynamic load test. Checking coefficients of most measuring points were between 0.5 and 1.0, which testified the structural stress condition satisfied the requirements.

Learn from static and dynamic loading test, structural stiffness and strength of Ningxia Baolan Railway separating interchange were improved effectively after prestressed CFRP and gluing steel plate strengthening. The reinforcement effectiveness was obvious and the expected strengthening aims were achieved. The prestressed concrete box girder bridge after reinforcement can operate safely in the service stage.

CONCLUSION

This paper has carried out bending experimental study for prestressed concrete small box girder with and without strengthening. According to analysis of the test results, it can arrive at the following conclusions:

- the 16cm concrete composite layer reinforced at top flange is the main influence factor for improving ultimate capacity. Strengthening technique in this paper can significantly increase the yield capacity and ultimate capacity. The yielding load increases by 16% and the ultimate load increases by 28%.
- prestressed CFRP plate strengthening technique can make full use of material properties of CFRP plate as well as postpone the crack development. Prestressed CFRP plate strengthening technique increases the rigidity of test girder.
- the results show the test girder strengthened by prestressed CFRP plate strengthening technique has enough energy dissipation capability as well as good deformation capacity.
- for the prestressed CFRP plate strengthening technique, the combined surface between the CFRP plate and concrete has good work performance. There is no relative slip and the structural integrality work performance is good.
- prestressed CFRP plate reinforcement method is applied for in-situ Baolan Railway Interchange Bridge. After prestressed CFRP plate strengthening, the structural stiffness and strength can be effectively increased, and the stress and deflection condition is good. So the strengthening effectiveness is obvious and the expected strengthening goal has been achieved, which can meet the requirements of the service stage.

ABSTRACT

A new law of tension-stiffening for reinforced concrete (RC) ties is proposed in the present study. It is based on the test data of 11 experimental programs of RC elements of various strength classes reported in the literature. The experimental programs covered a wide range of characteristics of mechanical and geometrical parameters of specimens such as compressive strength of concrete, reinforcement ratio and diameter of reinforcement bars. By eliminating the effect of shrinkage from the test load-strain diagrams of the ties, a simple model with no dependence on reinforcement ratio could be derived. The proposed tension-stiffening law is compared with the formulation in Eurocode 2. Statistical analysis of strain predictions of RC ties based on Eurocode 2 was conducted. It is found that the Eurocode 2 significantly underestimated strains in the RC ties with the errors reaching 50% for the lightly reinforced members. Nevertheless, when shrinkage effect was accounted for in the test load-strain diagrams, the predictive capability of the Eurocode 2 formulation could be significantly improved.

KEYWORDS

Reinforced concrete ties, tension-stiffening, shrinkage effect.

INTRODUCTION

The stiffness of a reinforced concrete (RC) member loaded in axial tension can be considered as the superposition of the stiffness of reinforcement and the stiffness of plain concrete. When the RC member is cracked, the stiffness of intact concrete is reduced to that of cracked concrete, this is referred to as tension softening. In addition, there is a stiffness component due to bond between concrete and reinforcement, this is referred to as the tension-stiffening component. Tension softening is a property of plain concrete and can be simulated by fracture mechanics models. Tension-stiffening is a property of cracked concrete under tensile stress in the presence of bar reinforcement. Due to the bond with reinforcement, the intact cracked concrete between cracks carries a certain amount of tensile force normal to the cracked plane and contributes to the overall stiffness of the structure.

Tension-stiffening has been vastly researched in a variety of approaches (Torres *et al*. 2004; Ng *et al*. 2010; Lam *et al*. 2010; Gilbert and Ranzi 2011). In the present analysis, a simplified approach based on smeared cracks is followed in which the stress in the concrete is taken as the combined stress due to both tension-stiffening and tension softening, collectively called the tension-stiffening. Based on this approach, a number of stress-strain constitutive relationships for cracked tensile concrete have been proposed, as exemplified by the studies of Prakhya and Morley (1990) and Christiansen and Nielsen (2001). However, most of the studies in the literature did not take into account the shrinkage effect. The influence of shrinkage on short-term and long-term strains and tension-stiffening in reinforced concrete members has been investigated by Bischoff (2001), Fields and Bischoff (2004), Kaklauskas *et al*.(2009), Kaklauskas and Gribniak (2011). A technique to exclude the shrinkage effect from the load-strain relationships of RC ties was proposed by Bischoff (2001). Based on this technique, he developed a shrinkage-free tension-stiffening law. However, limited amount of experimental data were used in deriving the constitutive relationship, and this might limit the applicability of the tension-stiffening law.

The present study proposes a new law of tension-stiffening for RC ties. Its derivation is based on the test data of 11 experimental programs of RC elements of various strength classes (Scott and Gill 1987; Stroband 1991; Farra and Jaccoud 1993; Lorrain *et al*. 1998; Noghabai 2000; Choi and Maekawa 2003; Wu and Gilbert 2008;

Yuguang *et al*. 2009; Danielius 2014; Gudonis *et al*. 2014; Kesminas and Tamulenas 2014). These experimental programs covered a wide range of characteristics of mechanical and geometrical parameters of specimens including the compressive strength of concrete, reinforcement ratio, and diameter of reinforcement bars. A distinctive feature of the proposed constitutive law is the expression of tension-stiffening stresses in terms of the compressive strength of concrete. This is desirable from practical viewpoint since the uncertainty and empiricism associated with the equation determining tensile strength of the concrete could be avoided. Furthermore, the study also reports the statistical analysis results of strain predictions of the RC ties using the Eurocode 2 formulation.

DESCRIPTION OF COLLECTED EXPERIMENTAL DATA

The present analysis is based on the data collected from 11 experimental programs, listed in Table 1, which involved 136 RC elements (3,498 measurements) of different strength classes. All specimens were subjected to short-term axial tension. All experimental programs involved prismatic specimens with square sections reinforced by a single bar. The specimens were tested either by controlling the deformations, as adopted in programs No. 1-8 and 11, or alternatively, controlling the applied tensile force, as adopted in programs No. 9 and 10.

The main characteristics of the specimens are given in Table 1, where the first four columns refer to the test program number, the literature source of the program, the numbers of the tested elements, and the number of measurements in this program, respectively. The experimental programs in Table 1 are listed in descending order of the number of the measurements, n. Further parameters in Table 1 are: the height (h) and width (b) of the section; the concrete cover (c); the length of the specimen (L); the diameter of the reinforcement bars (D); the total area the reinforcement (A_s); the reinforcement ratio (p); the compressive strength of the ∅150×300 mm concrete cylinder (f_{cm}), and the shrinkage strain (ε_{cs}) measured at the age of testing. When the values of the parameters varied within a range, the range of values rather than individual values are stated in the table.

Table 1. Main characteristics of the test specimens used for the constitutive modelling

Note: The shrinkage deformations ε_{cs} are negative; the symbol "–" indicates that the experimental shrinkage strain was not provided and is thus assessed using the Eurocode 2 formulation.

MODELLING OF TENSION-STIFFENING

The present study aims at developing a tension-stiffening model that combines the objectives of accuracy and simplicity. The original tension-stiffening relationships in terms of mean stress-mean strain diagrams were obtained from the load-mean strain relationships. The material characteristics of concrete such as the tensile strength, f_{ct}, and the modulus of elasticity, E_c, were assessed in accordance with the Eurocode 2 using the respective values of the compressive strength as stated in Table 1.

Derivation of Tension-Stiffening Law

A statistical data set was composed using the tensile stress-strain relationships obtained for each of the ties. It should be noted that the ties had different geometric and material characteristics (Table 1), resulting in different cracking resistance and ultimate strength. Moreover, the objectives of the experimental programs were different and different loading steps with different measurement intervals were considered in these programs. To assure an even contribution of each experimental specimen, the data set was composed by applying an interpolation procedure developed by the authors (Gribniak *et al*. 2013a, 2013b). To have equal representation of different

loading levels, the data set included the test points corresponding to certain levels of normalized strains ($\varepsilon_m/\varepsilon_{cr}$ = 1.0, 1.5, 2.0, 2.5,…). Here ε_m and $\varepsilon_{cr} = f_{ct}/E_c$ are the mean strain and the cracking strain of concrete, respectively. The tension-stiffening diagrams were terminated at the yield load.

Various tension-stiffening models suggest that tension-stiffening stress-strain relationship might be dependent on a number of parameters, the most important of which are the tensile strength of concrete, reinforcement ratio and modular ratio (Torres *et al*. 2004; Gribniak *et al*. 2015). As the starting point, Figure 1 plots the target points of normalized stress (σ_{ct}/f_{ct}) and relative strain ($\varepsilon_m/\varepsilon_{cr}$) generated from the experimental programs.

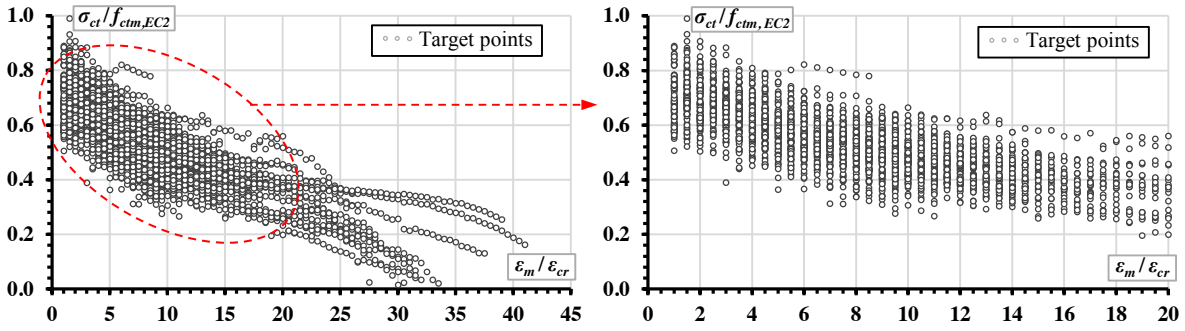

Figure 1. Normalized target tension-stiffening stresses versus the relative strain

The constitutive modeling was devised by curve fitting with the goal to minimise the error of the target tension-stiffening stresses σ_{ct} at different relative strain levels. An emphasis was placed on the strain interval of $\varepsilon_m/\varepsilon_{cr} <$ 20 which affects to a large degree the load-deformation response. From a number of possible fitting curves considered, as a compromise between accuracy and simplicity, the following form for the descending part of the σ_{ct}-ε_m relationship as given in Eq. (1) is proposed and is plotted in Figure 2:

$$\sigma_{ct} = 3 - 12.5/f_{cm}{}^{0.5} + 1.76 \cdot e^{-\varepsilon_m} \tag{1}$$

In the above, σ_{ct} is the tensile (tension-stiffening) stress, f_{cm} is the mean compressive strength, and ε_m is the mean tensile strain. A notable feature of the proposed constitutive law is that it is related to the compressive strength of concrete. Unlike most tension-stiffening laws that are expressed in terms of the tensile strength of concrete, the proposed model circumvents the empiricism associated with the equations determining tensile strength of the concrete. Per Eq. (1), the stress-strain relationship is plotted in Figure 2 with juxtaposition of the scattered target points. It is noted that the test data and the proposed model agree well with each other, in particular over the strain interval of $\varepsilon_m/\varepsilon_{cr} < 20$, as shown in the right hand side of Figure 2.

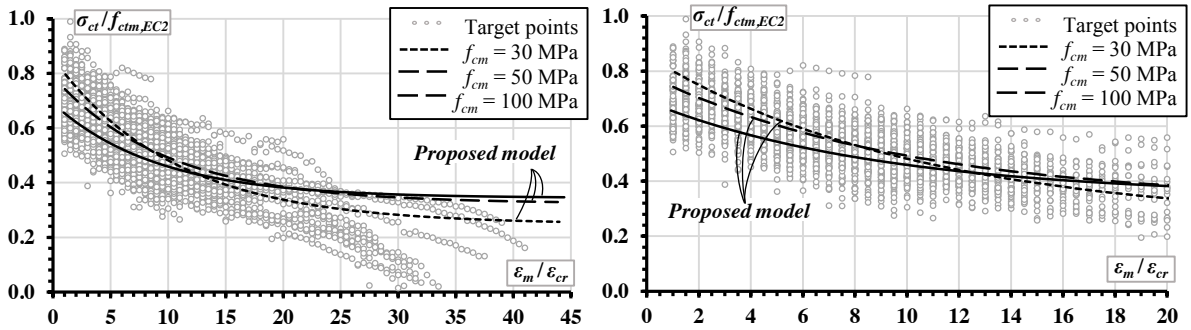

Figure 2. Proposed stress-strain relationship for RC members in tension

As can be seen from Figure 2, the maximum stresses do not reach the tensile strength of concrete f_{ct} as suggested in Eurocode 2. This is in line with previous research findings (Gupta and Maestrini 1990). For lower concrete grades, the maximum normalized stresses tend to be slightly larger, i.e. closer to unity. This would be attributed to the fact that for a given reinforcement area, a lower concrete grade would lead to greater contribution from the reinforcing steel to the overall resistance of the RC element.

Elimination of Shrinkage Effect

Tension-stiffening is significantly affected by the shrinkage of concrete occurring prior to loading. In general, the shrinkage behaviour is dependent on the properties of concrete (including the mix proportioning and the type of ingredients), environmental factors (including temperature and humidity), and geometrical characteristics of the RC member (including the effective thickness and exposed perimeter). The above factors have been accounted for in the formulas for estimating shrinkage in Eurocode 2. The elimination of shrinkage from the load-deformation response of RC elements is of key importance in deriving an universally applicable tension-stiffening law. Herein, the exclusion of shrinkage effect is principally in accordance with the shrinkage elimination techniques reported in Bischoff (2001) and Kaklauskas *et al*. (2009). Basically, the shrinkage is modelled by a fictitious force N_{sh} causing the equivalent deformation of the member taking into account the effect of creep. The fictitious force is determined by considering a plain concrete member having the sectional area A_c and deformation modulus E_{ca} (through which the creep deformation is accounted), and subjected to compression so as to impose the axial strain ε_{sh}, therefore:

$$N_{sh} = \varepsilon_{sh} E_{ca} A_c \tag{2}$$

where E_{ca} is related to the modulus of elasticity of concrete E_c by the creep factor φ and the ageing coefficient χ:

$$E_{ca} = E_c/(1 + \varphi\chi) \tag{3}$$

Regarding the shrunk RC member, the shrinkage-induced internal forces acting in the steel and concrete would be equal and opposite, and the deformation of member can be obtained based on the principles of equilibrium and compatibility. The stress of concrete can be deduced as shown in Eq. (4) and the strain state of the member is represented by the effective shrinkage strain $\bar{\varepsilon}_{sh}$ in Eq. (5) (Kaklauskas *et al*. 2009):

$$\sigma_{c,sh} = -\varepsilon_{sh} E_s \rho/[1 + (E_s/E_{ca})\rho] \tag{4}$$

$$\bar{\varepsilon}_{sh} = \varepsilon_{sh} \frac{1+(E_s/E_c)\rho}{1+(E_s/E_{ca})\rho} \tag{5}$$

By the principle of superposition, the experimental load-strain curves of the RC ties were adjusted to discount for the shrinkage. The superposition was applied to every discrete point along the stress-strain response to yield the target points for deriving the tension stiffening law herein. The target points with eliminated shrinkage effect are shown in Figures 1 and 2.

Theoretically, by virtue of Eqs (4) and (5), the tension-stiffening stress will be dependent on the reinforcement ratio. Nevertheless, the proposed law in Eq. (1) could provide acceptable results without significant error. Hence, the authors are of the view to simplify the model to omit the dependence on ρ.

Comparison with Eurocode 2

Stress-strain relationships of RC ties with different concrete strengths can be derived based on the proposed tension-stiffening law. The tension-stiffening stress curves corresponding to concrete grades C25, C35, C45 and C55 are plotted in Figure 3 for comparison with the Eurocode 2. The calculation procedures of tension-stiffening relationships for the RC ties according to Eurocode 2 are as follows. The governing equation relating the tensile strain and tensile stress is expressed in terms of the deformation parameter α as:

$$\varepsilon_m/\varepsilon_{cr} = \alpha/\left(f_{ctm,EC2}/E_{cm}\right) \tag{6}$$

where ε_{cr} is the cracking strain, $f_{ctm,EC2}$ is the mean tensile strength, and E_{cm} is the mean elastic modulus of concrete.

The deformation parameter α varies between the value at uncracked condition α_{I} and the value at fully cracked condition α_{II}, and the variation of α is described by the distribution coefficient ζ.

$$\alpha = \zeta\alpha_{\mathrm{II}} + (1 - \zeta)\alpha_{\mathrm{I}} \tag{7}$$

The variables in Eq. (7) are given mathematically by:

$$\zeta = 1 - \beta(P_{cr}/P)^2 \tag{8}$$

$$\alpha_{\mathrm{I}} = P/(A_c E_c + A_s E_s) \tag{9}$$

$$\alpha_{\mathrm{II}} = P/(A_s E_s) \tag{10}$$

In Eqs (8) to (10), β is a coefficient taking account of the influence of duration of loading or repeated loading and it has the value of 1.0 for short-term loading and 0.5 for sustained loading or repeated loading, P is the axial load, P_{cr} is the axial load at cracking, A_c is the cross sectional area of concrete, and E_s is the modulus of elasticity of reinforcing steel.

From the above, the equation of stress-strain relationship in Eurocode 2 can be expressed as:

$$\sigma_{ct}/f_{ctm,EC2} = \left(\frac{P-\alpha E_S A_S}{A_c}\right)/f_{ctm,EC2} \tag{11}$$

By using Eq. (11), stress-strain relationships of RC ties with reinforcement ratios varied amongst 0.2%, 0.5%, 1.0% and 2.0% were derived and they are included in Figure 3. As can be seen from the figure, the tension-stiffening relationships obtained from Eurocode 2 show a strong dependence on the reinforcement ratio, while the role of concrete grade is less influential on the normalized stress. The proposed law best fits the Eurocode 2 relationship of RC ties with reinforcement ratio of 2.0%.

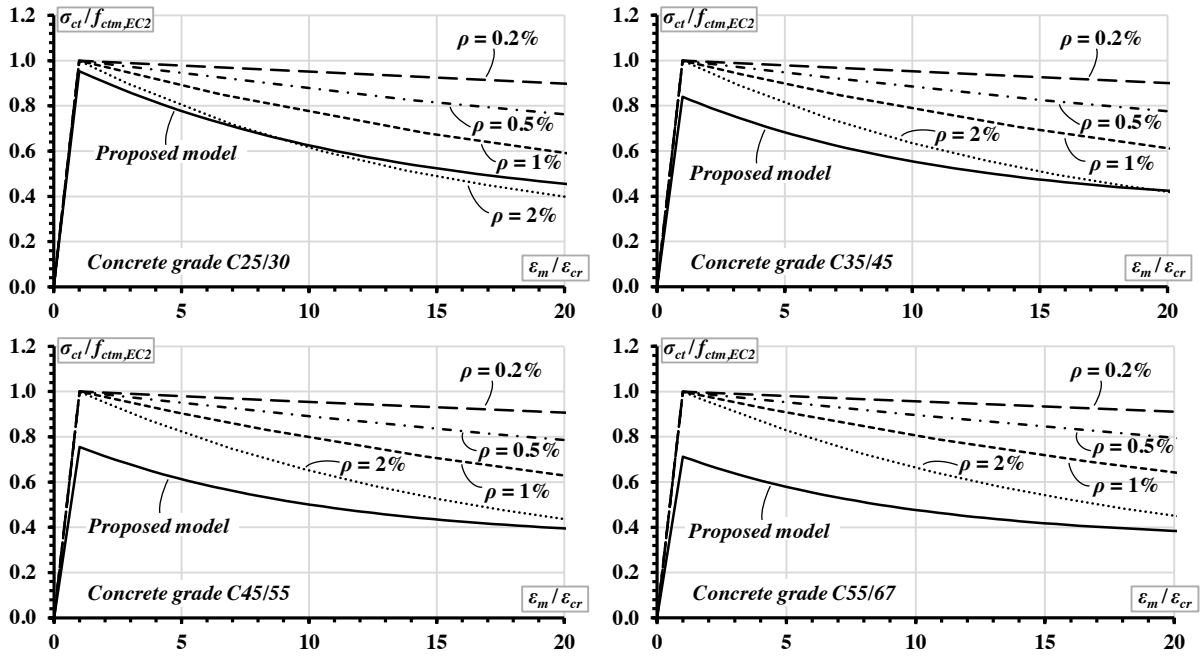

Figure 3. The proposed model compared to the tension-stiffening relationships obtained from Eurocode 2

STATISTICAL ANALYSIS OF STRAIN PREDICTIONS

The tensile strains of experimental specimens were compared with those predicted based on Eurocode 2. To conduct the analysis, ten levels of load intensity *P'* taken in relative terms between the cracking and ultimate tensile forces are established:

$$P' = (P - P_{cr})/(P_{ult} - P_{cr})\,;\; P' = \{0.1; 0.2; \ldots; 0.9; 1\} \tag{12}$$

where P_{ult} denotes the theoretical ultimate tensile force assuming the yielding strength of reinforcement f_y = 500 MPa. The cracking load P_{cr} is given by:

$$P_{cr} = f_{ct}(A_c + \eta A_s). \tag{13}$$

In the above, f_{ct} is the tensile strength of concrete, and η is the modular ratio and is equal to E_s/E_c. Thus, when *P'* is equal to 0, it corresponds to cracking; and when *P'* is equal to 1, it corresponds to the theoretical failure of the RC element.

The accuracy of predictions was evaluated by means of the relative error $\Delta_{i,k}$, which is calculated at each level of *P'* for each of the 136 experimental members:

$$\Delta_{i,k} = \varepsilon_{calc}/\varepsilon_{obs}\,, \quad i = 1;2;3;\ldots;10, \quad k = 136; \tag{14}$$

in which ε_{calc} and ε_{obs} are the strains interpolated at the level *P'* from calculation and from original test data, respectively. It should be noted that not all specimens contained eleven output points as their testing was terminated before the stress of reinforcement reached 500 MPa. The transformation resulted in 654 output points covering the post-cracking stage (compare to 3498 measured points).

It was intended at each normalized load level to define intervals of reinforcement ratio with normal probability distribution of relative error Δ. Such stratification aims at improving the reliability of strain prediction method. Analysis of the data has resulted in two such intervals:

$$1: p < 1.6\%; \quad 2: p \geq 1.6\%. \tag{15}$$

After applying the stratification based on the above intervals, the mean m_Δ and standard deviation s_Δ were calculated at each normalized load level. The statistics for each of the strain calculation method are presented in Table 2.

Table 2. Statistics (mean and standard deviation) for analytical strain calculations

0.9	10	0.556	0.358	15	0.624	0.272	9	0.909	0.059	9	1.012	0.045
1	10	0.570	0.365	11	0.689	0.277	8	0.910	0.054	9	1.015	0.038

Graphical representation of the statistical analysis results is given in Figure 4, where the 95% confidence intervals of expectation μ_Δ for the grouped data are shown. The width of confidence intervals characterizes the variations of the relative error of predictions:

$$\mu_\Delta \in \left[m_\Delta - t_{1-\alpha/2}(n-1) \times \frac{s_\Delta}{\sqrt{n}};\ m_\Delta + t_{1-\alpha/2}(n-1) \times \frac{s_\Delta}{\sqrt{n}}\right] \tag{16}$$

where $t_{1-\alpha/2}(n-1)$ is the *t*-statistics (i.e. following Student's *t*-distribution) having (*n*–1) degrees of freedom and significance level $\alpha/2$, and (1–α) is confidence coefficient.

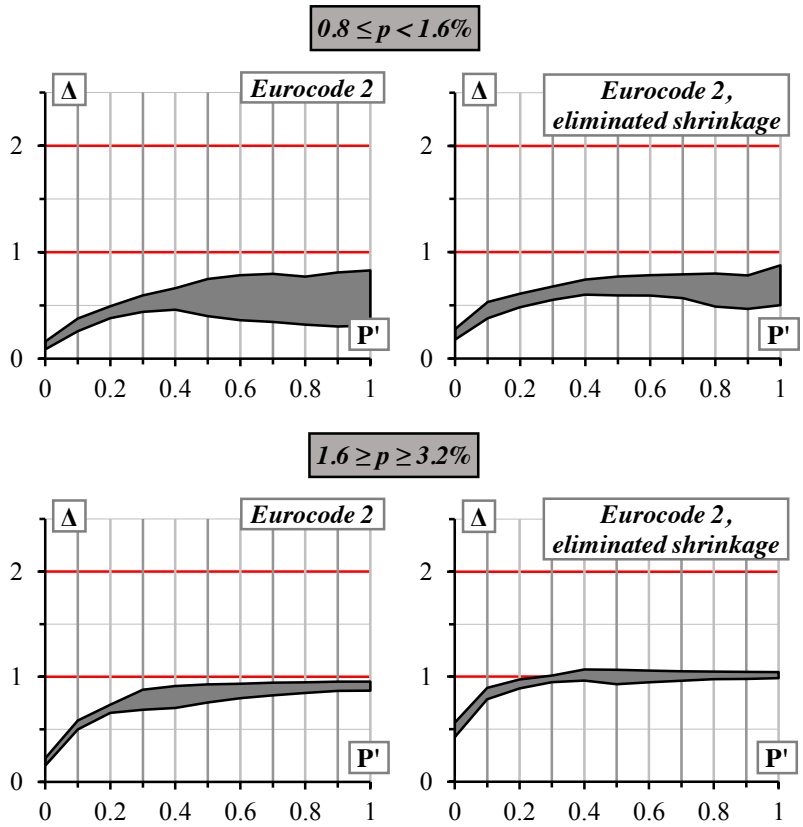

Figure 4. 95% confidence intervals ($0.8 \leq p \leq 3.2\%$)

From Figure 4, it is evident that the accuracy of strain predictions by Eurocode 2 varied significantly with the load intensity and amount of reinforcement. Generally, Eurocode 2 notably underestimated strains, particularly in the lightly reinforced members (p < 1.6%), for which the predictions on average were only 50% of the experimental values. Higher accuracy was achieved for the members with larger amounts of reinforcement with the predictions on average reaching 80% of the test results. However, at earlier loading stages, the accuracy of strain predictions was worse.

To reveal the shrinkage influence on the Eurocode 2 predictions, separate analysis was performed using the experimental load-strain relationships with elimination of the shrinkage effect, which is assessed in accordance with the provisions in Eurocode 2. In this case, the predictions for the members with higher reinforcement ratio became more accurate even at earlier loading stages, whereas the error for the lightly reinforced ties was reduced remarkably to about 20%. Elimination of the shrinkage effect also led to a much smaller scatter of the predictions with maximum standard deviation decreased by 30% among the lightly reinforced members (p < 1.6%) (refer to Table 2). Hence, by accounting for the shrinkage effect, the accuracy of strain prediction could be significantly improved. Desirable results in terms of consistency and variation are obtained. These findings of RC ties echo with the research findings by Gribniak *et al*. (2013c), who reported significant improvement in deflection prediction of RC beams by accounting for the shrinkage effect, as compared to the provisions in Eurocode 2.

CONCLUSIONS

A new law of tension-stiffening with exclusion of shrinkage effect has been developed. It is based on the test data of 11 experimental programs encompassing 136 reinforced concrete (RC) ties of various strength classes covering a wide range of characteristics of mechanical and geometrical parameters including compressive strength of concrete, reinforcement ratio and diameter of reinforcement bars. A distinctive feature of the proposed constitutive law is the expression of tension-stiffening stresses in terms of the compressive strength of concrete, thereby avoiding the uncertainty and empiricism of the equations determining the tensile strength of concrete. Based on the proposed law, the stress-strain relationships of RC ties of concrete grades C25, C35, C45 and C55 have been derived and compared with the Eurocode 2 formulations. Among the different reinforcement ratios of 0.5%, 1.0%, 1.5% and 2.0% considered for the Eurocode 2 relationship, it has been found that the proposed law best fits the Eurocode 2 curves of reinforcement ratio equal to 2.0%.

Statistical analysis of results from experimental programs and strain predictions of the RC ties using Eurocode 2 was performed. The analysis has evaluated the adequacy of the application of Eurocode 2. The following main conclusions can be drawn:

1. Accuracy of strain predictions by the Eurocode 2 varied significantly with load intensity and amount of reinforcement.
2. The Eurocode 2 significantly underestimated strains of the RC ties. For the lightly reinforced members (p < 1.6%), the predictions on average was approximately 50% of the experimental values. Higher accuracy was achieved for the members with larger amounts of reinforcement with the predictions on average reaching 80% of the test results. Generally, at earlier loading stages, the accuracy of strain predictions was worse.
3. The Eurocode 2 technique appears to be a much more accurate tool for predicting strains in the RC ties, if the prediction results are compared to the test results with the elimination of shrinkage effect. In the case of heavily reinforced ties, the predictions become more accurate even at earlier loading stages, whereas the error for the lightly reinforced ties is reduced to about 20%. Elimination of the shrinkage effect also led to much smaller scatter of the predictions.

ABSTRACT

Cracks occur in reinforced concrete structures wherever and whenever the tensile stress in the concrete reaches the tensile strength of the concrete. After concrete sets and hardens, tensile stress at any location may be caused by factors such as early-age heat of hydration, applied loads, restrained shrinkage, temperature changes, settlement of the supports and so on. This paper deals with the control of cracking caused by restraint to early-age cooling and shrinkage of concrete. Such cracking is inevitable in many situations and a significant amount of reinforcement crossing each crack is required for crack control. Rational procedures are proposed for determining the effects of internal restraint and external restraint, including restraint provided by embedded reinforcement and both end-restraint and side-restraint that may exist at the supports of beams, slabs and walls. Guidance is also provided for estimating the maximum width and spacing of cracks in a variety of situations.

Cracking, crack control, heat of hydration, shrinkage, reinforced concrete, restraint.

INTRODUCTION

Cracking in reinforced concrete structures is common and normal. In some situations, it is inevitable. Cracks occur wherever and whenever the tensile stress in the concrete reaches the tensile strength of the concrete. After the concrete sets and hardens, tensile stress at any location may be caused by many different factors, including early-age heat of hydration, applied loads, restrained shrinkage, temperature changes, settlement of supports and so on. Cracks caused predominantly by the internal actions resulting from the applied loads are often termed *structural cracks*, while cracks caused by restraint to load-independent deformation, including deformations due early-age cooling, shrinkage or ambient temperature changes, are termed *intrinsic cracks*. Often cracks are initiated by a combination of causes. For example, the bending moment at which cracking occurs in a beam or slab may be significantly reduced if tensile stresses caused by restraint to early-age temperature contractions and shrinkage have developed in the member before loading. Shrinkage induced deformation may also cause significant increases in crack widths with time.

Many variables influence the width and spacing of cracks, including the magnitude and duration of loading, the quantity, orientation and distribution of the reinforcement crossing the crack, the cover to the reinforcement, the bond characteristics of the reinforcement, the deformational properties of the concrete (including its creep and shrinkage characteristics) and the size of the member. Considerable variations exist in the crack width from crack to crack and in the spacing between adjacent cracks, because of random variations in the properties of the in-situ concrete.

Control of cracking in concrete structures is often achieved by limiting the stress in the bonded reinforcement at the cracked section to some appropriately low value and ensuring that the bonded reinforcement is suitably distributed within the tensile zone. Building codes usually specify the maximum bar spacing for bonded reinforcement and the maximum concrete cover. Some codes specify deterministic procedures for calculating crack widths, with the intention to control cracking by limiting the calculated crack width to some appropriately low value. However, the influence of shrinkage on crack widths is not properly considered in the major building codes and is therefore often not adequately considered in structural design. As a consequence, excessively wide cracks are a relatively common problem for many reinforced concrete structures throughout the world.

This paper deals with the control of intrinsic cracking caused by restraint to early-age cooling and shrinkage of concrete. Rational procedures are proposed for determining the effect of restraint and the development of tensile stresses in the concrete. Guidance is also provided for estimating the maximum width and spacing of cracks in a variety of situations

EARLY-AGE THERMAL STRESSES AND STRAINS

Heat of hydration in a concrete element in the first day or so after casting rises to a peak value and then dissipates. The peak temperature T_{peak} depends on the cement content, the thickness of the concrete element and the placement temperature. As the concrete element cools, restraint to the early-age contraction may cause cracking in the immature concrete. In many situations, early-age thermal cracking cannot be avoided, but it can be controlled by avoiding excessive heat of hydration, reducing restraint where possible and using an adequate quantity and distribution of reinforcement crossing the cracks.

In concrete elements, calculation of the tensile stresses that initiate cracking is complicated by the changing elastic modulus of the young concrete and the relaxation of stress resulting from tensile creep of the concrete. The change in temperature with time due to heat of hydration in a restrained concrete element is $\Delta T = \pm(T - T_a)$, where T is the temperature at any time and T_a is the mean ambient temperature. ΔT is taken to be positive for a rise in temperature and negative for a drop in temperature. The corresponding free temperature strain is $\varepsilon_T = \alpha_c \Delta T$, where α_c is the coefficient of thermal expansion for concrete. The actual strain ε_{actual} measured at a point in the member is significantly different from ε_T and the difference $\varepsilon_r = (\varepsilon_{actual} - \varepsilon_T)$ is the stress related strain resulting from restraint and consists of elastic and creep strains. After the temperature has dropped from T_{peak} to T_a at time t_a (i.e. $\Delta T_{max} = T_a - T_{peak}$), the tensile restrained strain due to temperature is given by:

$$\varepsilon_{r.ta} = -\alpha_c \, \Delta T_{max} \, R \tag{1}$$

where R is a restraint factor that depends on the thickness of the concrete element, the shape of the temperature differential across the member and the restraint provided by adjacent members and supports (i.e. the external boundary conditions). Determination of the restraint factor R is discussed subsequently.

In the design for early-age crack control, along with the temperature induced strain, it is prudent to include the autogenous shrinkage strain ε_{cse} that will have developed at time t_a, so that the total restrained strain at time t_a is given by:

$$\varepsilon_r = -\left(\alpha_c \Delta T_{max} + \varepsilon_{cse}\right) R \tag{2}$$

remembering that ε_{cse} is contraction (negative) and so too is $\alpha_c \Delta T_{max}$. Bamforth (2007) suggested that for the assessment of early-age cracking, the autogenous shrinkage at age 3 days should be considered.

The stress induced by the restraint to early thermal strains is initially compressive during heating, but due to the low elastic modulus and the high creep strains in the first few hours after initial set when the temperature is rising, the compressive stresses are relatively small. The stress becomes tensile as the concrete cools. Creep also relieves the tensile stress caused by cooling. Provided cracking has not occurred, the restrained strain in Eq. 2 can be expressed in terms of the tensile stress (σ_r) at time t_a as

$$\varepsilon_r = \varepsilon_{elastic} + \varepsilon_{creep} = (\sigma_r / E_c) + \chi\varphi(\sigma_r / E_c) \tag{3}$$

where φ is the creep coefficient associated with the heat of hydration time period and χ is an aging coefficient to account for the fact that σ_r is gradually applied to the concrete. Before cracking, the stress caused by restraint σ_r may therefore be determined from the restrained strain (given by Eq. 2) using:

$$\sigma_r = \varepsilon_r \overline{E}_e \tag{4}$$

where $\overline{E}_e$ is the age-adjusted effective modulus of the concrete given by:

$$\overline{E}_e = E_c / (1 + \chi\varphi_{cc}) \tag{5}$$

If cracking occurs, part of the average restrained strain (measured over a gauge length greater than the crack spacing) is relieved by the crack formation. This portion of the restrained strain is termed the *crack-induced strain* $\varepsilon_{r.cr}$ and is important for the calculation of crack widths. The restrained stress at the crack is zero and the average tensile stress between the cracks is now

$$\sigma_r = (\varepsilon_r - \varepsilon_{r.cr}) \overline{E}_e \tag{6}$$

Bamforth (1982) suggested that over the early age thermal cycle, creep reduces the stress by about 35%, while others have suggested that the reduction of stress due to creep is up to 50%. Taking $\chi\varphi$ =0.65 in Eq. 5 corresponds to reduction in stress of about 40% due to creep and is recommended here.

To avoid early-age thermal and shrinkage cracking, the tensile stress induced by restraint σ_r (Eq. 4) must be less than the direct tensile strength of the concrete at time t_a, $f_{ct}(t_a)$, which may be taken from:

For t_a = 3 days: $\quad f_{ct}(t_a) = 0.24 \sqrt{f_{cm}(28)}$ in MPa (7a)

For $t_a \geq$ 28 days: $\quad f_{ct}(t_a) = 0.40 \sqrt{f_{cm}(28)}$ in MPa (7b)

and $f_{cm}(28)$ is the mean compressive strength of the concrete at age 28 days in MPa.
Even if early-age thermal cracking does not occur, the stress σ_r should not be ignored. Additional stresses caused by restraint to subsequent shrinkage strains (both autogenous and drying shrinkage) may increase the tensile restraining stress to the tensile strength of the concrete and cause cracking. The design process for the control of cracking is the same, whether the tensile stress that causes cracking is caused by restraint to early-age temperature change or due to subsequent shrinkage, and the control of such cracking requires an adequate quantity and distribution of steel reinforcement.

RESTRAINT FACTORS

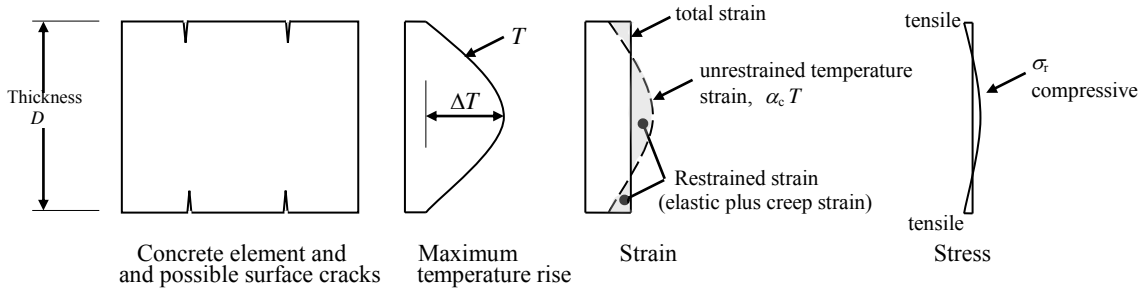
Internal restraint to temperature differentials

Consider a concrete element subjected a temperature differential across its thickness, as shown in Figure 1, with no external restraint and no embedded reinforcement. During hydration soon after setting, the temperature rises to its peak value at the centre of the member, dropping to its minimum value at the surfaces of the member, as shown in Figure 1a. The change in temperature between the concrete surface and the interior of the member is ΔT, as shown. As the temperature rises and the interior expands to a greater extent than at the surface, the surface is subjected to tensile stresses (due to the restrained tensile strain) and the interior of the member is in compression. These restrained stresses, known as *eigenstresses*, are self-equilibrating. If the temperature differential is high enough, cracking may occur at the concrete surfaces and the restrained stresses drop substantially. Even if cracking does not occur, at these elevated temperatures and at this very early age, the elastic modulus of concrete is low, creep is high and the stresses that develop during heating are rapidly relieved.

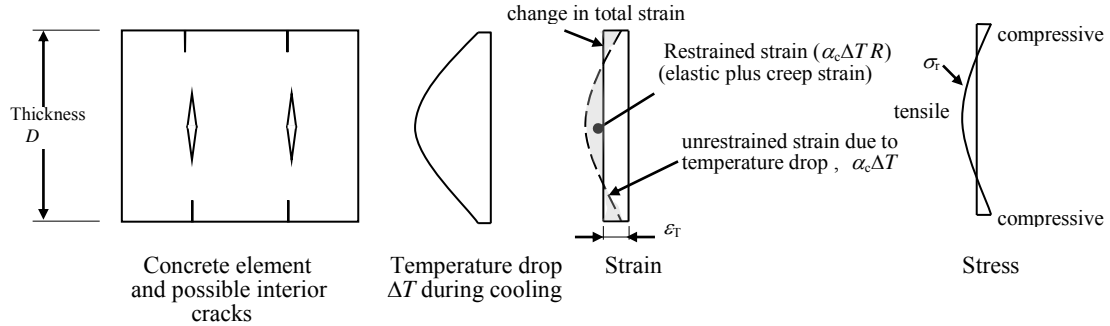
The restrained strain is calculated ignoring autogenous shrinkage which is uniform through the member thickness and does not contribute to the strain differential. As cooling takes place, after the peak temperature has been reached, the interior of the member cools and contracts more than the surface and tension develops at the interior of the member, as shown in Figure 1b. The concrete is now a little more mature, with a higher modulus, and the concrete stresses are often sufficiently high to cause interior cracks to develop, as shown. The maximum tensile stress that develops at the interior of the member before cracking is

$$\sigma_r = -\alpha_c \Delta T \, R \, \bar{E}_e \tag{8}$$

In Eq. 8, ΔT is negative, as it represents a drop in temperature. After cracking, the restrained stress drops, the crack-induced strain $\varepsilon_{r.cr}$ increases and the cracks will open with time due to restrained drying and autogenous shrinkage. Shrinkage may cause the interior cracks and the surface cracks that have developed during the heat of hydration cycle to join, resulting in full depth cracking.



(a) Strain and stress at peak temperatures



(b) Strain and stress during cooling phase

Figure 1 Development of strain, stress and possible cracking in a thick element due to early-age temperature differentials.

At the interior of the member, where both the temperature drop and the restrained tensile stress is greatest, the restraint factor R is readily determined by simple mechanics and depends on the temperature profile, which in turn depends on the mix characteristics, the member thickness and the environmental conditions. For a parabolic temperature profile, R = 0.33. For a triangular temperature gradient, R = 0.5. Bamforth (2007) recommended that R is taken as 0.42. A value of 0.4 is recommended here.

Internal restraint provided by embedded reinforcement

Symmetrically reinforced sections:

Consider the unreinforced and unrestrained concrete member of length L shown in Figure 2a and the symmetrically reinforced concrete member shown in Figure 2b. Except for the inclusion of longitudinal steel reinforcement of area A_s symmetrically placed about the centroid of the cross-section in the second member, the two members are identical. A gradual compressive strain in the concrete ε_{free} caused by early age cooling ε_T (shown in Figure 1b) and concrete shrinkage ε_{cs} would cause the unreinforced member to shorten by an amount $\varepsilon_{free} L = (\varepsilon_T + \varepsilon_{cs})L$, as shown in Figure 2a. If early-age cracking is being considered immediately after the heat of hydration cycle, ε_{cs} is equal to the autogenous shrinkage at 3 days. If restraint cracking is being investigated at a later time t, ε_{cs} is the sum of the autogenous and drying shrinkage strain components at that time (i.e. $\varepsilon_{cs} = \varepsilon_{cse} + \varepsilon_{csd}$).

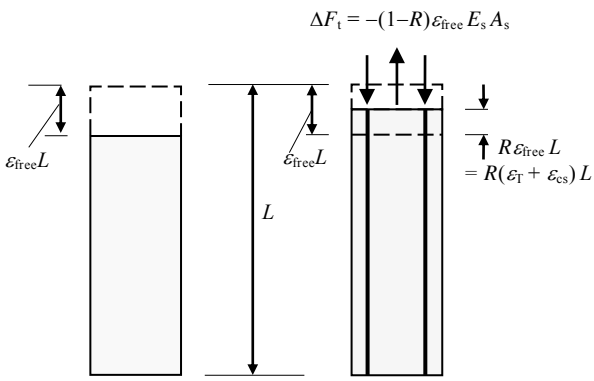


Figure 2 Internal restraint in a symmetrically reinforced concrete member.

The shortening deformation ε_{free} of the concrete in the reinforced member (Figure 2b), causes a gradual build-up of compression in the bonded reinforcement and this is opposed by an equal and opposite tensile force ΔF_t applied to the concrete. The gradually increasing tensile force results in tensile elastic strain and tensile creep strain, and the overall shortening of the member is reduced to $(1-R)\varepsilon_{free} L$ (as shown in Figure 2b), where R is the restraint factor ($0 \le R \le 1.0$), that depends on the amount of reinforcement. The stress in the steel σ_s and the compressive force in the steel F_s are:

$$\sigma_s = (1-R)\varepsilon_{free}\, E_s \tag{9a}$$

and

$$F_s = (1-R)\varepsilon_{free}\, E_s A_s \tag{9b}$$

where E_s is the elastic modulus of the steel. The reinforced concrete member is shortening, but it is subjected to tensile force that could possibly result in, or contribute to, cracking.

Using the age-adjusted effective modulus method for the time-dependent analysis of the member in Figure 2b, it can be readily shown (Gilbert and Ranzi, 2011) that the compressive concrete strain ε_c at time t caused by a free shortening strain of ε_{free} (= $\varepsilon_T + \varepsilon_{cs}$) and the restraint factor R are given by:

$$\varepsilon_c = (1-R)\varepsilon_{free} = \varepsilon_{free} / \left(1 + \bar{n}_e p\right) \tag{10}$$

$$R = \bar{n}_e p / \left(1 + \bar{n}_e p\right) \tag{11}$$

and the concrete tensile stress σ_{cs} at time t induced by the restraint to ε_{free} is given by

$$\sigma_{cs} = -\varepsilon_{free} E_s p / \left(1 + \bar{n}_e p\right) \tag{12}$$

where $\bar{n}_e$ is the age adjusted modular ratio ($= E_s / \bar{E}_e$), p is the reinforcement ratio (= A_s/A_c), and $\bar{E}_e$ is the age-adjusted effective modulus of the concrete given in Eq. 5.

The creep coefficient for use in Eq. 5 (φ) is the tensile creep coefficient at time t due to a stress first applied when contraction commenced. As already mentioned, when considering restraint immediately after the heat of hydration cycle, $\chi\varphi$ may be taken as 0.65. When considering the possibility of cracking after say 1 month, $\chi\varphi$ should not be taken greater than 1.8.

Taking E_s = 200000 MPa, E_c = 20000 MPa, $\chi\varphi$ = 1.625 (typical concrete properties for 30 MPa concrete when considering the possibility of restrained cracking at age 1 month), the restraint factor R is determined using Eq. 11 and is given in Table 1 for a wide range of reinforcement ratios. Also shown in Table 1 is the concrete tensile stress σ_{cs} induced by a free strain of $\varepsilon_{free} = \varepsilon_T + \varepsilon_{cs} = -600\times10^{-6}$. Even when these concrete stresses may not initiate cracking in the absence of other actions, such as when p is less than about 2.0%, they will substantially reduce the applied load required to cause cracking. Of course, this analysis assumes that the concrete

is uncracked and that the tensile stress σ_{cs} can develop in the concrete. If any early-age cracking occurs at the end of the initial cooling period, the concrete in the vicinity of that crack cannot carry tension and the crack will open due to the subsequent shrinkage.

Table 1 Internal restraint factor for symmetrically reinforced sections.

$p = A_s/A_c$	0.002	0.005	0.01	0.015	0.02	0.025	0.03	0.035	0.04
R	0.050	0.116	0.208	0.283	0.344	0.396	0.441	0.479	0.512
σ_{cs} (MPa)	0.23	0.53	0.95	1.29	1.57	1.81	2.01	2.19	2.34

Unsymmetrically reinforced sections:

If the reinforcement is not symmetrically placed on a section, restraint to early-age thermal and shrinkage contraction will induced a curvature on the cross-section and a concrete tensile stress that may initiate cracking. Consider the singly-reinforced member shown in Figure 3a and the small segment of length, Δz. The shrinkage/temperature-induced stresses and strains on an uncracked and on a previously cracked cross-section are shown in Figures 3b and 3c, respectively. As the concrete shrinks, with a free strain of $\varepsilon_{free} = \varepsilon_T + \varepsilon_{cs}$, the steel reinforcement is compressed and, in turn, the steel imposes an equal and opposite tensile force δF_t on the concrete at the level of the steel. This gradually increasing tensile force, acting at some eccentricity to the centroid of the concrete cross-section produces elastic plus creep strains and a resulting curvature on the section. The shrinkage-induced curvature often leads to significant load independent deflection of the member. The magnitude of δF_t (and hence the shrinkage induced curvature) depends on the quantity and position of the reinforcement and on whether or not the cross-section has previously cracked.

The curvature caused by ΔF_t obviously depends on the size of the (uncracked) concrete part of the cross-section, and hence on the extent of cracking, and this in turn depends on the magnitude of the applied moment and the quantity of reinforcement. For an uncracked section, the restraint factor depends on the reinforcement ratio. Taking E_s = 200000 MPa, E_c = 20000 MPa, $\chi\varphi$ = 1.625 and d/D = 0.9, the restraint factor R for the uncracked rectangular singly-reinforced cross section shown in Figure 3b has been determined using the age-adjusted effective modulus method and is given in Table 2 for a wide range of reinforcement ratios p ($=A_s/bD$). The restraint factor R, the restraining force ΔF_t and the extreme fiber concrete tensile stress σ_{cs}, caused by a uniform free strain of magnitude $\varepsilon_{free} = \varepsilon_T + \varepsilon_{cs}$ may be approximated by:

$$R = \frac{\bar{n}_e p(1+\lambda_1)}{1+\bar{n}_e p(1+\lambda_1)} \;;\; \Delta F_t = \frac{-\varepsilon_{free} E_s A_s}{1+\bar{n}_e p(1+\lambda_1)} \text{ and } \sigma_{cs} = \frac{-\varepsilon_{free} E_s p(1+\lambda_1\lambda_2)}{1+\bar{n}_e p(1+\lambda_1)} \qquad (13a,b,c)$$

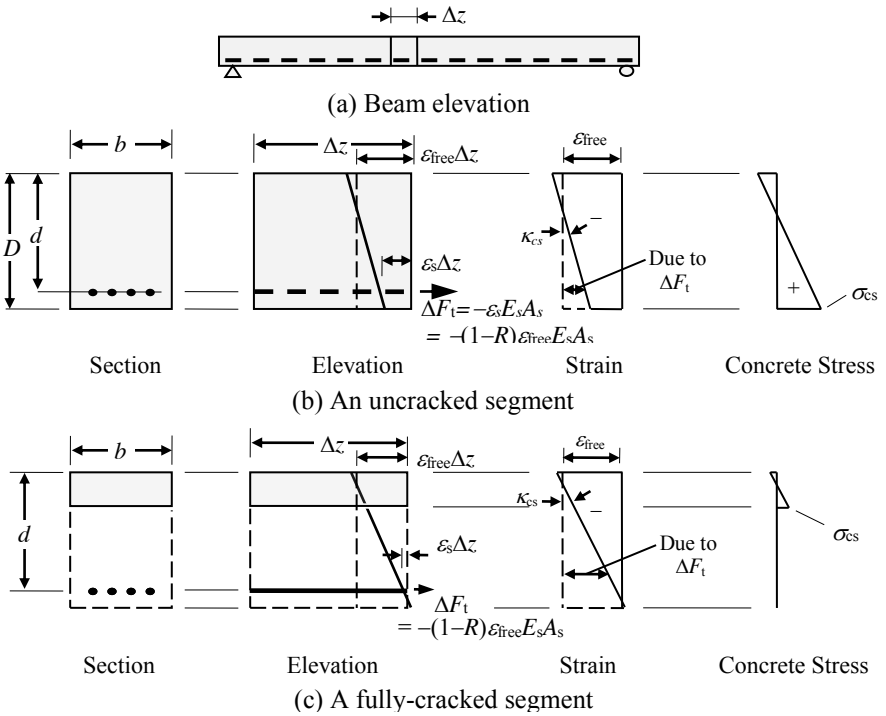

Figure 3 Shrinkage-induced deformation and stresses in a singly-reinforced beam.

where λ_1 and λ_2 depend on the geometry of the cross-section and are given by:

$$\lambda_1 = 12\,[(d/D) - 0.5]^2 \qquad \text{and} \qquad \lambda_2 = 0.5D/(d - 0.5D) \tag{14a, b}$$

Also shown in Table 2 is the extreme fiber concrete tensile stress σ_{cs} induced by a uniform free strain of $\varepsilon_{free} = \varepsilon_\Gamma + \varepsilon_{cs} = -600\times10^{-6}$.

For a cracked section, the restraint factor is close to 1.0. Taking E_s = 200000 MPa, E_c = 20000 MPa, $\chi\varphi$ = 1.625, the restraint factor R for the cracked singly-reinforced cross-section shown in Figure 3c has been determined using the age-adjusted effective modulus method and is given in Table 3 for a wide range of reinforcement ratios p (=A_{st}/bD). Also shown in Table 3 is the extreme fiber concrete tensile stress σ_{cs} at the bottom of the uncracked part of the concrete induced by a uniform free strain of magnitude $\varepsilon_{free} = \varepsilon_\Gamma + \varepsilon_{cs} = -600\times10^{-6}$. Although shrinkage strain is independent of stress, it appears that shrinkage curvature is not independent of the external load. The shrinkage induced curvature on a previously cracked cross-section is considerably greater than on an uncracked cross-section, as can be seen in Figure 3.

Edge restraint in a slab or wall

Frequently, walls and slabs are subjected to *edge (or side) restraint*, where shortening due to early-age contraction and shrinkage is restrained on one or more sides of the element. Examples of side restraint are shown again in Figure 4. In Figure 4a, contraction in the secondary direction of the one-way slab is restrained by the more massive supporting beams (that will be contracting at a slower rate than the slab). The restraining forces applied to the slab along each supported edge cause a direct tension in the secondary direction of the slab that may cause the cracking shown in the isometric view. The spacing and width of these cracks depend on the amount and distribution of reinforcement in the secondary direction of the slab. Figure 4b shows a wall where contraction ($\varepsilon_{free} = \varepsilon_\Gamma + \varepsilon_{cs}$) is restrained on one edge by the footing. The restraint to contraction may result in cracking, initiated at the base of the wall, where the resultant of the tensile restraint force is acting, and then extending the full height of the wall, as shown in the isometric view. A wall restrained on two adjacent edges is shown in Figure 4c, together with crack pattern initiated by restrained shrinkage in the two orthogonal directions. The cracks resulting from restrained shrinkage are direct tension cracks caused by the tensile restraining force(s), F_t. They generally extend completely through the restrained slab and, if uncontrolled, can become unserviceable and lead to waterproofing and corrosion problems. They may even compromise the integrity of the member.

Consider the wall and footing shown in cross-section in Figure 5a. Using the notation specified in the figure, the area, section modulus and second moment of area about the centroid of the wall are $A_1 = D_1h_1$, $Z_1 = D_1h_1^2/6$ and $I_1 = D_1h_1^3/12$ and, for the footing, $A_2 = D_2h_2$, $Z_2 = D_2h_2^2/6$ and $I_2 = D_2h_2^3/12$. If the wall is cast at some time after the base, it will be cooling and shrinking at a faster rate than the base. At some time t after the wall is cast, the free contraction strain in the wall is $\varepsilon_{free.1} = \varepsilon_{\Gamma.1} + \varepsilon_{cs.1}$, while the contraction of the base is $\varepsilon_{free.2} = \varepsilon_{cs.2}$ (where $\varepsilon_{free.2} < \varepsilon_{free.1}$). The elastic modulus, creep coefficient, aging coefficient for the wall and base are $E_{c.1}$, φ_1, χ_1 and $E_{c.2}$, φ_2, χ_2, respectively. The corresponding age-adjusted effective moduli $\overline{E}_{e.1}$ and $\overline{E}_{e.2}$ are determined using Eq. 5. The self-equilibrating restraining forces that develop with time, F_t (tensile) in the wall and $-F_t$ (compressive) in the base, act at a distance $\bar{y}$ below the interface between the wall and the base, as shown in the elevation in Figure 5b. The longitudinal strains and stresses are shown in Figures 5c and 5d. It can be readily shown that distance $\bar{y}$ depends on the age-adjusted flexural rigidities of the wall and the base, $\overline{R}_{I.1} = \overline{E}_{e.1}I_1$ and $\overline{R}_{I.2} = \overline{E}_{e.2}I_2$, and is given by:

$$\bar{y} = 0.5(h_2\overline{R}_{I.1} - h_1\overline{R}_{I.2})/(\overline{R}_{I.1} + \overline{R}_{I.2}) \tag{15}$$

The restraining force F_t depends on the age-adjusted axial and first moment rigidities and the difference in free contraction of the wall and base, $\Delta\varepsilon_{free} = \varepsilon_{free.1} - \varepsilon_{free.2}$ and may be obtained by enforcing strain compatibility at the wall-footing interface giving:

Figure 5 Restraint actions, strains and stresses in an edge-restrained wall.

$$F_t = -\Delta\varepsilon_{free}/(\bar{a}_1 + \bar{a}_2 + \bar{b}_1 + \bar{b}_1) \tag{16}$$

where $\bar{a}_{.1} = 1/(\bar{E}_{e.1}A_1)$, $\bar{a}_2 = 1/(\bar{E}_{e.2}A_2)$, $\bar{b}_1 = e_1/(\bar{E}_{e.1}Z_1)$ and $\bar{b}_2 = e_2/(\bar{E}_{e.2}Z_2)$. The terms e_1 and e_2 are the distances from the line of action of F_t to the centroids of the wall and the base, respectively, i.e. $e_1 = 0.5h_1 + \bar{y}$ and $e_2 = 0.5h_2 - \bar{y}$. The tensile stress at the bottom of the wall caused by the restraining force F_t is

$$\sigma_{cs} = (F_t/A_1) + F_t(\bar{y} + 0.5h_1)/Z_1 \tag{17}$$

and the restrained strain ε_r at this point and the corresponding restraint factor R is

$$\varepsilon_r = \sigma_{cs}/\bar{E}_{e.1} \quad \text{and} \quad R = \varepsilon_r/\Delta\varepsilon_{free} = \sigma_{cs}/\bar{E}_{e.1}\Delta\varepsilon_{free} \tag{18a, b}$$

CRACKING CAUSED BY EDGE RESTRAINT

Before cracking, the deformation resulting from a restraining force F_t over a gauge length L_o is $\varepsilon_r L_o = (\sigma_{cs}/\bar{E}_e)L_o$. When the concrete stress σ_{cs} exceeds the tensile strength f_{ct}, cracking occurs. The crack opens and the concrete stress at the crack drops to zero. Either side of the crack, the concrete stress gradually increases due to the steel-

concrete bond until at some distance s_o from the crack the concrete stress is unaffected by the crack. Cracks form at a spacing of between s_o and $2s_o$. If the gauge length L_o is long enough to contain m cracks, the deformation caused by restraint $\varepsilon_r L_o$ may now be expressed as

$$\varepsilon_r L_o = (\varepsilon_{r.cr} + \varepsilon_{r1}) L_o \tag{19}$$

where the *residual restrained strain* ε_{r1} is the sum of the elastic and creep strains caused by the average tensile concrete stress between the cracks and $\varepsilon_{r.cr}$ is the *crack-induced strain* (introduced in Eq. 6). The length $\varepsilon_{r.cr} L_o$ is the sum of the widths of the m cracks within the length L_o, i.e.

$$\varepsilon_{r.cr} = \left(\sum_{i=1}^{m} w_i \right) / L_o \qquad \text{and} \qquad \varepsilon_{r1} = \varepsilon_r - \varepsilon_{r.cr} = \frac{\sigma_{av}}{\overline{E}_e} \tag{20a, b}$$

In a member subjected to edge restraint (or one with restraint provided by eccentric reinforcement), the average spacing between cracks depends on the concrete cover, the bond characteristics between the reinforcement and the concrete, the bar diameter, the ratio of reinforcement area to the effective area of the tensile concrete. The maximum crack spacing $s_{r.max}$ recommended by Eurocode 2 (2004) is:

$$s_{r.max} = 3.4c + 0.425 k_1 d_b / p_{p.eff} \tag{21}$$

where c is the concrete cover to the reinforcement; k_1 depends on the bond characteristics of the reinforcement and may be taken as 0.8 for high bond bars (Eurocode 2, 2004), but when good bond cannot be guaranteed, such as when early-age cracking at $t_a = 3$ days is being considered, k_1 should be increased to 1.14; d_b is the diameter of the reinforcing bars; $p_{p.eff}$ is the ratio of the tensile reinforcement area to the effective area of the tensile concrete ($=A_{st}/A_{c.eff}$). For a wall or slab subjected to edge restraint, $A_{c.eff}$ may be taken as the gross area of the cross-section. For a member in bending, $A_{c.eff}$ is the product of the member width at the tensile steel level and $h_{c.ef}$, where $h_{c.ef}$ is the smaller of (0.5 × member thickness) and $2.5(c + d_b/2)$.

The maximum crack width w_{max} is determine from

$$w_{max} = s_{r.max} \varepsilon_{r.cr} = s_{r.max} (\varepsilon_r - \varepsilon_{r1}) \tag{22}$$

Bamforth (2007) conservatively approximated the residual strain ε_{r1} (given by Eq. 20b) by f_{ct}/E_c and therefore the crack-induced strain $\varepsilon_{r.cr}$ may be taken as:

$$\varepsilon_{r.cr} = \varepsilon_r - \varepsilon_{r1} = \varepsilon_r - (f_{ct} / E_c) \tag{23}$$

WORKED EXAMPLE

Determine the stress and strain distribution due to the restraint to early-age contraction and shrinkage of the wall shown in Figure 6a. Also determine the crack spacing and crack width at the base of the wall, if each face of the wall is reinforced with 12mm deformed bars running horizontally at 250 mm centres. The concrete cover to the steel bars is 30 mm and the bond conditions are assumed to be good. Assume that cracking occurs when $f_{ct} = 2.0$ MPa.

For the wall: $E_{c.1} = 20000$ MPa, $\varphi_1 = 2.5$, $\chi_1 = 0.65$, $\varepsilon_{free.1} = -0.0006$; and, from Eq. 5, $\overline{E}_{e.1} = 7619$ MPa.

For the footing: $E_{c.2} = 35000$ MPa, $\varphi_2 = 1.5$, $\chi_2 = 0.65$; $\varepsilon_{free.2} = -0.0002$, and, from Eq. 5, $\overline{E}_{e.1} = 17722$ MPa.

For the wall, $D_1 = 200$ mm and $h_1 = 4000$ mm, and for the base, $D_2 = 1000$ mm and $h_2 = 600$ mm. The age-adjusted rigidities are:

$\overline{R}_{A.1} = \overline{E}_{e.1} A_1 = 6.095 \times 10^9$ N; $\overline{R}_{B.1} = \overline{E}_{e.1} Z_1 = 4.063 \times 10^{12}$ Nmm;

$\overline{R}_{I.1} = \overline{E}_{e.1} I_1 = 8.127 \times 10^{15}$ Nmm^2; $\overline{R}_{A.2} = \overline{E}_{e.2} A_2 = 1.063 \times 10^{10}$ N;

$\overline{R}_{B.2} = \overline{E}_{e.2} Z_2 = 1.063 \times 10^{12}$ Nmm; and $\overline{R}_{I.2} = \overline{E}_{e.2} I_2 = 3.190 \times 10^{14}$ Nmm^2.

From Eq. 15, the distance $\bar{y}$ below the interface between the wall and the base at which the resultant restraining force F_t acts is:

$$\bar{y} = 0.5(h_2 \overline{R}_{I.1} - h_1 \overline{R}_{I.2}) / (\overline{R}_{I.1} + \overline{R}_{I.2}) = 213.1 \text{ mm}$$

and, with $\Delta\varepsilon_{free} = -0.0004$, $e_1 = 0.5h_1 + \bar{y} = 2213.1$ mm and $e_2 = 0.5h_2 - \bar{y} = 86.9$ mm, Eq. 16 gives:

$$F_t = -\Delta\varepsilon_{free} / (\bar{a}_1 + \bar{a}_2 + \bar{b}_1 + \bar{b}_1) = 452.3 \text{ kN}$$

From Eqs. 17 and 18:

$$\sigma_{cs} = (F_t / A_1) + F_t (\bar{y} + 0.5h_1) / Z_1 = 2.44 \text{ MPa};$$

$$\varepsilon_r = \sigma_{cs} / \overline{E}_{e.1} = +321 \times 10^{-6} \text{ ; and } R = \varepsilon_r / \Delta\varepsilon_{free} = 0.801$$

The longitudinal stress and strain distributions due to restrained contraction are shown in Figures 6b and 6c.

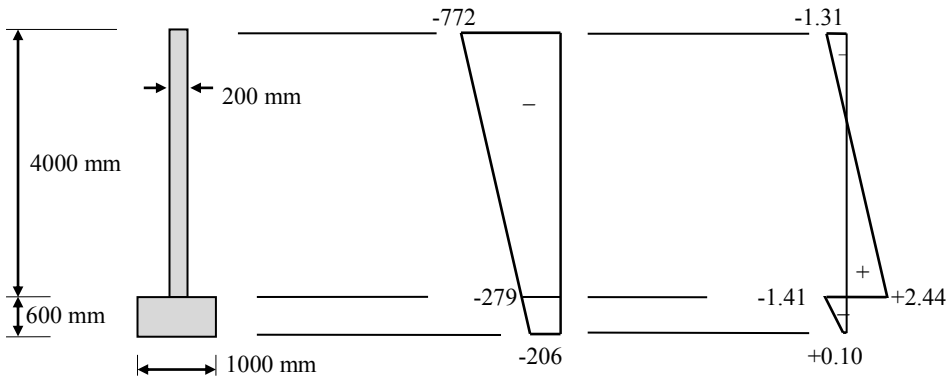

Figure 6 Cross-section of wall and footing and strain and stress distributions due to restrained deformation.

For this example, with A_{st} = 452 mm^2/m on each face of the wall, the reinforcement ratio is $p_{p.eff}$ = (2×452)/(200×1000) = 0.00452 and the maximum crack spacing is determined using Eq. 21:

$$s_{r.max} = 3.4 \times 30 + \frac{0.425 \times 0.8 \times 12}{0.00452} = 1005 \text{ mm}$$

Due to the restrained contraction at the base of the wall, $\varepsilon_r = 321 \times 10^{-6}$ and, after cracking, Eq. 23 gives:

$$\varepsilon_{r.cr} = 321 \times 10^{-6} - \frac{2.0}{20000} = 221 \times 10^{-6}$$

and the maximum crack width is calculated using Eq. 22:

$$w_{max} = 1005 \times 221 \times 10^{-6} = 0.222 \text{ mm}$$

CONCLUSIONS

Rational procedures have been proposed for determining the degree of restraint and the control of cracking caused by early-age cooling of concrete and by shrinkage of concrete. Restraining forces and concrete tensile stresses caused by temperature and shrinkage strains in a variety of situations have been considered, including concrete members subjected to temperature and/or shrinkage differentials, reinforced concrete members containing embedded reinforcement, and reinforced concrete slabs and walls subjected to edge-restraint. Calculation of the width and spacing of cracks caused by any one, or any combination, of these restraining forces is outlined and illustrated by a worked example.

ABSTRACT

It is well known that confinement introduced by CFRP (Carbon Fiber Reinforced Polymer) jackets highly increases the ultimate compressive strength and ductility of concrete. Various experimental research programs have been carried out to express the increase in strength and strain by the use of CFRP jackets, but, in the majority of cases, the additional effects of reinforcing elements, like ties or spirals, have not been analyzed very well. This paper provides investigations on wrapped short concrete columns with and without ties and spirals. In an extensive research program the volumetric ratio of the CFRP jacket and the ratio of transverse reinforcement were varied. Thereby, columns with different geometrical shape, different CFRP thickness, and different transverse reinforcement elements were produced. Executed deformation controlled compression tests provided investigations concerning the structural behavior of the test specimens. The main results of these tests will be explained. It was able to find regression curves in order to explain mathematically the influence of the unconfined concrete strength and of the confinement pressure, which is provided by the CFRP confinement and the transverse reinforcement. Further data bases, which are available in literature, confirmed the own proposals. It was possible to find proper common regression curves despite the fact those different testing machines, test setups, and raw materials (for concrete and CFRP confinement) were deployed. As a result, the paper will present a common empirical model for predicting the compressive axial behavior of CFRP confined, short concrete columns with and without reinforcement.

KEYWORDS

RC columns, strengthening, CFRP confinement, transverse reinforcement, confinement pressure, tie, spiral.

INTRODUCTION

Confinement is generally applied to members in compression with the goal to increase their strength and ductility. Besides conventional transverse tie reinforcing steel also advanced FRP (Fiber Reinforced Polymers) materials have recently recognized as favorable confinement devices. FRP consists of strengthening fibers (for example carbon fibers) in a resin system. The FRP confinement appears by orienting the fibers transverse to the longitudinal axis of the concrete member. Through FRP strengthening by confinement, concrete's lateral expansion is efficiently restricted in cases of imposed axial compressive deformation; therefore, the elastic FRP resisting response generates an ever increasing lateral compressive stress state on concrete, leading to structural upgrade of the member core to provide sufficient deformability. If concrete cylinders are of interest, the confining pressure σ_l (also denoted as f_l) can be found from Eq. 1.

$$\sigma_l = \frac{1}{2}\rho_j \cdot \sigma_j = \frac{1}{2}\rho_j \cdot E_j \cdot \varepsilon_j = E_{jl} \cdot \varepsilon_j \quad \text{with} \quad \rho_j = \frac{4 \cdot t_j}{D} \tag{1}$$

Where ρ_j = volumetric ratio of FRP jacket, σ_j = stress in FRP jacket, E_j = modulus of composite material, ε_j = circumferential strain in FRP jacket, t_j = FRP thickness, E_{jl} = confinement modulus, and D = diameter of concrete cylinder.

Maximum confinement pressure can be calculated, if rupture strain of CFRP jacket is inserted. We receive Eq. 2.

$$f_l = \frac{2 \cdot t_j \cdot E_j \cdot \varepsilon_{ju}}{D} \quad \text{with} \quad \varepsilon_{ju} = \varepsilon_{FRP} \cdot k_\varepsilon \tag{2}$$

Where ε_{FRP} = ultimate tensile strain found from flat coupon tensile tests, and k_ε = efficiency factor (cf. Chapter "Rupture strain of deployed CFRP jacket").

In the past, various experimental research programs had been carried out by other researchers to express the increase in strength and strain by the use of CFRP (Carbon Fiber Reinforced Polymer) jackets.

Some of them were adopted by design recommendations. Examples are the stress-strain model by Lam and Teng (2003) in ACI 440.2R-08 or the model by Spoelstra and Monti (1999) in technical report by the fib.

In general, models provide equations for the calculation of the new concrete strength f_{cc} and accompanying axial strain ε_{ccu}. Different proposals are given in Table 1.

Table 1 Different equations for predicting f_{cc} and ε_{ccu}

Authors	Confined concrete compressive strength	Ultimate axial compressive strain
Samaan *et al.* (1998)	$f_{cc} = f_{c0} + k \cdot f_l$ $k = 6.0 \cdot f_l^{-0.3}$	$\varepsilon_{ccu} = \frac{f_{cc} - f_o}{E_2}$ $E_2 = 245.61 \cdot f_c^{0,2} + 1.3456 \cdot \frac{E_j \cdot t_j}{D}$ $f_o = 0.872 \cdot f_{c0} + 0.371 \cdot f_l + 6.258$ MPa
Lam and Teng (2003)	$f_{cc} = f_{c0} + k \cdot f_l$ $k = 3.3$	$\varepsilon_{ccu} = \varepsilon_{c0} \cdot 1.75 + \varepsilon_{c0} \cdot 12 \cdot \frac{f_l}{f_{c0}} \cdot \left(\frac{\varepsilon_{ju}}{\varepsilon_{c0}}\right)^{0.45}$
Teng *et al.* (2009)	$f_{cc} = \begin{cases} f_{c0} + f_{c0} \cdot 3.5 \cdot (\rho_K - 0.01) \cdot \rho_\varepsilon & \text{if } \rho_K \geq 0.01 \\ f_{c0} & \text{if } \rho_K < 0.01 \end{cases}$ $\rho_K = \frac{2 \cdot E_j \cdot t_j}{(f_{c0} / \varepsilon_{c0}) \cdot D}$; $\rho_\varepsilon = \frac{\varepsilon_{ju}}{\varepsilon_{c0}}$	$\varepsilon_{ccu} = \varepsilon_{c0} \cdot 1.75 + \varepsilon_{c0} \cdot 6.5 \cdot \rho_K^{0.8} \cdot \rho_\varepsilon^{1.45}$
Xiao and Wu (2003)	$f_{cc} = \alpha \cdot f_{c0} + k \cdot f_l$ $k = 4.1 - 0.45 \cdot \left(\frac{f_{c0}^2}{E_{jl}}\right)^{1.4}$; $\alpha \approx 1.1$	$\varepsilon_{ccu} = \frac{\varepsilon_{ju}}{10 \cdot (f_{c0} / E_{jl})^{0.9}}$

To describe the entire material behavior, in common, a stress-strain curve consisting of a parabolic first portion and a straight-line second portion (second modulus) is introduced. An example is given with stress-strain model by Lam and Teng (2003).

$$\sigma_c = \begin{cases} E_c \cdot \varepsilon_c - \frac{(E_c - E_2)^2}{4 \cdot f_{c0}} \cdot \varepsilon_c^2 & (0 \leq \varepsilon_c \leq \varepsilon_t) \\ f_{c0} + E_2 \cdot \varepsilon_c & (\varepsilon_t \leq \varepsilon_c \leq \varepsilon_{ccu}) \end{cases} \quad (3)$$

$$E_2 = \frac{f_{cc} - f_{c0}}{\varepsilon_{ccu}} \quad (4)$$

Where E_2 = second modulus, f_{c0} = unconfined concrete strength, and E_c = modulus of elasticity, ε_t = transition between parabolic curve and straight-line second portion.

Figure 1 shows examples of predictions from existing models for two specimens with normal (30 MPa) and high unconfined concrete strength (60 MPa). Especially for a high unconfined concrete strength remarkable differences between the calculated stress-strain curves can be witnessed. The same can be said concerning f_{cc} and ε_{ccu}. It is obvious that the differences between the predicted results tend to spread strongly with increasing unconfined concrete strength.

Furthermore, with the presented models and equations only the contribution of the CFRP jacket is explained. It is only possible to calculate confined plain concrete, but the presented Equations are not suitable for reinforced concrete. The contribution of the internal transverse steel reinforcement and other effects, like, for example, the buckling of the longitudinal steel reinforcement, can not be taken into account. Only a few confinement models (for instance Hu *et al*. (2012), Eid and Paultre (2008), Rousakis and Karabinis (2008) or Pellegrino and Modena 2010)) consider the interaction between the internal lateral steel reinforcement and the external FRP sheets. The cause is that the theme of confinement of RC elements exposed to compressive actions in order to increase strength and ductility is actually a very complex problem and not completely solved.

EXPERIMENTAL INVESTIGATIONS

Emphases of research

As mentioned before, in the majority of cases, the additional effects of reinforcing elements, like ties or spirals, are not analyzed very well. This can be attributed in particular to the limited experimental evidence on the area of FRP confinement of real-size RC columns. Additionally, these limits have not allowed the appropriate implementation of key effects in current models. Hence, the goals of the research work presented in this paper are the production and test of circular columns with different diameters (from 15 up to 30 cm) and concrete strength, different steel ties and steel spirals, and with CFRP jackets of different thickness and material properties.

Experimental program

In an extensive research program the volumetric ratio of the CFRP jacket ρ_j as well as the ratio of transverse reinforcement ρ_{st}, which are mainly accountable for effective confining pressure, were varied. Columns with different geometrical shape, different strength f_{c0}, different CFRP thickness, CFRP material (SikaWrap®-200C, SikaWrap®-230C, Tenax® UTS50), and with different transverse reinforcement elements (steel ties and spirals) as well as different amount of longitudinal bars were produced and tested. During the tests, two different measurement systems were used. For all specimens, beside the strain gauges on the FRP jacket (at midheight), two LVDT's were fixed at two opposite sides of each specimen in order to measure the axial shortening.

Figure 2 presents the experimental setup, and it explains typical stress-strain curves in longitudinal and transverse directions derived from the compression tests. More details have been presented, for instance, in Kaeseberg and Holschemacher (2015).

In Figure 2 the stress-strain curves of specimens with a diameter of 150 mm, which where confined with one up to three layers of CFRP, are shown. The stress-strain behavior (longitudinal and transverse) of the CFRP confined specimens was bilinear in general, and consisted of a three phase behavior like predicted by the different material models in Figure 1. The second modulus E_2 could be observed in longitudinal (E_2) as well as in transverse ($E_{2,q}$) direction (cf. Figure 2). The failure of CFRP confined plain or steel reinforced specimens was 'explosive' due to the sudden and noisy fracture of CFRP sheets at ultimate strength f_{cc} and strain ε_{ccu}. Furthermore, Figure 2 also explains the interrelationship between E_2 and the volumetric ratio of the CFRP jacket. More layers of CFRP produce higher volumetric ratios, and this circumstance results in higher second modulus and in higher ultimate states of strength and strain. These connections were used for the discussion of the compression tests in the next sections.

RESULTS AND DISCUSSION

CFRP confined plain concrete

This section explains the results on confined plain concrete. Columns with different geometrical shape and different CFRP thickness were produced to vary the CFRP thickness t_j and the diameter of the column D. Both are responsible for the volumetric ratio of the CFRP jacket. Like explained in Eq. 2, ρ_j and the material properties of the carbon fibers dictate the maximum confinement pressure, provided by the CFRP confinement. The investigations unveiled that f_l has a strong impact on f_{cc} and ε_{ccu}. Furthermore, the investigations revealed the unconfined concrete strength f_{c0} as a second impact factor. Figure 3 explains this circumstance.

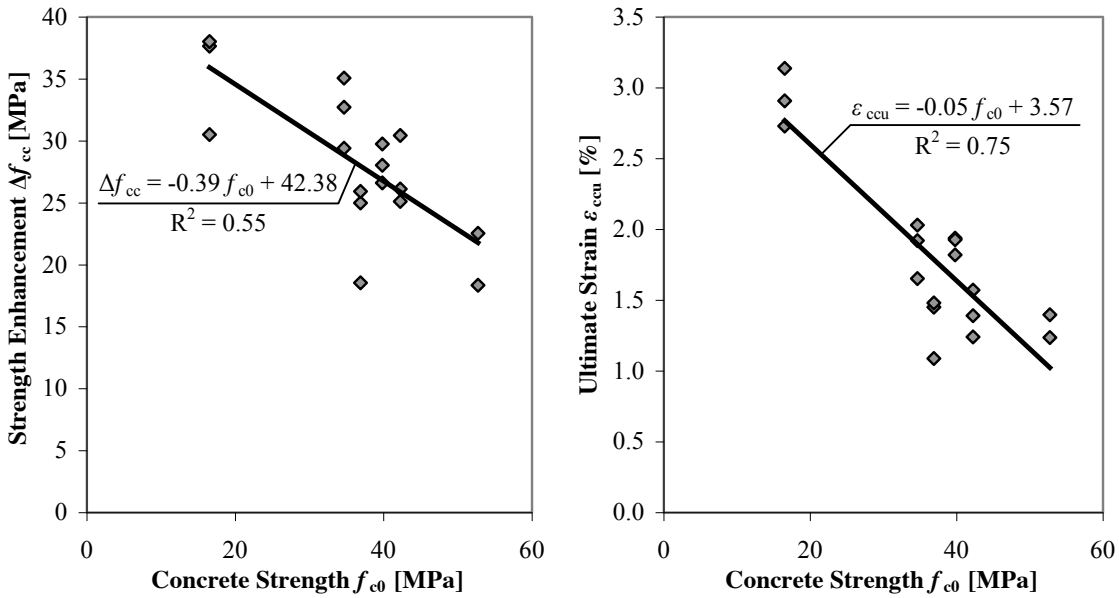

Figure 3 f_{cc} and ε_{ccu} as functions of f_{c0}

In this case, only f_{c0} was changed. The column diameter (150 mm) and the properties of the deployed CFRP system remained unchanged. In both cases, an impact of f_{c0} on f_{cc} and ε_{ccu} can be recognized, but a sufficient correlation can not be found.

Because of this, the proposal of Xiao and Wu (2003) was used to involve the unconfined strength into analysis. If f_l is deployed in relation to f_{c0}, very good regressions can be found to explain f_{cc} and ε_{ccu}. Figure 4 provides an example. Herein, the strength enhancement Δf_{cc} is now described as a function of the ratio between f_l and f_{c0}.

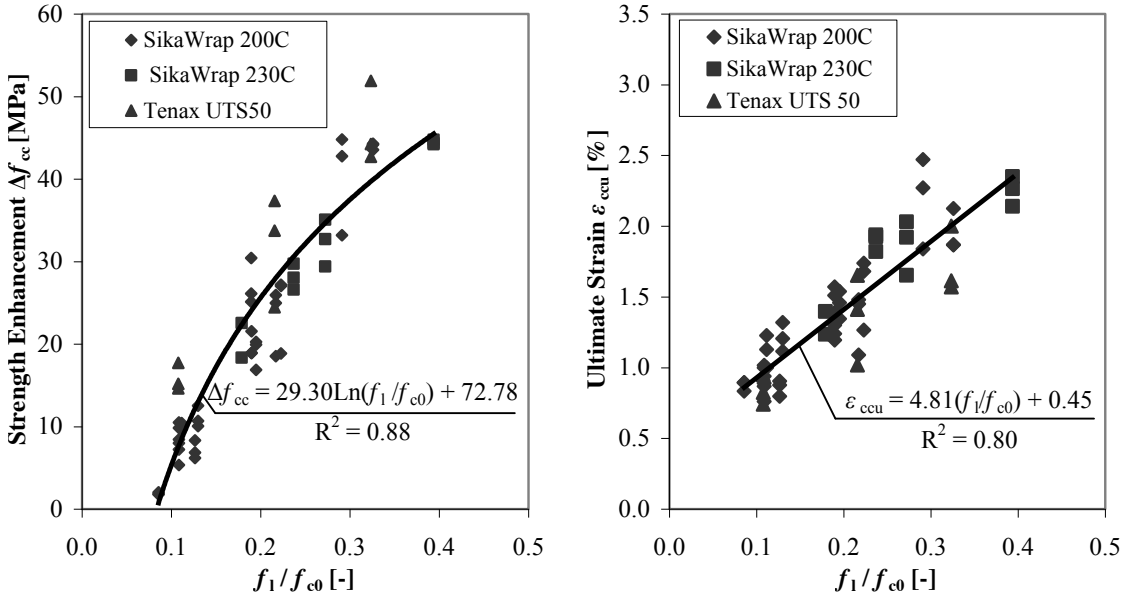

Figure 4 f_{cc} and ε_{ccu} as functions of relationship between confinement pressure and unconfined concrete strength

The high coefficient of determination of the regression curve indicates the reliability of the ratio between confinement pressure and unconfined concrete strength to predict the load bearing capacity of a CFRP confined concrete member.

It appears not sufficient to work with a fixed value to describe the factor k in Equations for predicting f_{cc} in table 1, as supposed by Lam and Teng (2003). Accordingly, it becomes urgent to take into account the relation between CFRP confinement system and concrete properties.

Rupture strain of deployed CFRP jacket

Lam and Teng (2003) proposed that in material models ε_{ju} should be taken as the actual hoop rupture strain $\varepsilon_{j,rup}$ measured in the FRP jacket rather than the FRP material ultimate tensile strain ε_{FRP}. Reason is the circumstance that at the rupture of FRP the hoop strain reached in the jacket ε_{ju} is generally considerably smaller than the ultimate tensile strain found from flat coupon tensile tests ε_{FRP}. Because of this reason, Lam and Teng (2003) established an FRP efficiency factor k_ε. Their investigations revealed that the value of k_ε varies with the type of FRP (carbon fibers (CFRP) or glass fibers (GFRP)). For CFRP confinements, they proposed an average value of 0.586 for k_ε.
